The tooling employed in the production of sliding transmission gears is one of the most highly developed equipments used for machining automotive parts. Before the gears go to the double-spindle production lathe equipped with the tooling shown in Fig. 4, the rough forgings have the holes rough-drilled in a drilling machine. The work is held in the lathe by air chucks. The boring-bars in positions A1 and B1 carry roughing cutters which are immediately followed in the same feeding movement by finish-boring tools and rough butt-facing tools that machine the hub face. After the parts have been machined by these tools, the tools are withdrawn, the cross-slide automatically shifts, and the tools in positions A2 and B2 are brought up to the work. These tools finish-ream the holes and finish-face the hubs.

Fig. 5 shows a machine set up for this operation and gives a good idea of the construction of the automatically operated air slide. This machine is not classed as an automatic, but its results are comparable with those of a full automatic, because only a small effort is required of the workman. The operator runs two spindles, both of which are constantly under his observation, so that feeds and speeds may be used which would not be safe if he were tending a number of machines spread over a wide area.

The blanks now have the bore and one hub finished and are next sent to a broaching machine to be splined; in this operation the work is located against the finished hub. The facing of the opposite hub is next in order, and this is best done under a two-spindle drilling machine, which permits one spindle to be used for roughing and the other for finishing. The fixture used in this operation was shown in Fig. 3 of the article "Machining Automobile Transmission Gears" which appeared in March, 1920, MACHINERY.

The next operation on the sliding transmission gears is performed in a Fay automatic lathe equipped with the tooling set-up shown in Fig. 8. Tools *A* first feed in radially and face the sides of the gears, and then feed toward the left and turn the fork flanges, while tools *B* turn the outside circumference. The rear holder, in the meantime, is also fed radially, but the grooving tools *C* do not come into contact with the work until after the scale has been removed by tools *A*. The finishing operation is similar, except that additional tools are provided where necessary to break corners and to obtain a finished job.

A somewhat more elaborate set-up for machining transmission gears on a Fay automatic lathe is illustrated in Fig. 6. It will be noted that while the arbor in Fig. 8 carries two gear blanks, the one on the machine in Fig. 6 carries three. It is seldom that the machining of three blanks at a time is practicable; usually only two may be handled satisfactorily, and sometimes only one.

The conditions that determine how many pieces can be handled at one time are as follows: First, the size of the hole in the work (which determines the slenderness of the arbor) relative to the outside diameter and the amount of metal to be removed. Second, the required accuracy of the hub length; if the tolerance is too large and three blanks are placed on an arbor, the outside blank may be considerably shifted from its normal position so that its rim is displaced with reference to the hub. Third, the construction of the arbor and the spacing collar. As no particular pains have been taken to face the outside hub of the gear true with the inside one or with the bore, the arbor is likely to spring somewhat when two blanks are clamped on it, and a great deal when three blanks are clamped on it.

A remedy for this condition lies in the construction of the arbor and particularly in that of the spacing collar *D*, Fig. 8. This collar fits loosely over the arbor and its splines and has a narrow

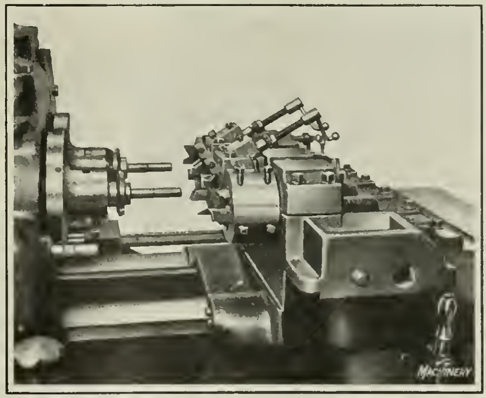

Fig. 9. Equipment for machining Differential Gears, Similar to that shown in Fig. 10 except that Hand-operated Recessing Tools are used

bearing against the opposing hubs of the gears, the bearing on one side of the collar being located 180 degrees from that on the opposite side. The collar thus has a solid seat against both hubs, whether they are true or not, and does not cramp itself, the arbor, or the work. By this means, the bending of an arbor is avoided. Of course, the same precautions must be taken in subsequent operations and especially in the cutting of the gear teeth. This is generally recognized, and tool designers usually arrange to clamp blanks by the rims so that the hubs have no influence on the truth of the arbor.

Production Lathe Set-ups for a Differential Gear

In the production of a differential gear, the work is first drilled and broached and then sent to a double-spindle productiou lathe provided with the tool set-up shown in Fig. 10. There are four double-ended arbors *B* supplied with each equipment, two of the arbors being used on the machine while the other two are having the work changed on them. These arbors drive the work by the splined hole and have bearings in hardened bushings, one of which is in the spindle fixture and the other in the cat-head tool-holder at the opposite end. An equalizing driving plate *C* keeps each arbor turning with the spindle, and spring *D* and the pressure of the cut hold the work back against the spindle fixture. When the tools are withdrawn, the arbor and work can be pulled out by hand.

The work is placed in the rear spindle and has one side roughed and finished by the two tool sets shown at the left-hand end of the plan view. The work is then withdrawn and inserted in the front spindle, where the other side is roughed and finished by the two tool sets shown at the right-hand end of the plan view. Both operations, of course, take place at the same time. A tool carried in the overhead fixture *E* cuts a recess on the work to facilitate the subsequent face- and cylindrical-grinding operations on the part. All other cuts are done by direct end cutting, and the tools for the different cuts can be readily identified by the legends on the illustration. The output of this machine for roughing and finishing both sides of the gears complete runs as high as thirty-six per hour for small gears. The set-up shown in Fig. 9 differs from the one in Fig. 10 only in that it is provided with simpler hand-operated recessing tools.

RAPID DRILLING OF NAMEPLATE HOLES

One of the jobs performed on a quantity basis in the plant of the General Electric Co. at Rochester, N. Y., is the drilling of nameplate holes in stators. In order to obtain a high rate of production on this job, a special-purpose two-spindle drilling machine is employed for this work, which was designed by the Leland-Gifford Co., Worcester, Mass. The machine is equipped with two spindles set at an angle in a horizontal plane, each of which is driven by an individual motor mounted on the spindle. The two spindles are operated simultaneously by a handwheel, which is placed between them and is connected with each by a universal joint, so that as the wheel is turned, the spindles feed at an angle corresponding to that of the nameplate pins. The stator is slipped over a horn in a jig, and by a single movement of the handwheel the two holes are rapidly drilled. The production time on this job, with an unskilled operator in attendance, is 10,000 nameplate holes a day, two holes each in 5000 nameplates.

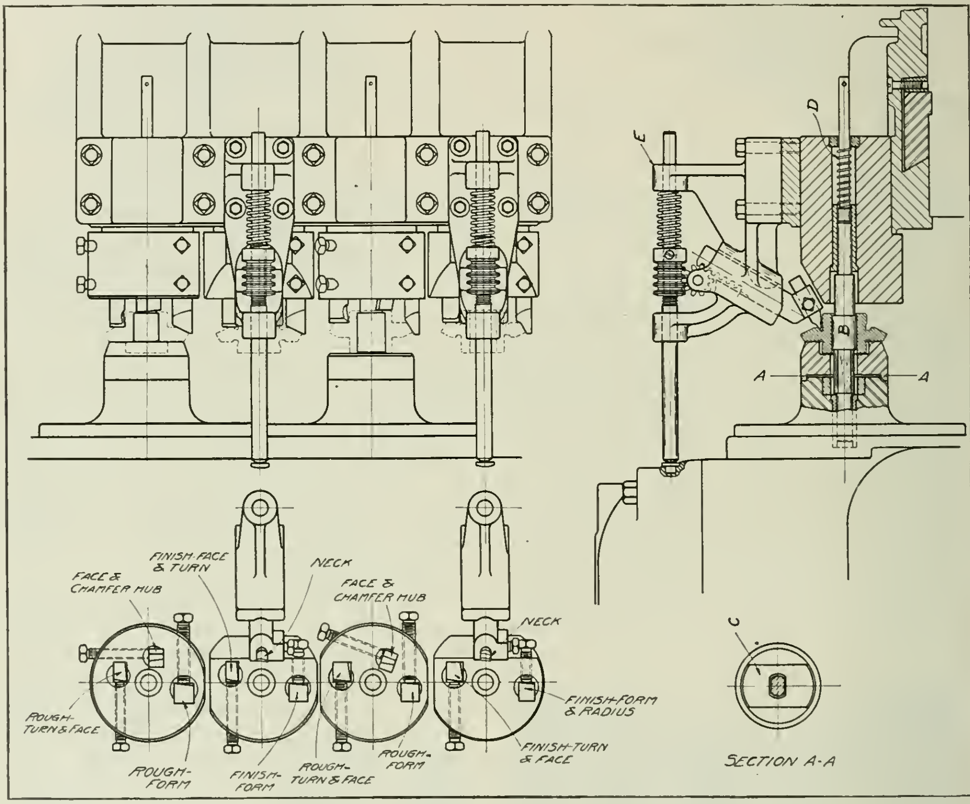

Fig. 10. Equipment supplied on a Double-spindle Production Lathe for machining Differential Gears

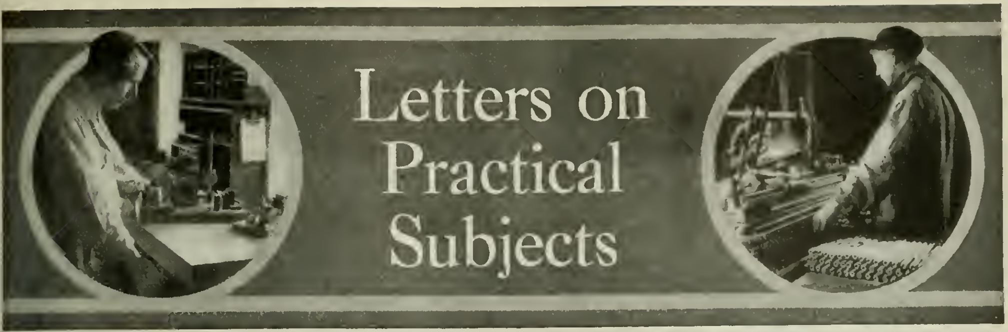


SPLINING FIXTURE FOR VALVE ROCKER ARMS

The fixture shown in the accompanying illustration was designed and built for the purpose of locating and holding valve rocker arms in a double-spindle automatic spline milling machine during the machining operation. The chief advantage of this fixture is that loading is performed while the machine is in operation and no time is lost, therefore, in putting in and taking out work. The table of the machine travels back and forth continuously while the cutters are fed into the work, backed out, and fed into the next piece of work automatically and without interruption.

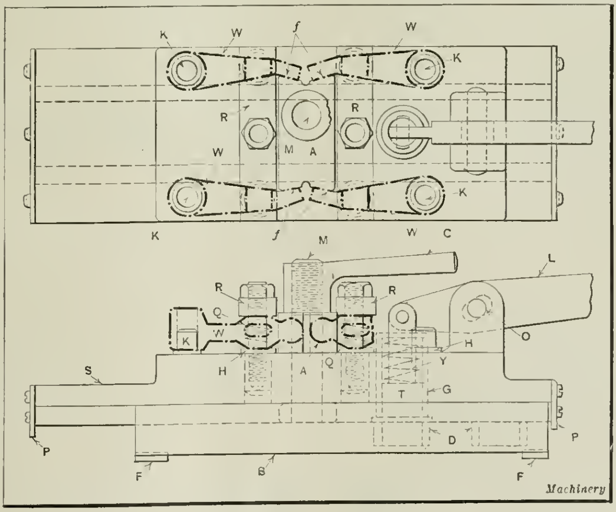
Referring to the illustration, base *B* is grooved on its under side to receive two fixture keys *F*, which, in turn, fit into the T-slot in the bed or table of the spline miller, thus squaring up the sides of a female dovetail in the top of the base with the spindles of the machine. It should be understood that the machine spindles are located on each side of the table and would meet each other if sufficiently extended. Two screws (not shown in the illustration) are used to hold the base to the table of the machine. There are two holes in the base fitted with bushings *D*, which are counterbored so that the bushings do not come through the bottom of the base. A slide *S*, with a male dovetail, is fitted to the base and is prevented from sliding too far in either direction by two retaining plates *P*, each of which is fastened in place with three screws.

Before the slide is assembled to the base, however, it is necessary to insert the guide bushing *G* in the hole in the slide provided for that purpose and place the locating plunger *T* with spring *Y* in the guide bushing, connecting plunger *T* with lever *L* by means of a pin. Lever *L* is also pinned to the lug *O* on the slide. Four parts or pieces of the work *W* are shown by heavy dot-and-dash lines in the upper view, but for clearness only one complete part is shown in the lower view. It will be noted that the work is located at three points. The reamed hole in the piece fits over plugs *K*, which results in machining the spline square with the hole. A block *A*, centrally located, which is attached to the slide, has four hardened and ground angular surfaces *f*, which serve as stops for the free ends of the work. It will be seen that these surfaces locate the rocker arm in the correct angular position for cutting the spline.

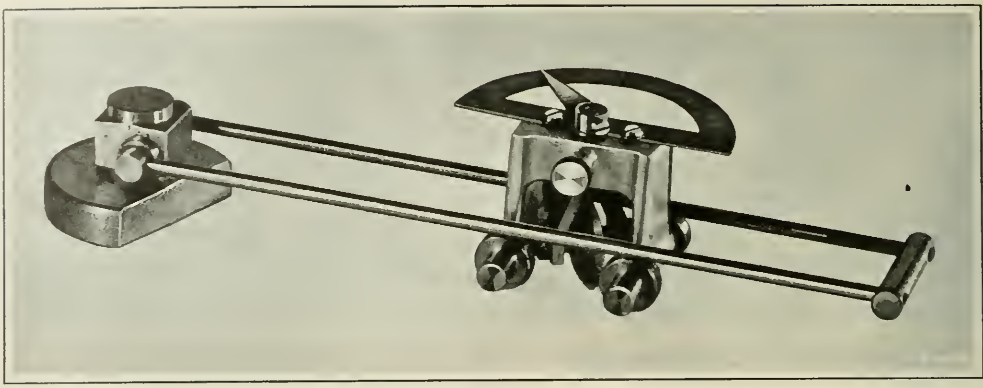
The third locating point is governed by the distance from the top of the table to the center line of the spindles. The base and the slide are made sufficiently thick to bring the center of the work to the proper height when it rests on the hardened pins *H*. This distance must be accurate, but the dimensions of the slide and base may be made to the nearest even figure, and the exact distance can be obtained by increasing or decreasing the thickness of the head of the pins on which the work rests. The steel bars *R* are used to clamp and hold the work. A bolt and nut accomplishes this, the former being threaded into the slide. These bars are forced up by springs *Q*, as soon as the nut is loosened, and are prevented from turning by the block *A* which is fastened to the slide.

A heavy bolt with a large head, one side of which is beveled to correspond to the dovetail, is shown at *M*, and is placed in the slide so that it wedges against the side of the dovetail in the base when the clamp *C* is tightened. The main function of this clamping arrangement is to prevent chattering of the cutters, since the plunger *T* insures the correct location of the work with respect to the cutters. The spring on the plunger *T* counterbalances the weight of the handle or lever *L*. The lever *L* is provided with an elongated hole at *O* in order to avoid the use of a link.

When two pieces of work are clamped in the fixture in the two right-hand positions, the machine may be started. While these two parts are being splined the operator will have ample time to load several fixtures in succession and start each one going. Another pair of parts can then be loaded in each fixture by placing each over plugs *K*, at the left-hand end and swinging them against block *A*, holding them in with the fingers while tightening clamps *R*. When the first pair is finished, the cutters back out and the operator loosens clamp lever *C*, pushes down on lever *L*, and pushes the fixture slide to



Splining Fixture for Valve Rocker Arms



Instrument designed to facilitate the Drawing of Logarithmic Spirals

the right allowing the plunger to drop into the other hole in the base. Clamp *C* is then tightened, and the next pair is brought in line with the cutters, ready for machining. The parts which have been machined can then be removed and two more blanks inserted. One man can operate a battery of several machines in this manner. B. S.

INSTRUMENT FOR USE IN DRAWING LOGARITHMIC SPIRALS

In the accompanying illustration is shown a device for tracing logarithmic spirals, which the writer made some time ago and which he believes possesses some advantages over the one described in August MACHINERY, page 1146. The design of this instrument is based on the fact that in a logarithmic spiral, radii to all points on the curve make the same angle with tangents to the curve at their extremities. The construction of the device is apparent from the illustration. It consists simply of a sharp-edged tracing wheel mounted in a slide which can move radially on an arm that is pivoted to swing about one end. When the tracing wheel is set at an angle other than 90 degrees to the arm, the slide will be drawn in or out as the arm is revolved about its pivoted end.

One advantage of this instrument is that spirals of any angle may be drawn in either direction, by simply adjusting the plane of the tracing wheel to whatever position is required, by means of the scale and pointer shown at the top of the slide. In case it is necessary to construct a curve outside the range of the instrument, it is only necessary to draw a spiral of the required angle, and then extend it by drawing several radii and dividing them internally or externally into some proportion that will carry the curve in or out as desired. A more complete description of the construction and operation of this device was published in the *Sibley Journal of Engineering* (Cornell University, Ithaca, N. Y.), April, 1920.

Niagara Falls, N. Y. HOWARD G. ALLEN

SIMPLIFYING DESIGN OF A WATER-COOLED JOURNAL BOX

In Fig. 1 is shown a water-cooled journal box made with a cored water circulating chamber at *A*. The metal between the chamber *A* and the bronze liner *B* is 3/4 inch in thickness. When the box is cast, four small cores are employed to support the chamber core in the mold. The vents for carrying off the gases pass through the four cores which are located at the outer ends of the casting at *C*. After the casting has been cleaned, these cored holes are drilled and tapped. The two holes at the left-hand end are drilled and tapped to receive the water inlet and outlet pipes, respectively. The holes at the opposite or right-hand end of the casting are drilled and tapped to receive threaded plugs.

The bronze liner *B* is held in place on the water-cooled box by means of brass pins *D*. While a casting made in this manner may appear satisfactory and pass a critical examination of the outside surface, there is no assurance that the water cooling chamber is perfect or that the water can circulate through the chamber as intended. To overcome this objection a new box was designed which is shown in Fig. 2. The pattern for this cast-iron water-cooled journal box is easily made, and no cores, core-prints, or core-boxes are required. It will be noted that the water-cooling chamber is open or exposed. This enables the molder to inspect the mold thoroughly, and also enables a thorough inspection of the casting produced by the mold.

The open top cooling chamber is divided into narrow pockets or spaces *E* by dividing ribs *F*. There are four

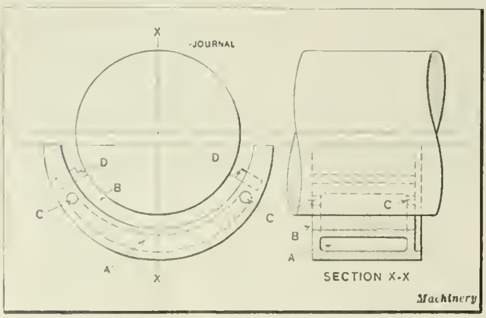


Fig. 1. Water-cooled Journal Box presenting Difficult Molding Problem

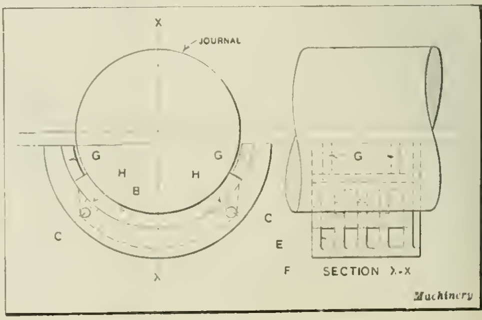

Fig. 2. Redesigned Journal Box which simplifies Molding Problem

stops *G* cast integral with the main casting. Two of these stops are located at each end of the casting. As these stops are in line with the pockets, it is possible to bore out the inside diameter or the supporting ribs *F*. The casting is, of course, finished all over. The bronze liner *B* covers the water chamber, and the water pipe connections are located to suit conditions. The ribs are cut out at *H* to permit proper circulation of the cooling water.

DIAGRAM FOR DETERMINING RADII OF ELLIPSES

On complicated drawings it is frequently inconvenient to construct approximate ellipses by the methods given in engineering handbooks, because of the preliminary laying out involved in determining the radii required. By means of the accompanying diagram these radii can be determined readily and an approximate ellipse developed with little work. In using the chart, it is only necessary to know diameters *A* and *B*. Dividing these in two gives *a* and *b*, respectively. Corresponding radii of *R* and *r* are found by laying a straightedge across the known values of *a* and *b*. Assume that it is desired to find the radius required in constructing an ellipse of which *A* is 1 inch and *B* is ¾ inch. In this case *a* equals ½ inch and *b* equals ⅜ inch. By drawing a line connecting these values on the *a* and *b* scales as indicated by the dot-and-dash line, the value of *R* will be found on the *R* scale to be ⅝ inch, and *r* on the *r* scale to be 5/16 inch.

Frankfort, Ind.

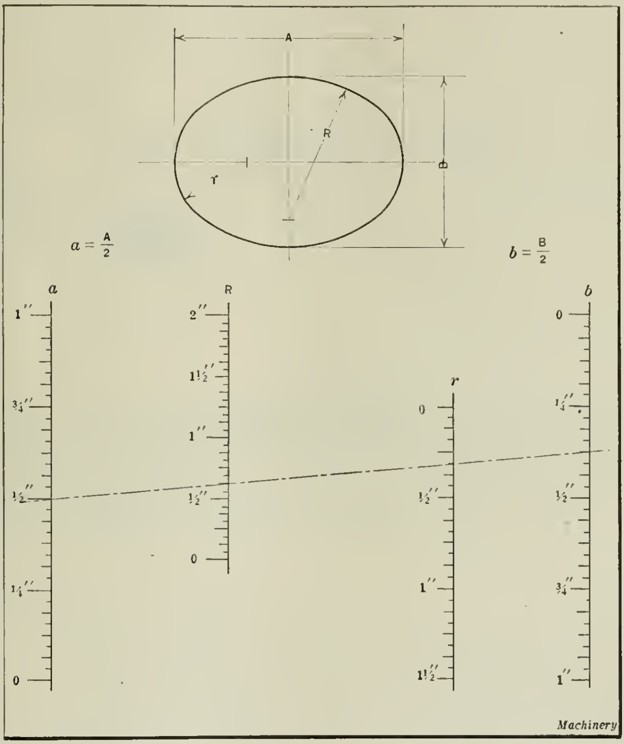

Diagram for rapidly obtaining Values required in constructing an Approximate Ellipse

A SIMPLE PATTERN NUMBERING SYSTEM

The plan for numbering patterns, explained in the following, has been found to have many advantages. The pattern number is composed of three distinct elements, or groups, each representing one of the three essential points to be considered in the identification of a pattern, namely, the kind of machine of which it is a part, the type or size of the machine, and the detail number which identifies the casting on the machine.

The number is so constructed as to contain as few digits as possible, and, at the same time, conform to all the requirements of the system. To this end both letters and figures are made to follow one another in a compact sequence, without the use of dashes or spaces, the letters of the alphabet being used in the first and last groups, and the figures placed between, forming the intermediate group. In this way a distinction of the three parts of the number is effected.

The first group indicates the kind, or general classification, of machine. The middle group gives the detail number of the part, and the last group represents the size or type, or both size and type of machine, which in such a case can be indicated by one symbol that is composed of one or two letters.

As an example, suppose a concern is manufacturing a line of engines and pumps. The engines would be in one classification, represented by a letter, such as A, and the pumps in another, represented by B, these letters being first in the sequence of the number. Suppose the cylinder head of the engine has the detail number 10, and the base of the pump 13. The size of the engine in the example may be represented by the letter A, and that of the pump by H. Then the number A10A would designate the cylinder head of a size A engine, and B13H the base of a size H pump.

The plan for assigning the detail numbers should be independent of that for all other numbers. The detail numbers should be taken from a list, in rotation, as the parts are placed on the drawings; thus 10 need not stand for the cylinder head for any other size or type than the one cited, since that one size or type may be very simple, with few parts, while another type may be elaborate in design and require a large variety of details. The letter indicating the kind of machine or product should be assigned at the time it is determined to make or design such a product, and should be taken in its turn from a list. The letters for the size or type should be assigned in a similar way, and a separate list of letters for sizes belonging to each general class or kind should be kept distinct from all other classifications; thus "A" representing a size of engines should have no relation to "A" in sizes of pumps.

If the products of the concern should increase so as to cover many classes and types of machines, it might be necessary to use two letters, either for classification or for size, and if the details of one machine run higher than ninety-nine, in number, it would be necessary to use three figures. The longest pattern number that is likely to occur under this system, however, would contain seven characters, such as AA107AB, but even such a case would be extremely rare. It is not likely that there would be over one letter in the end groups, or two figures in the middle, in most cases, making four altogether, which is as compact as it can usually be made.

There are some letters that are objectionable for use on patterns, when used in connection with figures, for the following reasons: The letter O is identical with the zero of the numerals, and the letter I can hardly be distinguished from the figure one. The letter C could be made from O if a portion of the side should be washed out in the mold, and a portion of the letter Q could be washed out in a similar manner and made to look like O or C. If the lower portion of E were washed out it would look like F, and if A were shown indistinctly, and were read upside down, as is often the case on a casting, it might be taken for V. By eliminating all such objectionable letters, and having it known that the system does not contain them, there would be no chance of mistaking one for another. The letters to be eliminated would then be C, F, I, O, Q, and V, there being six in all, and that would leave twenty to be used, which are, A, B. D, E, G, H, J, K, L, M, N, P, R. S, T. U, W, X. Y, and Z.

These twenty letters, if used in combination like numbers, would form a double decimal system giving a combination of 399 numbers where two letters are employed, which would more than take care of the needs of any concern. The twenty letters would usually be sufficient for all needs.

North Judson, Ind. William H. Kellogg

WINDING COIL SPRINGS

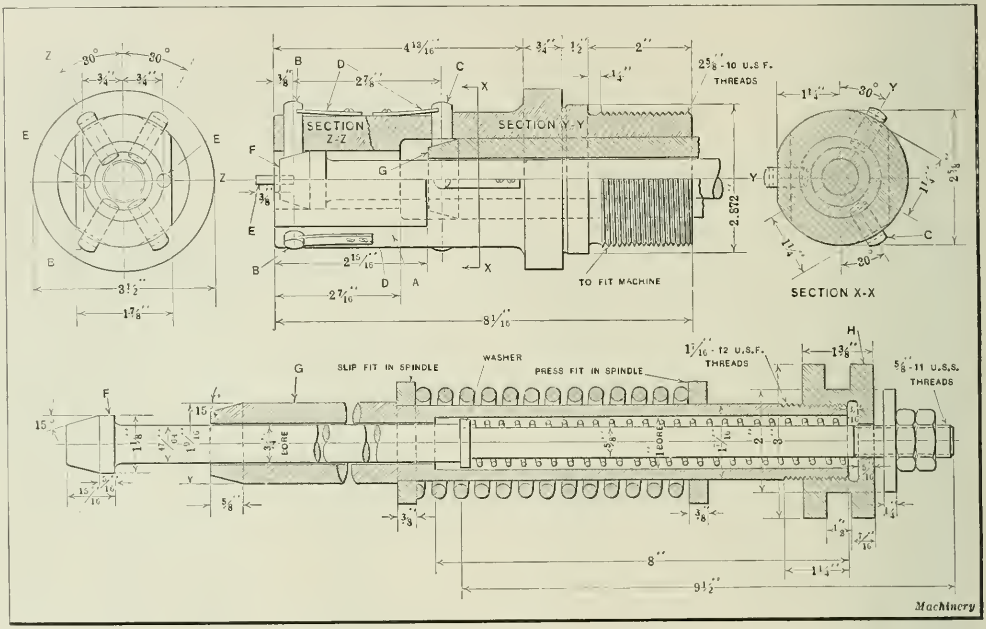
The following is a simple method of winding a coil spring. A piece of steel tube or pipe about 6 inches long with a ½-inch or ⅜-inch hole is fastened in the toolpost of the lathe, using a boring-bar vee to secure rigidity. The wire is passed through this tube, and the end gripped in the chuck or dog of the arbor on which the spring is to be wound. The lathe is geared to the pitch of the coil wanted, or in the case of the closed coil spring, it may be geared for a pitch slightly less than the number of coils per inch. In using this device, the end of the tool through which the wire is fed should be as close as possible to the winding arbor.

New Britain, Conn. W. C. Betz

PISTON CHUCK

The writer has noted with considerable interest the various designs of devices for chucking pistons from the inside while rough-turning the outside surfaces. The best results are obtained by chucking pistons in this manner; however, nearly all manually operated chucks designed for this purpose require the use of wrenches, and consequently result in increasing production costs. In the accompanying illustration is shown a type of piston chuck that does not require the use of wrenches and that can be operated by one lever.

The body of the chuck with the various operating parts assembled is shown in the upper half of the illustration, while in the lower half a sectional view of the actuating arrangement for the two plungers is shown. The machine-steel body *A* has flats milled on each side to a width which will permit it to fit between the wrist-pin bosses on the inside of the piston and thereby act as a driver. There are



End and Sectional Views of Piston Chuck and its Actuating Mechanism

four hardened tool-steel pins *B* carried in the outer end of the body to accommodate the nose of one plunger, and three similar pins *C* operated by the nose of the other plunger. These two sets of pins are held in place and moved radially inward by flat springs *D*. Two pins *E* projecting from the end of the body act as stops against the closed end of the piston and take up the end thrust of the cutting tool.

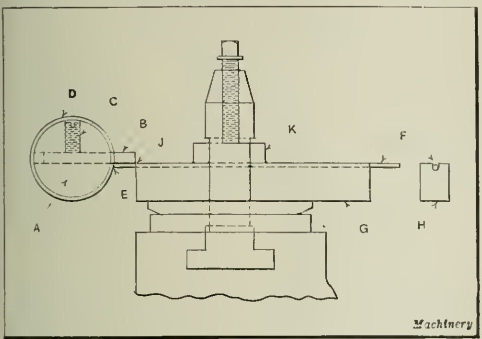
The plungers *F* and *G* are actuated by coil springs. The chuck is operated by a lever with a forked end, located at the rear of the machine above the spindle, which engages collar *H*. Movement of this lever is all that is required to operate the two plungers by means of which the piston is chucked. When the lever is moved to the right, the pins *B* and *C* are drawn in to permit the piston to be slipped over them preparatory to chucking. When the lever is released, the springs force the plungers to the left, thereby expanding the pins and securely chucking the pistons in place. An air chuck could be substituted for the larger spring, but if the proper springs are used, a hand-lever will be found satisfactory. This type of chuck has been used to chuck pistons when taking cuts that were as much as ½ inch eccentric.

Chicago, Ill. Harold A. Peters

CUTTING RIVETS IN THE LATHE

As about 6000 rivets, 1/16 inch in diameter, were required and nothing better than a hand shear was available for cutting the rivets from wire stock, it was decided to equip a lathe for the wire-cutting operation. The accompanying illustration shows how this was accomplished. An ordinary milling machine boring-bar *A* was set up in the lathe and a 5/16-inch tool bit *B*, ground on the face and end, was fastened in the boring-bar by a set-screw *C*, as indicated. Next, a piece of 1/16- by ½-inch cold-rolled steel was bent around a piece of shafting slightly smaller than the boring-bar in order to form a sleeve *D* which could be sprung on bar *A* to cover the back end of the tool recess and the set-screw hole. This sleeve formed a smooth surfaced stop for the end of the wire stock *F* which makes contact with it at *E*.

The high-speed steel lathe tool *G* was then ground smooth on its top surface and on one end. A groove was cut the full length of tool *G* on its top surface as indicated in the end view at *H*. This groove was made slightly larger than the wire except at the cutting edge *J* where it conforms to the size of the wire used for the rivets. The tool was fastened in the toolpost with a steel block *K* on its top surface to keep the wire in the groove while it is being fed forward. In operation, the cutting edge of the tool bit in the boring-bar is set a certain distance from the face of sleeve *D*, according to the length of the rivets or pins required.



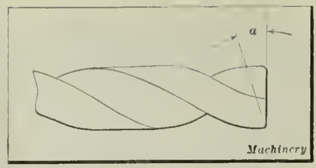
Lathe Equipment for cutting Rivets

The cutting edge of the lathe tool at *J* is fed up until it will just cut thin paper when the arbor is rotated. The carriage and the tailstock are then clamped tightly in place. The lathe can be run at a fairly high speed, depending upon the size of stock to be cut. The highest speed obtainable with an open belt was used in cutting the 1/16-inch wire. The wire is fed through under constant tension, and should jump forward and strike the stop sleeve *D* as each piece is cut off. With this arrangement 3000 rivets were cut within five minutes.

East Walpole, Mass. JAMES A. KIRK

USING A TWIST DRILL FOR AN END-MILL

The following describes a method that was employed for finishing a thin-walled core-box which was comparatively deep. The corners forming the sides of the box were joined with a 3/16-inch radius, and the bottom was filleted to the sides with a 1/16-inch radius. Ordinarily a ¾-inch end-mill would have been used, but on account of the depth of the box such a tool could not be conveniently employed. Consequently, a ¾-inch twist drill was especially ground in the manner shown in the accompanying illustration. The lips of the drill were ground with suitable clearance, but the cutting edges were produced nearly flat, as is sometimes done for bottoming a hole. A 1/6-inch radius was ground at the outer corners of the lips, to suit the fillets at the bottom of the box. The box had previously been planed so that it would seat evenly on the table of a drilling machine, where the finishing of the interior was accomplished. The drill was set to depth by the regular stop on the machine spindle, and was fed down to this stop in the course of routing out the metal. By moving the box around under the drill on the table, the operation was completed without difficulty.



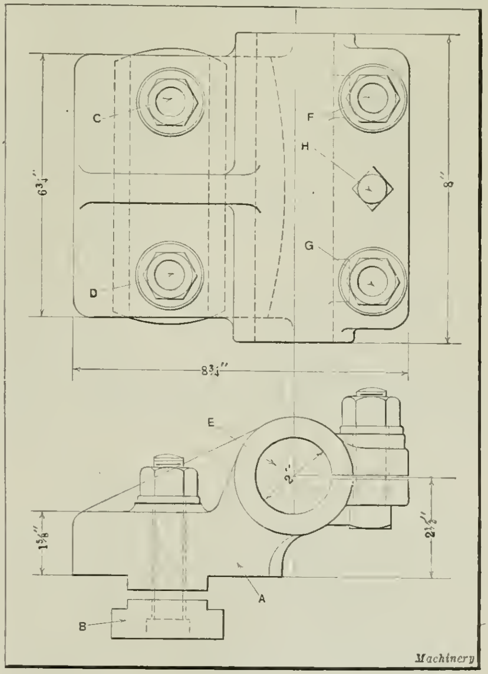
Twist Drill ground to serve as an End-mill

Since using the drill on this job, it has also been employed on a number of occasions for removing lumps and excess metal in core-boxes. It has been found that if proper care is taken in grinding, the drill will work easily and cut smoothly, and will not chatter nor gouge into the work. The angle *a* should not be greater than is necessary to provide clearance, and the center should be just a little above the two cutting edges of the drill. If the center is ground much above the edges of the drill, it will be found that the drill will cut freer, but it will not produce a smooth surface. It is not to be expected that a drill ground in this manner can be used in place of an end-mill in all cases, but in an emergency a tool of this kind will bridge over the difficulty very well.

Detroit, Mich. NELSON HALL

BORING-BAR HOLDER

The accompanying illustration shows one of a number of similarly designed boring-bar holders, intended for fast, heavy cutting on comparatively large work, such as big gears, sheaves, and large piston-ring castings of the pot type. The holder shown is used on a 24-inch gap-bed lathe, which



Boring-bar Holder for Heavy Cutting on Large Work has a swing of 48 inches when the gap is open. The cast-iron holder *A* and the steel slide *B* are made with tongues that are a snug fit in the tool-rest. When in use, the holder is clamped tightly down to the tool-rest by means of the two ¾-inch bolts *C* and *D*. The 2-inch boring-bar is a sliding fit in the reamed hole *E* of the holder, and is securely clamped by the two bolts *F* and *G*, located in the projecting ears.

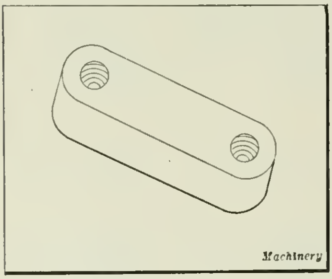
The upper ear is tapped for a ¾-inch set-screw *H*, which is used as a jack to loosen the grip of the holder when it is necessary to remove the boring-bar. When a bar smaller than 2 inches in diameter must be used, a split cast-iron sleeve is slipped over the bar, and both bar and sleeve are clamped in the holder. This design of holder has proved satisfactory for general maintenance work requiring accurate boring at high speeds and feeds. The holder and the boring-bar used with it are more rigid and have greater bearing surfaces than are ordinarily found in commercial holders.

Baltimore, Md. WILLIAM L. HAMPSHIRE

REMOVING KEYS FROM KEYSEATS

The width of a keyseat in small diameter shafts is usually given a tolerance of 0.001 inch, limiting the maximum width to the standard dimension, and the minimum width to 0.001 inch smaller than the standard dimension. The width of the key usually varies from the standard size to 0.001 inch large. It is possible, therefore, for a man, working within these limits, to take an allowance of the extremes in both cases and give to the key a force fit of 0.002 inch. To remove from a shaft any key having a forced fit is a difficult job, and very often an attempt to do so results in spoiling the key.

The ordinary practice is to tilt one end of the key up above the keyway by means of quick, sharp blows, using a chisel and hammer for the purpose, and then pry the key from its seat with a screwdriver. Even when extreme care is used, a badly marred key usually results. Another common method is to hold the key in a vise and tap the shaft with a lead hammer. These methods may appear crude, but nevertheless they represent common practice.



Key provided with Tapped Holes to facilitate Removal from Seat

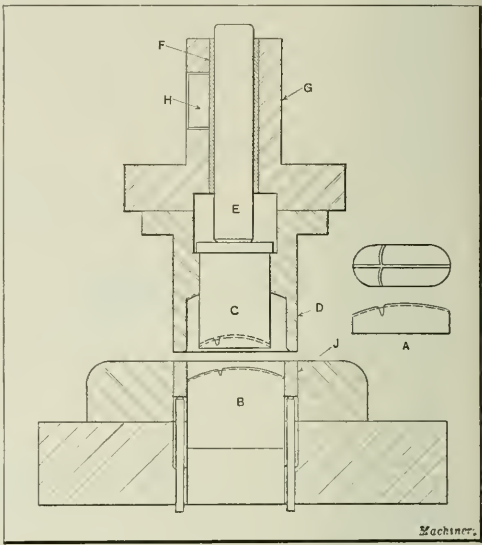
The illustration shows a key provided with two tapped holes. The removal of such a key is a simple matter, because all that is required to extract it is the insertion of two standard screws and the use of a screwdriver. The screws used in this manner are in reality miniature jack-screws. If the tapped hole projects into the shaft the threads on the ends of the screws that go into the shaft should, of course, be removed.

R. J. S.

FRICTION PAD FOR DRAWING DIE

The combination blanking and drawing die shown in the accompanying illustration is used on a single-action press to produce small shells of the shape shown at *A*. Considerable trouble was experienced in drawing these shells until the friction pressure-pad *C* was incorporated in the die. Before the pressure-pad was used, many pieces were spoiled from the slipping of the blank on the forming punch *B* during the drawing operation. The friction pad *C*, which entirely eliminated this trouble, is fitted in the combination blanking and forming punch *D* as shown. The hardened tool-steel pin *E*, in contact with pad *C*, is fitted in a hard fiber collar *F* which is held tightly in holder *G*. A tool-steel block *H* is set in a slot in punch-holder *G* so that it is located under a heavy set-screw in the ram of the press.

When the die is in operation, the set-screw in the press ram is screwed up fairly tight against block *H*. It should be adjusted until the proper amount of friction is obtained as determined by trial. As the ram descends, pad *C* comes against the blank as soon as it has been cut, and the friction between *E* and *F*, caused by the tightening of the screw on block *H*, is sufficient to emboss the grooves in the metal, thereby locating the piece and holding it firmly during the forming process. At the end of the downward stroke, the



Combination Blanking and Drawing Die

pad *C* is, of course, flush with the inside of the forming punch *D* and remains there until the top of the stroke, when the pin *E* is pushed down again by the knock-out of the press, which causes the shell to be ejected from the punch. This friction device, of course, takes the place of the spring which is commonly used for such work; a spring cannot be used in this case as the pressure would be maintained during the up stroke and the thin shell would therefore be crushed between pad *C* and pressure ring *J*. This die has been in use for some time, and has given satisfactory results.

East Orange, N. J. W. B. GREENLEAF

STEAM TURBINE LOCOMOTIVE

A locomotive has been put in service on the Swiss Federal Railways which is provided with a steam turbine and condensing plant. The engine is designed and constructed by the Swiss Locomotive & Machine Works, Winterthur. The locomotive frames carry the boiler in the usual way, and the steam turbine is placed in front on the smokebox. The turbine drives, through double spur gearing, a jack-shaft placed across the frame, which, in turn, transmits the power to the driving wheels. The surface condenser is placed between the frames under the boiler, the simplification of the mechanism, due to the use of the turbine, making this space available. The condensing water is cooled by the current of air produced by the movement of the locomotive. In the trial runs that have been made in ordinary railway service, the arrangement has proved successful, and considerable economy is expected from the design.

Reducing Costs by Electric Welding

Specific Examples of Savings Effected in a Number of Industries by the Use of the Electric Welding Process

THE electric welding process has been developed during the last ten years to a point where instead of being an unusual method, it is now commonly employed in the manufacture of a great number of devices and appliances. The following article gives details relating to the application of electric welding in metal-working plants using machines built by the Winfield Electric Welding Machine Co., and the Taylor Welder Co., both of Warren, Ohio. The data are presented in order to bring to the attention of manufacturers generally what has already been accomplished in securing economy and reducing costs by electric welding—a method which should be investigated whenever production work is contemplated for which the process would prove suitable. In the following, the data relating to each class of manufacture are given briefly and concisely, as a record of performance.

Electric Welding in Automobile Work

A manufacturer of sheet-metal parts for automobiles, trucks, and tractors in the Middle West uses the electric welding process for materials of a thickness from 1/4 inch down to No. 24 gage. On account of the variety of parts welded, it is difficult to state specifically the number of welding operations performed per hour, but on ordinary flat pieces requiring five or six welds, this company averages about 200 pieces per hour. The estimated increase in production as compared with the riveting process on this class of work is from 100 to 150 per cent.

In another plant, 1/4-inch soft cold-rolled steel is welded, four welds being made in each piece. As compared with the old method of performing this work, the saving is approximately $40 per 1000 pieces, and the production has been increased from 12 to 70 pieces per hour.

Welding Metal Furniture and Metal Doors

One plant making fireproof metal cabinets employs five welding machines for welding sheet steel of from 10 to 28 gage. In this plant electric welding has been applied for ten years, and riveting operations have been practically eliminated except in cases where it is considered impracticable to use a weld. Compared with riveting, however, it is estimated that the increase in production by electric welding is something like 500 per cent, and the company states that even this figure may be considered conservative. On the average work in this plant, sixty welding operations per minute are easily performed.

In another metal furniture plant parts of from 10 to 24 gage are welded at the rate of from 100 to 200 parts per hour. In this case practically all the assembling work is done by welding. The estimated saving in the cost of production is 50 per cent and, at the same time, the rate of production is increased about 50 per cent.

A well-known manufacturer of hollow metal doors and trimmed metal moldings and shapes, stampings, and various other metal specialties, employs both the butt-welding and spot-welding processes. The welding material ranges from 14 to 22 gage and varies in width from 2 to 10 inches. A material saving in cost is shown, and the estimated increase in production ranges from 25 to 500 per cent over methods formerly used, according to the particular operation performed.

Welding Foundry Supply Material

An Ohio manufacturer employs the electric welding process for double chaplets and plate-fitted chaplets, such as are used in foundry work. In making up the double-head chaplet, a plate is welded on each end of a round stem in one operation. On the plate-fitted chaplet, a single plate is welded to a stem in one operation. Stems 3/16 inch in diameter and plates of 18 and 20 gage are successfully welded by these processes, these dimensions being the minimum for which the machine is used. It is employed for either type of chaplet having stems up to 5/8 inch in diameter, with either 1/8-inch or 3/16-inch plate. The smaller sizes mentioned are welded at the rate of from 300 to 350 per hour, while the heavier sizes vary with the diameter and length of the stem.

Welding Curb and Gutter Rails

Another Ohio manufacturer making curb and gutter rails uses a spot-welding machine for welding the sleeves and reinforcing cleats to these rails. The material used is Nos. 10 and 11 gage. It has been found that 100 6-inch rails may be welded per hour, there being fourteen spots on each rail. At this rate of welding, the time required for placing the sleeves and cleats previous to welding is included. There is a saving effected in the cost of material, as compared with riveting, of 10 cents per rail, and the increase in production, which is the biggest factor, amounts to about 75 per cent.

Use of Electric Welding in the Manufacture of Household Utilities and Toys

A manufacturer in New York employs the electric welding process for welding operations on household utilities, such as wire soap-dishes and bathroom fixtures. The sizes of wire mostly welded range from 1/16 to 3/16 inch, and in this case each machine used welds approximately from 63,000 to 65,000 welds per day. As an indication of the reliability of the electric welding machine in its present state of development, this manufacturer mentions that for the last six years the cost of repairs on his machines has been negligible.

A New England manufacturer of children's play wagons uses electric welding machines for the welds on wheels and other metal parts, using principally black sheet and band iron and some light channel iron. The number of welds per hour for the different sizes of wheels vary from 150 to 300. This manufacturer states that while the saving in the cost of material is merely that of rivets, this item in the course of a year would amount to the cost of two welding machines. The saving in labor cost over the riveting method is estimated to be about double that of the saving on rivets.

The Metal-working Industries

DURING the last three months there has been improvement, although slight, in the machine tool industry. December is usually a quiet month in the machinery business, and as this year is no exception, the improvement noted goes back to the months of October and November. The improvement has not been uniform; generally there has been less demand for heavy machine tools than for the medium and small sizes. The demand has been more for the standard lines—especially the medium and low-priced types—than for automatic or high-production machinery. A few exceptions are noted, one of the leading builders of heavy machine tools reporting some very good sales. There has been only a limited amount of railroad buying, and the best trade has been in small machines for trade school use and for repair work. One builder, devoting himself exclusively to trade school machines, has been running at 50 per cent capacity during the entire year without adding to his stock.

Activity in the Small Tool Business

By comparison, the small tool business is very much better than the machine tool business at the present time. Whenever the metal-working shops begin to be active, even to a limited extent, they must have small tools—taps, dies, reamers, milling cutters, drills, etc., whereas they need not add to their machine tool equipment until they have reached capacity production. There has been a surplus stock of drills on the market during the past year, but the stock of other small tools in the hands of users and dealers appears to be exhausted, and one manufacturer of small tools is now operating at 45 per cent capacity, with present indications in the trade pointing toward 55 or 60 per cent within another month. Another of the leading makers of small tools is running at 40 per cent capacity, without adding to his stock. The hardware plants are among the best customers at the present time for tools of this kind, as many of the leading hardware factories are fully occupied. This, in turn, would indicate that there is expectation of increased building activity next year, which, if it materializes, would react favorably on all lines of business.

Machine Tool Prices

The substantial reductions in machine tool prices during the past year were made possible by reductions in pig iron, castings, and steel, brass and bronze, and also by reductions in wages, but there are many costs entering into machine tool building that have not come down, notably freight rates and taxes. The higher cost of transportation has increased the selling expense to a point where it is greater than ever before. While the increased cost of selling is due to many factors, high passenger fares and the higher cost of hotel accommodations are important items. In neither of these costs is there much prospect of any immediate or material reduction. These expenses become a permanent addition to the selling price, because they are definite factors that increase costs.

In the special machinery field and in the manufacture of parts as well as in jobbing work, competition is very keen—in some cases almost ruinous. In the parts manufacturing field, purchasing agents have been taking advantage of present conditions in the industry to force quotations so low that the seller loses instead of making a margin of profit; and sometimes the methods employed to get the lower prices would not stand the test of good business ethics. Some of the parts manufacturers, naturally anxious to get work for their idle plants, have too eagerly played into the hands of the purchasing agent.

A number of machine tool builders are partially occupied on contract work for machinery and devices outside of the machine tool field. In some cases it is likely that the plants will be permanently occupied on such work in addition to the regular machine tool business. In this way the excess capacity of some of the machine tool building plants will eventually be absorbed. There have been consolidations in the machine tool field also, and shops have been dismantled and added to the plants of other companies controlled by the same financial interests.

Perhaps the most serious factor in the machine tool field at the present time is the large stocks on hand. Even if buying should be fairly brisk within the next few months, it would be quite some time before the shops could run at anywhere near capacity. Foreign trade presents a new problem in the machine tool field, where 25 per cent of the production usually has been disposed of abroad. In some lines over 50 per cent of the business in pre-war years was foreign. Now the European trade has been reduced to almost nothing, and only the trade with Australia, Japan, China, and India—a comparatively small trade at best—is normal. There has been a fair trade with South America during the past year, but competition in the South American field with British and German machinery is very keen. The total foreign trade in machine tools during the month of October, the last month for which the Department of Commerce has issued complete detailed statistics, was only about 15 per cent of the trade early in 1920.

The Iron and Steel Industry

The iron and steel industry—the barometer for the entire metal-working field—is steadily though slowly improving. The average operation of the steel mills is from 40 to 43 per cent, but the November output was the largest of the year. There have been further price concessions, and a considerable agitation for lower freight rates; even though prices at base points may not be reduced further, lower freight rates would enable the consumer of iron and steel to obtain his raw materials at a considerable reduction, because freight rates are a very important item in the price of pig iron and steel at points removed from the iron-producing districts.

The Railroad Situation

It is estimated that the railroads will save $50,000,000 a year by the application of the revised working rules governing railroad shop employes, accepted by the United States Railroad Labor Board, which went into effect December 1. According to these new rules, the open shop principle is recognized on all railroads, and members of certain crafts are permitted to do minor jobs previously required to be done by members of other crafts. The new rules supplant the National Agreement made during Federal control of the railroads, and constitute one of the most important advances in restoring efficiency in railroad operation.

On account of the hampering influence of the unions, a number of railroads are understood to be considering leasing their repair work to outside shops. The Erie and the New York Central railroads have already had some of their repair work done in this manner, and it is stated that a considerable saving has been the result.

The net earnings for the month of October, the last month for which complete figures are available, show the highest increase for the year, and it is confidently expected that the railroads will soon be in the market for new equipment—both rolling stock and machine tools.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW AMERICAN METAL-WORKING MACHINERY

The New Tool descriptions in MACHINERY are restricted to the special field the journal covers machine tools and accessories and other machine shop equipment. The editorial policy is to describe the machine or accessory so as to give the technical reader a definite idea of the design, construction, and function of the machine, of the mechanical principles involved, and of its application.

How To Reduce Production Costs ?

Fellows High-speed Gear Shaper

A NEW high-speed gear shaper designed to meet the requirements of manufacturers having a large number of gears of one particular size to cut, but which is so arranged that by the provision of suitable work-holding fixtures it can be adapted for many classes of work, is being introduced to the trade by the Fellows Gear Shaper Co., Springfield, Vt. This new machine is in many respects similar to the standard gear shaper built by this concern. External, internal, and helical gears can be handled. A special feature of the machine is that it can automatically take roughing and finishing cuts in one setting and with the same cutter. This is obviously an important factor in a production machine, as it eliminates the performance of second operations.

Principle of Operation

The principle of operation is fundamentally the same as that of the standard gear shaper in that the cutters used resemble gears and are employed on the generating principle. These cutters are standard and have the teeth generated with precision after hardening. Because of the high speed at which the cutter is operated and the short stroke of the machine it is not the practice to machine several gears at one time, except when they are very thin; but even though only one gear is machined at a time, high rates of production are secured. An advantage obtained by this method is that inaccuracies produced when a number of gears are held on one arbor are eliminated.

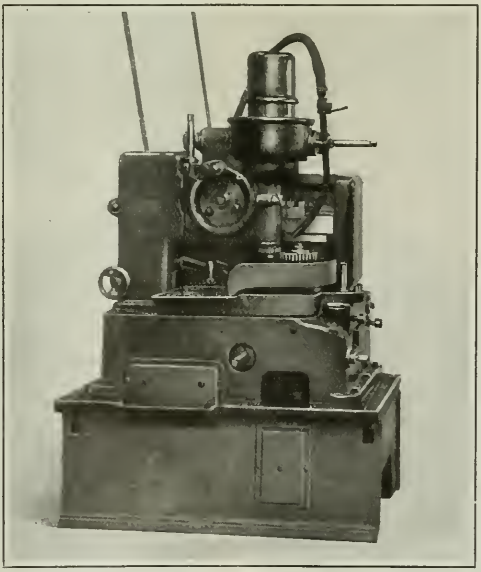

Fig. 1. High-speed Gear Shaper made by Fellows Gear Shaper Co.

As the cutter has a comparatively short stroke, and can therefore be operated at a high rate of speed, it remains in contact with the work for only a short period of time. This contact is so short that the cutter does not become heated and so its keen cutting edge is not impaired. As the work also does not become heated, variations in the teeth due to changes in temperature are not met with. Cutting compound is pumped to the cutter and the work to keep them cool, and this enables the machining of alloy steel gears to be done rapidly and accurately.

As on the standard gear shaper, change-gears are provided for taking care of the difference between the number of teeth on the cutter and the number of teeth on the gear being cut, but owing to a modification in the design of this machine the ratio is different, as will be explained later. The method of obtaining the rotary feed for the cutter also differs, and this too will be dealt with subsequently.

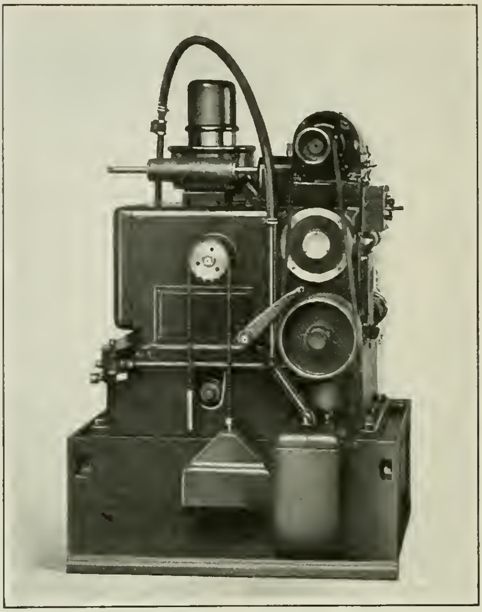

Fig. 2. Rear View of the Fellows High-speed Gear Shaper equipped with Individual Motor Drive

The Cutter-spindle and Saddle

The cutter-spindle is guided in a straight path by accurately finished guides, being reciprocated by means of a connecting-rod and crank-arm which may be clearly seen in Fig. 3. The operating end of the crank-arm has a hardened steel gear segment on it which meshes with rack teeth on the cutter-slide. The crank-arm has a bronze bushing at the fulcrum, and is equipped with ball bearings where it is attached to the connecting-rod. The connecting-rod is operated through a crankshaft having an adjustable crankpin, the position of which governs the length of the cutter stroke. The lower end of the connecting-rod is mounted on a self-aligning ball bearing on the crankpin, this construction permitting the use of high reciprocatory speeds.

The crankshaft is made from an alloy steel forging, and is driven from the rear through a single-pulley drive. This construction enables a group of gear shapers to be driven from a jack-shaft, without the employment of a countershaft. As shown in the rear view of the machine, Fig. 2, provision has also been made for the installation of an individual motor drive, a bracket being fastened to the top of the machine for attaching the motor. A 1-horsepower motor provides sufficient power for operating a single machine. When a group of machines is installed, it is economical to bolt the machine bases together and operate the machine as one unit. When this is done a 6-horsepower motor furnishes ample power for ten machines.

The position of the saddle carrying the cutter-slide is adjusted to suit different gear diameters by means of a worm, worm-wheel, pinion, and rack, and can be withdrawn to permit the location and removal of work. The saddle is mounted on accurately machined guides on the face of the housing. For the depth feed it is advanced toward the work by means of a cam which may be seen in Fig. 3, provision being made on this cam for automatically taking both roughing and finishing cuts. The cutter is gradually fed to the proper depth as the blank and cutter are rotated together. The cutter overlaps on the finishing cut so as to prevent variations in the thickness of the teeth.

Work-spindle and Relieving Mechanism

The work-spindle is almost identical in design with that on the standard gear shaper in that it carries a reverse taper work-arbor. It is rotated by means of worm-gearing which is directly connected through gears and shafts to the upper worm and index-wheel which operate the cutter. The spindle is held in an apron located in an accurately machined seat in the bed. The work is withdrawn from the cutter on the return stroke by means of a relieving mechanism consisting of a cam at the rear of the machine which operates the apron lever through a connecting-rod. This mechanism may be seen in Fig. 5.

Speed and Feed Mechanisms

As previously stated, the proper relation between the number of teeth on the cutter and on the work is secured through change-gears which the operator is in the act of changing in Fig. 5. Owing to the fact that the upper and lower worm-wheels have the same number of teeth, the ratio between the cutter- and the work-spindles is 1 to 1, and so the computation necessary in selecting the proper change-gears for a job is easy. Any needed pair may be determined by the use of a simple formula, which is cast on a plate fastened to the machine just above the change-gears. After a set of gears has been placed on the shafts, the gears are protected by a cover. The time for a gear-cutting operation is controlled by the speed at which the cutter-spindle is operated, in conjunction with the rotary feed. Change-gears are also provided for this feed, which are accessible by removing a plate; this was done prior to taking the photograph

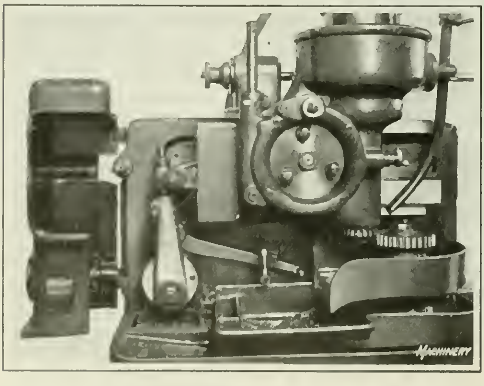

Fig. 3. Close-up View of Mechanism which imparts Reciprocating Movements to the Cutter-spindle

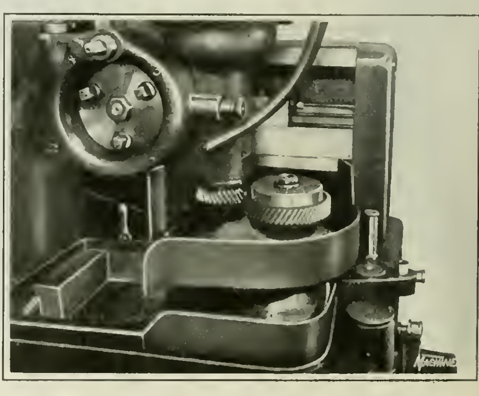

Fig. 4. Cutting an Automobile Engine Helical Timer Gear on the Gear Shaper

reproduced in Fig. 6. The plate is held in place by means of four safety set-screws. The rotary feed is expressed in strokes of the cutter per revolution, and gears are provided for securing seven different feeds ranging from coarse to fine. A feed chart is attached to the plate covering the feed gears. The coarsest feed is 435 strokes per complete revolution of the cutter, while the finest feed is 1735 strokes per complete cutter revolution. The selection of a feed is governed by the material being cut, a coarser feed, of course, being used for cast iron than would be possible for alloy steel. Roughing and finishing cuts are taken at the same rates of feed and speed.

Oiling Provisions

The machine has been designed to run with little attention so far as oiling is concerned. All high-speed shafts are mounted in ball bearings and are automatically lubricated. A reservoir in the bed holds two and one-half quarts of light machine oil, which is pumped to additional reservoirs from which wicks carry it to the different bearings. The cutter-spindle shoe and guide are lubricated from a reservoir in the saddle housing which may be exposed by removing a cover. A reservoir provided on the apron may be filled after unscrewing a cap. Only three grease cups are furnished on the machine, these being supplied because it was found that for a slight oscillatory movement, grease is more satisfactory than oil. Only one turn of the cups per day is sufficient to keep the working members well lubricated.

As previously mentioned, a 1-horsepower motor furnishes ample power to cut any type of gear within the capacity of the machine; this is due to the fact that all reciprocating members are light in weight and all high-speed shafts are mounted on ball bearings.

Provisions for Cutting Internal, Helical and Herringbone Gears

This gear shaper will handle any form of gearing used in standard automobile construction, as well as some gears of special design. It may be used for cutting both steps on a countershaft gear and the external and internal teeth on an internal clutch gear. In adapting the shaper for cutting internal gears, a slight modification is necessary in the design of the machine, owing to the fact that in cutting an internal gear the cutter must work on the right-hand side relative to the center of the work-spindle, instead of on the left-hand side. A special crank-arm is necessary with this arrangement, but all other members of the machine are identical in design with those on a machine for cutting external gears only.

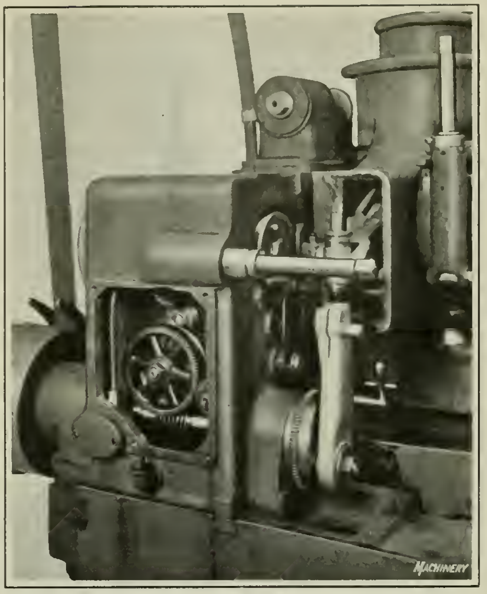

Fig. 6. View taken from the Left-hand End of Machine, showing Feed-change Gears, Crankshaft, Connecting-rod, etc.

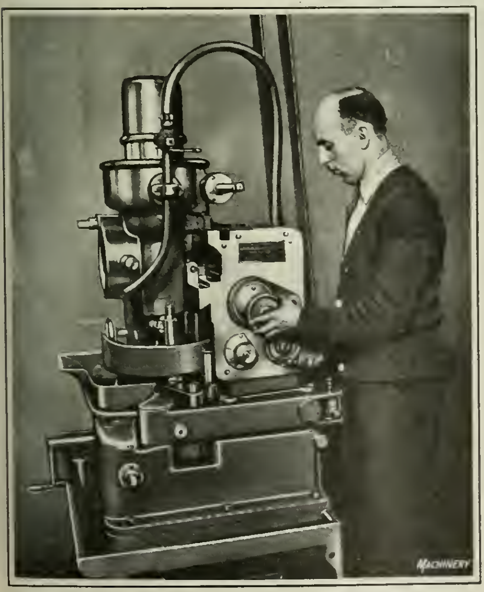

Fig. 5. View of Right-hand End of Machine showing Speed-change Gears and Relieving Arm connected to Work Apron Lever

By another slight modification somewhat similar to that used on the standard gear shaper for the same purpose, this high-speed shaper can be adapted for cutting helical and herringbone gears. Fig. 4 illustrates an operation on a timer gear for an automobile engine.

BARBER-COLMAN AUTOMATIC HOB-SHARPENING MACHINE

The proper sharpening of any cutting tool is essential if maximum efficiency is to be obtained in the operation of the tool, but in the case of formed cutters and hobs, it is a matter of exceptional importance, because tools of these types have their teeth relieved to allow for sharpening and still retain the form of each tooth throughout its entire length. To enable a cutter or hob to produce its true form continuously, it must be so sharpened that the cutting face of each tooth is on a radial line with the center of the cutter. In order to eliminate the personal element in the performance of such cutter grinding operations, the Barber-Colman Co., Rockford, Ill., has developed the automatic hob-sharpening machine here illustrated. Although primarily designed for sharpening hobs up to 4 inches in diameter and 4 inches in length, it is equally applicable to sharpening formed cutters of sizes within the capacity of the machine.

The hob to be sharpened is mounted on a mandrel carried in the headstock spindle and having the outer end supported by a sliding tail-center. A reciprocating motion is imparted to the work-slide, so that the hob moves back and forth under the grinding wheel. After each forward and return stroke of the table, the hob is indexed by a mechanism which provides for indexing hobs with different numbers of gashes. It is an easy matter to change the machine to grind a different hob. The machine is readily set for grind-

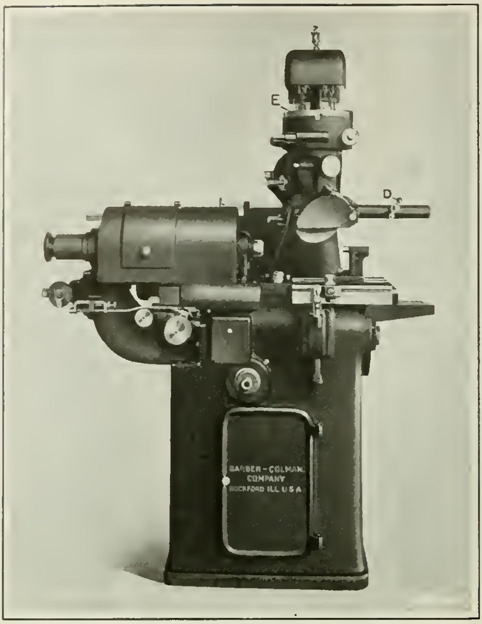

Fig. 1. Automatic Hob-sharpening Machine brought out by the Barber-Colman Co.

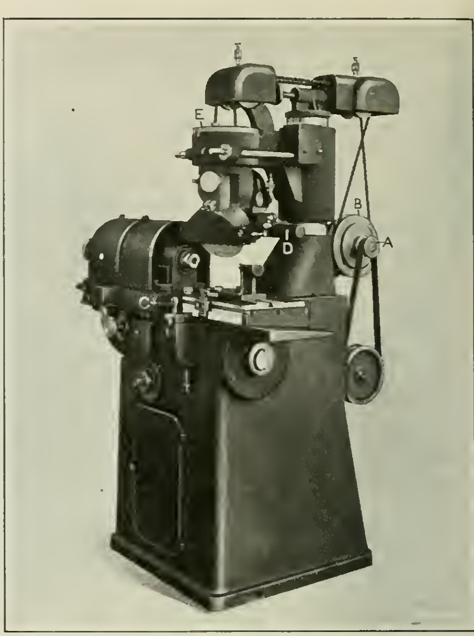

Fig. 2. Driving End of Barber-Colman Belt-driven Hob-sharpening Machine

ing hobs with either straight or spiral gashes, of various degrees of angularity, and either right- or left-hand. Provision is also made for feeding the hob to the grinding wheel after each complete revolution of the work, regardless of the number of gashes. The faces of the hob teeth are always ground or sharpened to conform with true radial lines from the hob center, irrespective of whether the gashes are of straight or spiral form.

The machine is driven from a countershaft *A*, Fig. 2, which carries tight and loose pulleys, but when motor drive is desired, the countershaft is dispensed with and pulley *B* is mounted directly on the motor shaft, the motor being set on a base substituted for the countershaft bracket. Power for driving the grinding wheel spindle is furnished by means of an endless belt running over grooved idler pulleys mounted on ball bearings, and is transmitted to the grinding wheel spindle by spiral bevel gears at the back of the wheel-head. The wheel-spindle is also equipped with Norma ball bearings which are mounted in a sleeve so that the entire construction is self-contained.

At the rear end, the wheel-spindle is extended through and loosely splined within the hub of the driven gear, affording the equivalent of a floating drive for the wheel-spindle which does away with any tendency toward vibration or loss of accurate alignment. Reciprocation of the work-table is accomplished through a drum cam driven from the rear of the machine. The friction clutch may be disengaged at any time by lever *C*, to stop the work in any desired position relative to the wheel. A diamond wheel-truing device *D* provides for keeping the grinding wheel accurately dressed.

In grinding hobs with spiral gashes, it is necessary to impart a reciprocating rotary movement to the work as the hob moves back and forth under the grinding wheel; no such movement is, of course, necessary in the case of straight-gashed hobs. The grinding wheel must also be set to suitable angles for grinding hobs with various forms of gashes. The wheel-head has a graduated dial *E* by means of which the wheel may be set to any desired angle with the line of travel of the work-table.

The reciprocating rotary movement of the work is accomplished by means of a slide *F*, Fig. 3, the top of which

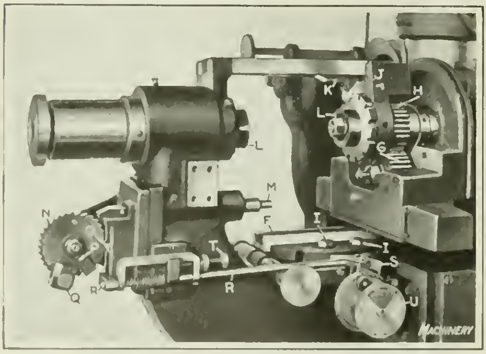

Fig. 3. Mechanism for Imparting Reciprocatory Rotary Movement to Spiral-gashed Hobs, for indexing and for feeding

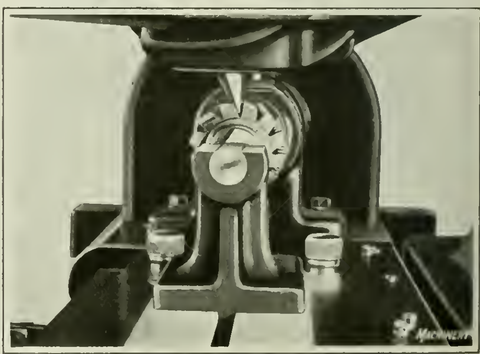

Fig. 4. Close-up View of Tailstock showing Setting of Grinding Wheel for sharpening Spiral-gashed Hobs

is grooved to receive a sliding block secured to the under side of a transverse rack. This rack meshes with idler pinion *G* which, in turn, transmits movement to pinion *H* secured to the work-spindle. Slide *F* may be set to various angles, either right- or left-hand, or located parallel to the line of travel of the table, according to the form of the gashes in the hob. The support on which slide *F* is mounted is furnished with a graduated dial, similar to dial *E*, so that angular settings may be accurately made without loss of time. After the setting has been accomplished, the slide is locked by means of two nuts *I*.

The mechanism employed for indexing the hob to suit the number of gashes is also clearly shown in Fig. 3. While a forward and return stroke of the work under the grinding wheel is in progress, the work is held in a definite position relative to the wheel by means of a dog *J* that enters a notch in the index-plate. As the slide approaches the end of its return stroke, cam *K* draws this dog out of the notch in the index-plate, and at the same time the two ratchet members *L* come into engagement. The left one of these members has a coarse-pitch screw running in a nut in the supporting bracket. Continuation of the table movement pushes the left-hand ratchet member *L* toward the left, the screw causing it to rotate and thus turn the index-plate. Immediately after the rotation commences, the catch carried by cam *K* releases dog *J*, so that it slides over the face of the index-plate and is free to snap into the next notch, thus locating the work for grinding the next consecutive gash.

While movement of the table toward the left indexes the work, it also provides for feeding the work toward the grinding wheel. This is accomplished by the engagement of the left-hand end of the table with plunger *M* that actuates a pawl and ratchet *N*. At each forward and return stroke of the table, this ratchet is turned and locked in place by means of a catch *O*. When the work has made one complete revolution, dog *P* disengages catch *O* to allow ratchet *N* to return to its starting position, and at the same time dog *Q* strikes the end of the feed mechanism plunger *R* and, through the action of a ratchet and pawl *S*, turns a feed-screw that imparts a transverse movement to the cross-slide on which slide *F* is mounted. This movement of the slide, through the medium of the rack and gears *G* and *H*, rotates the hob in such a way that it moves toward the grinding wheel and provides for taking a deeper cut. This indexing takes place after each complete rotation of the work. A graduated slide can be set by thumb-screw *T* for taking a cut from 0.0005 to 0.002 inch deep, according to requirements. Hand feeding may be accomplished by turning wheel *U*.

When furnished with an individual motor drive a two-horsepower motor running at 1800 revolutions per minute is furnished. The machine will handle spiral hobs with gashes of any angle from 30 degrees left-hand to 30 degrees right-hand. The grinding wheel is 7 inches in diameter. Seven index-plates are furnished for hobs having from ten to sixteen gashes. The machine weighs about 2250 pounds.

GLEASON 4-INCH SPIRAL BEVEL GEAR GENERATOR

The increasing demand for spiral bevel gears in preference to the straight-tooth type for certain purposes has led to the development of interesting and ingenious designs of machines at the Gleason Works, Rochester, N. Y. A 4-inch spiral bevel gear generator especially adapted for cutting small gears for sewing machines, motion picture machines, etc., is illustrated in Figs. 1 and 2. This machine finishes the tooth space from solid stock in one operation instead of cutting one side of a tooth at a time, as is frequently done when using machines designed for larger work. One of the distinguishing features of this 4-inch generator is that all the generating motion is applied to the gear, instead of rolling the gear and cutting tools together, as is done on the larger spiral bevel gear generators, and also on the machines used for generating straight-toothed bevel gears.

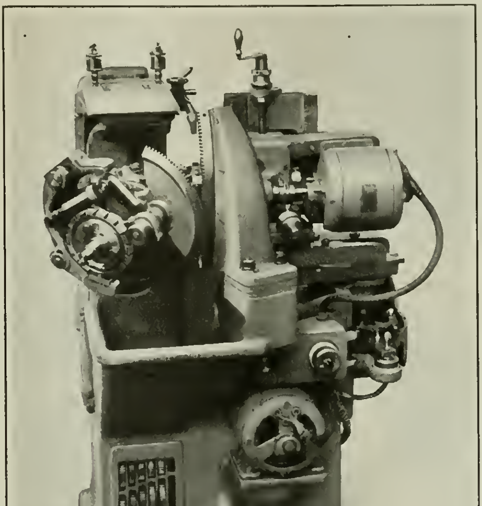

Fig. 1. Gleason 4-inch Spiral Bevel Gear Generator

The work-spindle is carried by a segment-shaped base and has the indexing mechanism at its outer end. The work-spindle is adjusted, according to the angle of the gear or pinion to be cut, upon this segment-shaped base which is attached to a drum or cradle that is given a rolling motion. This rolling cradle is oscillated by a crank mechanism through a connecting link. The crank mechanism consists of an ordinary slotted crank, for varying the amount of rolling motion, and is driven by worm-gearing and a Whitworth motion which accelerates the movement of the cradle after a tooth space is finished and the motion has been reversed.

The rolling movement of the cradle causes the work-spindle axis to swing about axis *A*, Fig. 2, which is the axis of both the cradle and the crown gear segment *B*. Segment *B* is fixed and is engaged by a master gear segment *C* having an arm or extension connecting with the work-spindle sleeve. The latter is locked to the work-spindle, except when the indexing pawl is released; consequently, as the work-spindle swings bodily about the axis *A*, gear segment *C* rolls upon the stationary crown gear segment *B*. The result is that the movement of the work-spindle axis corresponds to the path described by the axis of an imaginary gear rolling upon a crown gear; moreover, the rotation of the work-spindle about its own axis, as derived from segment gears *B* and *C*, corresponds to the rotation of the imaginary gear about its axis. The motion of the gear blank relative to the cutter is the same as on machines which are designed to apply the generating motions to both gear blank and cutting tools. The latter machines, however, are so arranged that the work-spindle and gear blank rotate about a *fixed* axis, while tools representing the sides of crown gear teeth are also given a rolling motion corresponding to the rotation of a crown gear about its axis.

The action of the machine when cutting a gear is as follows: The cutter, which is given an in-and-out movement, begins to cut as the work-spindle approaches the bottom of the rolling movement. As the gear rolls upward, one tooth space is finished on both sides, and when near the upper end of the rolling movement the cutter begins to withdraw. Then as the downward or backward motion begins, the work indexes, the cutter gradually advancing into the work during the remainder of the downward movement. The indexing movement is derived entirely from the generating motion through an ingenious mechanism located at the outer end of the work-spindle.

This machine is driven by two ½-horsepower motors. One motor drives the cutter-spindle through a flexible coupling and a pinion meshing with a large gear located just back of the cutter-head. The other motor supplies power for the feeding movement of the cutter-spindle head, and also for the generating action. The feeding movement of the cutter-head is obtained from a cam designed to give a relatively slow movement while the cutter is at work and a rapid return. The in-and-out movement can be varied according to the depth of the tooth by means of an adjustable cam-lever, which is similar in principle to the design used on other types of Gleason machines.

The cutter-spindle slide with its driving motor may be adjusted vertically, and a horizontal adjustment is also provided for the cutter-head. These adjustments permit setting the cutter in the correct position relative to the gear blank, according to both the spiral angle and the "hand" of the spiral. A reversible motor is used for the cutter-spindle, so that the rotation can be changed for using either a right- or a left-hand cutter. Graduated dials on the horizontal and vertical adjusting screws for the cutter-slide enable the latter to be set accurately to any given position by referring to a chart worked out for different gears.

The cutters are made either right- or left-hand and range in diameters from 1.10 to 3.5 inches. The small cutters are made solid and have four blades, two cutting on the inside and two on the outside. The larger cutters have eight adjustable blades, four cutting inside and four outside. The same cutter may be used for both gears and pinions, but the vertical position relative to the center of the work must be changed. Thus if the center of the cutter is below the center of the gear, it must be set above the center when cutting the mating pinion, since the latter must have left-hand teeth if the gear has right-hand teeth, or vice versa. The time required for cutting gears on this machine varies widely for different classes of work, the range being from five to twenty-six seconds per tooth.

The capacity of this machine is shown by the following specifications covering the 3½-inch cutter. Longest cone distance, 30-degree spiral angle, 2⅛ inches; longest face, ½ inch; greatest pitch angle, shafts at 90 degrees, 75 degrees 58 minutes; smallest pitch angle, shafts at 90 degrees, 14 degrees 2 minutes; extreme ratio, shafts at 90 degrees, 4 to 1; largest pitch diameter, 4 to 1 ratio gear, 4 inches; largest pitch diameter, 4 to 1 ratio pinion, 1 inch; largest pitch diameter, 4 to 1 ratio, 3 inches; largest diametral pitch, 10.

The equipment regularly furnished includes a set of eight cutter speed-change gears; a set of twelve feed-change gears; a set of eleven segments; an index-plate; a cutter gage; an automatic stop; and a gear-driven cutting-oil pump. The machine weighs approximately 2000 pounds, and occupies a floor space of 33 by 44 inches. A description of the Gleason 8-inch generator for spiral bevel gears was published in April, 1921, MACHINERY, and an article on the first machine of this type built by the Gleason Works appeared in April, 1914, MACHINERY.

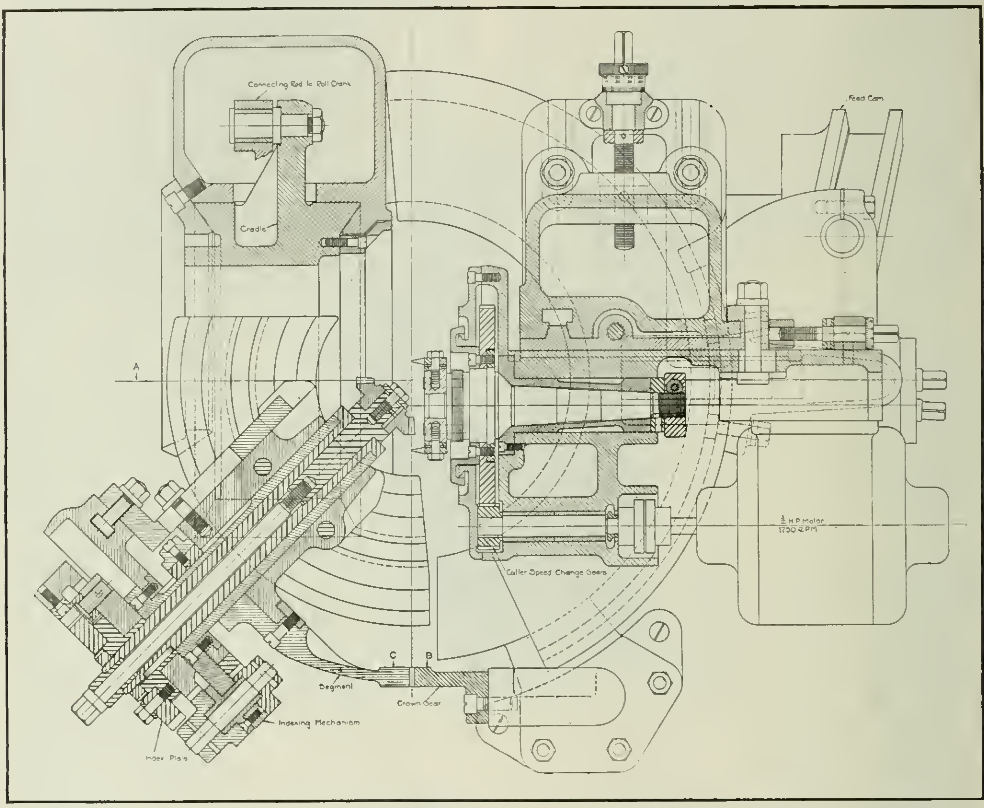

Fig. 2. Sectional Plan View of Generator for cutting Small Spiral Bevel Gears

UNIVERSAL "TRI-WAY" HORIZONTAL BORING MACHINE

A newly designed horizontal boring machine intended for handling heavy work in railroad and other shops, which is known as the "Original Tri-way" from the fact that the bed has three flat ways, has been placed on the market by the Universal Boring Machine Co., Hudson, Mass. The front one of the three ways and the center way serve as guiding surfaces for the sliding members on the bed, while the rear way helps to support the long carriage. The construction will be apparent by reference to Fig. 1. The bed is also designed for a coolant system, the top sloping toward the head end so that the coolant runs into a settling chamber at the end of the bed. From this settling chamber it overflows into another chamber from which it is pumped through piping to the work.

The design of the carriage and table is similar to that of the No. 3-A and 3½ machines built by this concern, except that the members are heavier and are designed to take care of coolant without piping. The head post has been provided with wide bearing surfaces for the head. The head has a reversing lever for the boring-bar, slow hand-feed for the boring-bar, and a lever for throwing in the higher boring-bar speeds. The handwheel on the head is used to obtain the fine hand-feeds, and the sprocket wheel for rapid hand-feeds. The vertical lever between the two is for reversing.

The starting and stopping lever of the machine is at the front of the bed and operates a friction clutch that controls the rotation of the main driving shaft. The gears for obtaining the various speeds and feeds are arranged in geometrical progression, and are operated by levers at the right-hand end of the bed. Attention is called to the convenient location of all control levers at this end of the machine. The left-hand upright lever is employed for throwing in either the table cross-feed, the longitudinal carriage feed, or the vertical head feed. The central upright lever is used to throw in all feeds and to effect rapid traverses, while the right-hand upright lever is used to reverse the feeding of the various members.

Wear of the rear post elevating screw may be compensated for by means of the nuts at the upper end of the screw. From the end view of the machine shown in Fig. 2, the method of mounting the driving motor may be readily observed. A few of the principal dimensions of the machine are as follows: Automatic travel of main boring-bar, 30 inches; travel of main boring-bar by resetting, 60 inches; size of table, 30 by 63 inches; power cross-feed of table, 48 inches; power longitudinal feed of carriage, 40 inches; power vertical feed of head, 30 inches; maximum distance from table to center of boring-bar, 30 inches; and greatest distance from faceplate to outer support, 72 inches.

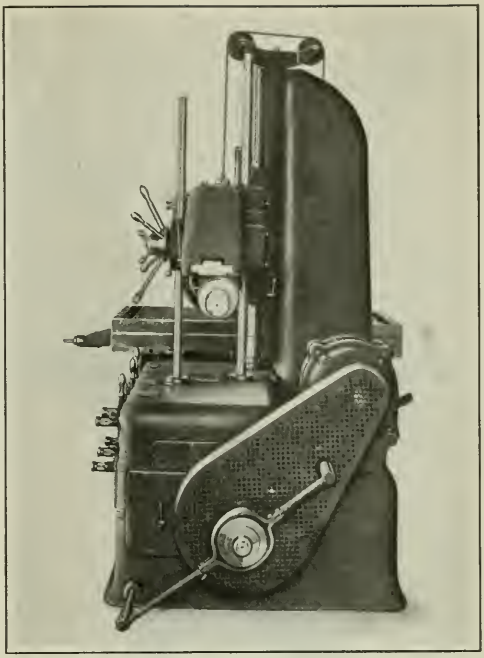

Fig. 2. End View of Boring Machine, illustrating the Motor Driving Arrangement

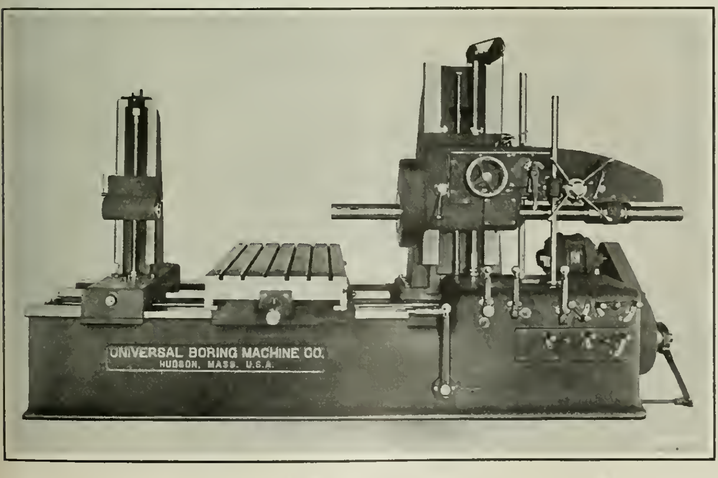

Fig. 1. "Tri-way" Horizontal Boring Machine developed by the Universal Boring Machine Co.

BRYANT WRIST-PIN HOLE GRINDING MACHINE

A double-head internal grinding machine primarily designed for finishing the wrist-pin holes of automotive engine pistons, but which can also be adapted for grinding holes in opposite ends of long pieces that cannot be handled conveniently on a single-wheel machine, has been placed on the market by the Bryant Chucking Grinder Co., Springfield, Vt. The main features of design of this machine are the same as on other machines built by this company. From the front view, shown in Fig. 1, it will be noted that the two grinding wheel heads are carried on the same slide. In the positions shown, the wheels are withdrawn from the hole preparatory to swinging the wheel-heads to the rear to permit gaging or changing of the work.

The work-holding fixture is mounted on the bed at about the middle, and from the sectional view of this fixture shown in Fig. 2, it will be seen that the piston is located in a vee and held securely in place by a clamp that operates against the inner surface of the piston directly over its contact points with the vee surfaces. The clamp is operated by a half turn of the wing-screw *A*. Body *B* of the fixture is provided with a stationary race C for the balls placed between this member and the rotating ring. The latter is held in place by the ball thrust bearing D which is secured to the chuck by ring E. The rotating members of the chuck are driven from the countershaft by belt F.

Fig. 3 shows the open side of the chuck after a piston has been removed. The clamp is in position for gripping the work at points G. In locating a piston, its skirt is slipped under the clamp, and the hand centering plug H, which fits a hole in the closed face of the fixture, is put in place and passed through the wrist-pin holes. This plug, of course, is of a size to fit the wrist-pin holes before they are ground. With the piston in place ready for grinding, the wheel-heads are swung down into the positions shown in Fig. 1, by turning handwheel I. Slide J is attached rigidly to the slide bar K, while slide L can be moved longitudinally on the bar. The movable slide is prevented from rotating on the slide bar by means of a bar located at the rear of the machine, which allows longitudinal movement between the two wheel-heads but keeps the wheels in correct alignment.

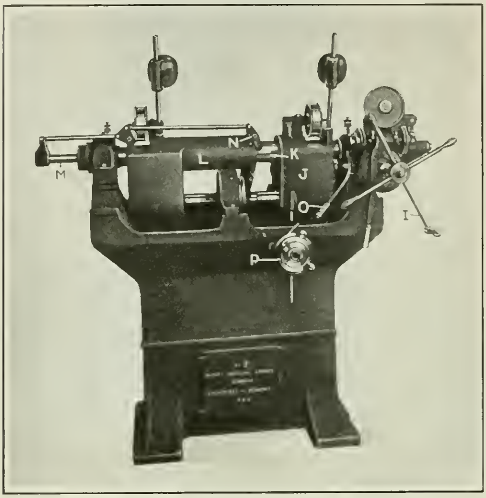

Fig. 1. Double-head Internal Grinding Machine developed by the Bryant Chucking Grinder Co.

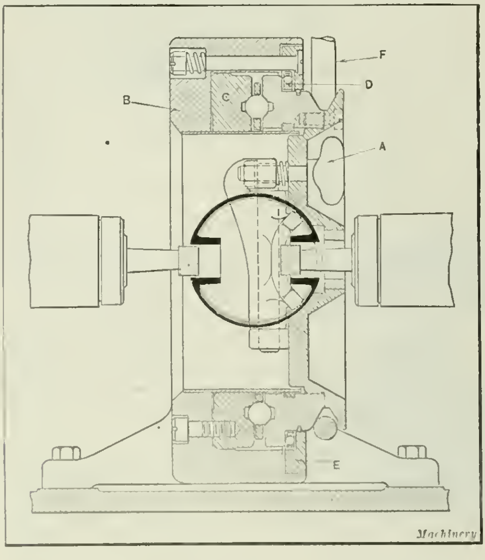

Fig. 2. Sectional View of Fixture for holding Automotive Pistons in Position for Operation

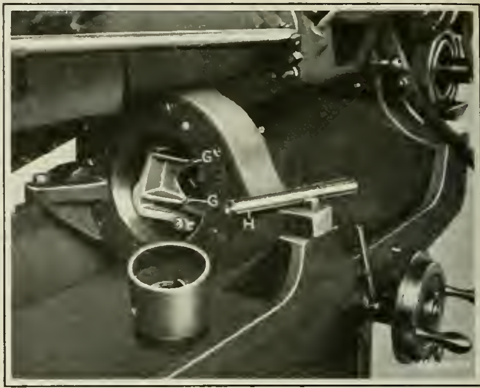

Fig. 3. Close-up View of Work-holding Fixture

The relative movement of the slides is obtained by means of racks which operate through bar M. As the wheels are advanced toward each other, crank-arm N strikes a stop and causes the movable slide to be clamped to the bar in the proper position. As previously stated, these actions of the machine are all obtained by one movement of handwheel I. Dropping lever O disengages one rack, and the two wheel-heads may then be operated as a single unit. The wheel traverse when grinding is provided for by a "load and fire mechanism" having reversing stops that are adjustable to give the desired length of stroke. This reversing mechanism is driven by a belt from the countershaft.

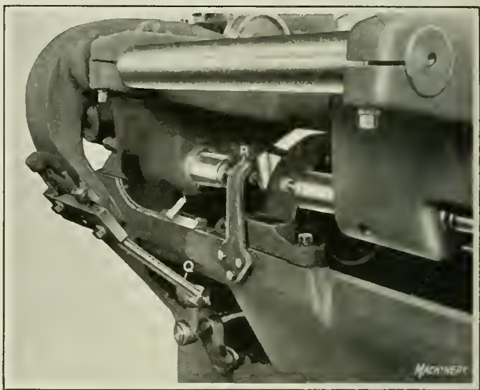

Fig. 4. Method of dressing the Grinding Wheels

The cross-feed is obtained by means of handwheel P at the front of the machine, which operates against a control plate clamped to an arm on the wheel-slide at the back of the machine, as shown in Fig. 4. The cross-feed extension Q is swung into position between the end of the feed-screw and the control plate, and adjusted so as to bring the wheels in contact with diamond R. The wheels must necessarily be separated in order to clear the fixture when they are being swung into the truing position. However, they are brought together again before dressing, to the same relative positions they occupy when grinding work. This insures that the two wheels will be dressed with the grinding points in line. The machine has a capacity for pistons up to 4½ inches in diameter and 4½ inches in length. The work-spindle operates at a speed of 250 revolutions per minute. The entire equipment weighs about 2300 pounds.

GORDON CRANKSHAFT-CHEEK TURNING LATHE

All the cheeks of automobile engine crankshafts are turned simultaneously on the machine shown in the accompanying illustrations which was developed by the Gordon Form Lathe Co. and is being built by the Willard Machine Tool Co., A St., Box 784, Cincinnati, Ohio. The particular machine illustrated is equipped with eight rocker arms, each of which controls a tool held in a block that swivels in the rocker arm, the number of rocker arms corresponding to the number of cheeks on the crankshaft. The rocker arms are located back of the work and swing from an over-arm shaft to and from the crankshaft to suit the contour of the cranks. The rocker arms are spaced to coincide with the spacing of the various crankshaft cheeks, by means of collars on the over-arm and guide plates fixed to the main frame of the machine. The guide plates are inserted in the rocker arms below the tool-blocks.

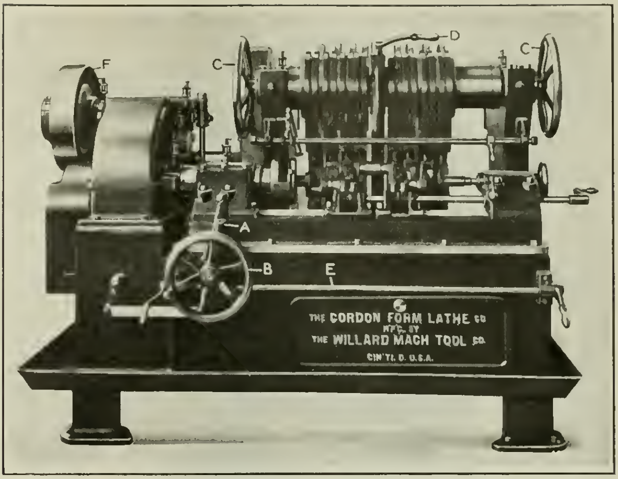

Fig. 1. Crankshaft-cheek Turning Lathe developed by the Gordon Form Lathe Co. and built by the Willard Machine Tool Co.

Feeding of the work is accomplished by movement of the platen, which is fed by a screw. A gear quadrant connected to the feed-screw at the front end of the machine provides a large range of fine and coarse feeds. An automatic trip serves to throw out the feeding movement through lever *A* at the conclusion of the cuts across the crankshaft cheeks. At the completion of an operation, the platen is returned to its starting position by turning handwheel *B*. The headstock, tailstock, and steadyrests are bolted to the platen to make one unit and travel as a unit with the work.

The machine has been arranged for taking both roughing and finishing cuts, this being controlled by two eccentric bushings which are located in the outer bearings of the over-arm and may be adjusted to a fixed stop by the large handwheels *C*. After the over-arm has been adjusted to either the roughing or finishing position, it is locked in place by lever *D*. The locking of the over-arm is at its central support which is a housing bolted to the main frame of the machine. The starting and stopping of the machine is accomplished quickly by means of shaft *E*, which has an operating lever at each end. Ample chip clearance has been provided between the bottoms of the rocker arms and the platen. The chips fall directly into a chip pan within the machine, and can be removed through the large door on the front of the bed. Cutting lubricant is supplied to the tools through a pipe extending past the rocker arms and having a tube leading to each tool. The lubricant pump is driven by belt as will be seen by reference to Fig. 2.

The main drive of the machine is through the friction-clutch pulley *F* which is geared directly to the main intermediate shaft *G*. It will, of course, be evident that there is a varying distance between the center line about which the crankshaft revolves and the point of contact of each tool with the crankshaft. The angularity of the surface presented to the cutting tool also constantly changes. To compensate for such conditions, it is necessary to have the positions of the cutting tools gradually change to enable them to conform to the contour of the work and at the same time to maintain theoretically correct cutting positions relative to the angular surfaces of the work. This is accomplished by swinging the rocker arm and rotating the tool, these movements being controlled by cams, mounted on the upper and lower shafts which are directly connected to shaft *G* through gearing. Fig. 3 shows a complete rocker-arm unit consisting of rocker arm *H*, tool-block *I*, tool *J*, upper master cam *K*, lower master cam *L*, and two levers connecting the roller of the upper cam with a gear segment having teeth that mesh with teeth cut on the circular flange of tool-holder *I*. These members are in the relative positions they occupy when assembled. The illustration also shows the position of the tool relative to the surface being machined.

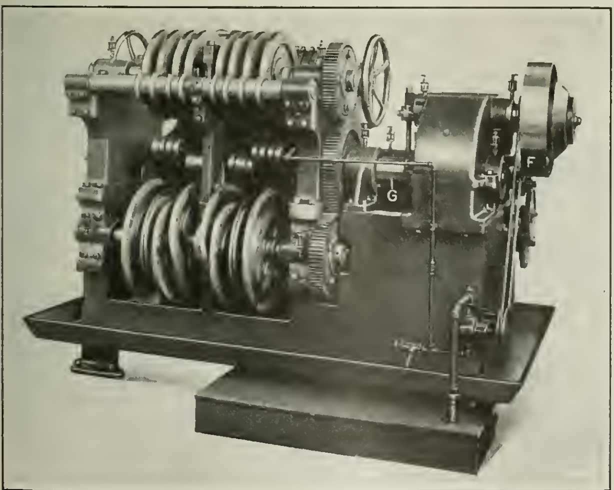

Fig. 2. Rear View of Crankshaft-cheek Turning Lathe showing Location of Master Cams

The large hole near the top of the rocker arm is provided for the over-arm. The cutting point of tool *J* is at the center of the tool-block and, this being the case, as the tool-block swivels to give the tool the proper cutting angle, the tool point itself remains in one position relative to the tool-block. Swiveling of the tool-block is accomplished by means of the upper cam and its roller, the motion of the latter being transmitted to the gear segment through the levers previously referred to. The form of the crank is obtained by swinging the rocker arm, the movement of which is controlled by the roller traveling in the track of cam *L*.

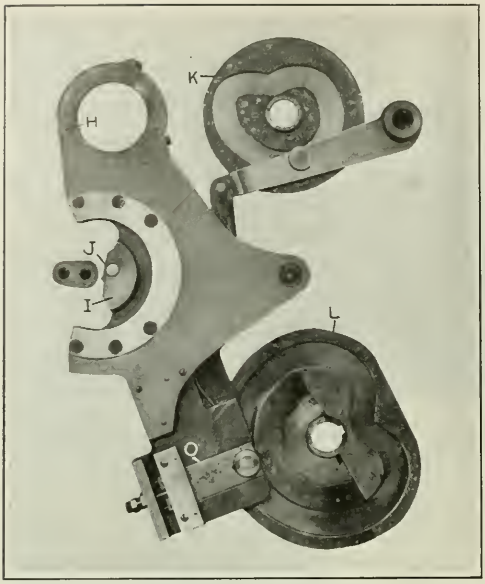

Fig. 3. Parts of the Rocker-arm Unit

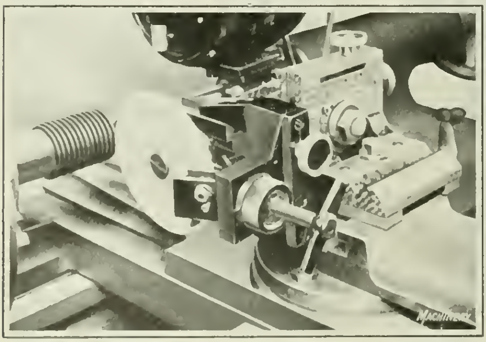
Adjustments of the tool to suit different diameters are obtained through slide *O* at the bottom of the rocker arm, to which the roller of cam *L* is attached. The adjustments are made through a screw which may be locked in position. A gage provides for accurate resetting of the tool after it has been removed for regrinding. An adjustment at the tool point is effected through a worm in the tool-block which engages teeth cut on the tool.

PRECISION WHEEL-TRUING HEAD

The Precision & Thread Grinder Mfg. Co., 1 S. 21st St., Philadelphia, Pa., is now manufacturing the grinding wheel truing head here illustrated. In the illustration, the device is shown applied to the precision thread grinder made by this concern, but it may also be used as an auxiliary truing head on any grinding machine. The device is said to keep the wheel always in correct alignment with the thread being ground. It is feasible to dress the V-form on the wheel to a sharp point so as to facilitate the grinding of fine threads. There is no limit to the length of thread which may be accurately ground, because the wheel may be trued while grinding.



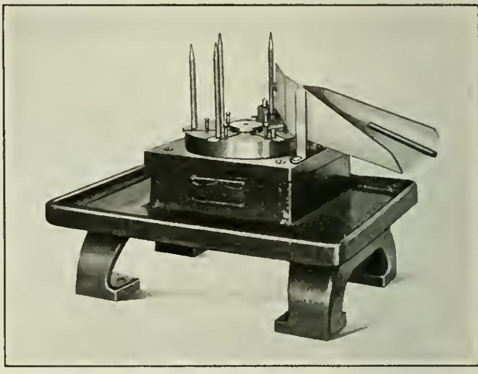
Two-diamond Grinding Wheel Truing Head made by the Precision & Thread Grinder Mfg. Co.

The mechanism for feeding the head has a dial graduated to 0.001 inch to enable the attachment to be fed forward sufficiently to make up for the reduction in wheel diameter by wear and dressing. The grinding wheel is trued by means of two diamonds, the form to which it is dressed being always in line with the axis of the work-centers. The diamonds are traversed by operating the double-ended handle on the extended screw, and they do not cut the wheel simultaneously but in progressive order; thus if one diamond becomes dull and the wheel springs away from it, the other and sharper one will not gouge the wheel.

When the diamonds become slightly worn, they can be rotated a fraction of a turn in order to present a new point to the wheel. The new point will always be sharp, and so the diamond can be worn down to its setting. A stop provided for regulating the return traverse of the diamonds can be utilized for predetermining the amount of flat produced at the bottom of the thread, thus insuring the same amount of flat, regardless of redressings and without subsequent regaging.

NOBLE & WESTBROOK TUBE-MARKING MACHINE

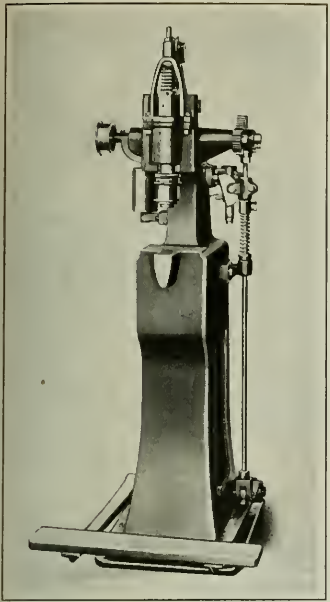
A marking machine produced by the Noble & Westbrook Mfg. Co., 19 Asylum St., Hartford, Conn., for marking names and patent marks on small tubes is here illustrated. The particular machine shown is employed for marking metal pencil tubes. The machine is driven by a three-step cone pulley from which power is transmitted to worm-gearing for revolving the table. The latter has six equally spaced mandrels upon which the work is placed by hand, and as the table revolves, the work is passed over a die which produces the desired marks on it. Then a cam raises a small lever that automatically removes the work from the mandrels and the machine. The possible production of this machine is over 10,000 marked tubes per day. The machine can be furnished for marking the ends of any size tubing in short lengths, and weighs about 90 pounds.



Small Tube-marking Machine which is a Product of the Noble & Westbrook Mfg. Co.

BLOMQUIST-ECK PNEUMATIC RIVETING MACHINE

The accompanying illustration shows a riveting machine built by the Blomquist-Eck Machine Co., 1146 E. 152nd St., Cleveland, Ohio. It consists primarily of a standard pneumatic hammer so mounted on the upright of the machine that it can be controlled entirely by a foot-treadle, leaving both of the operator's hands free to handle the work or the work-holding fixture in which the work is held. When the foot-treadle is moved downward, the hammer is brought



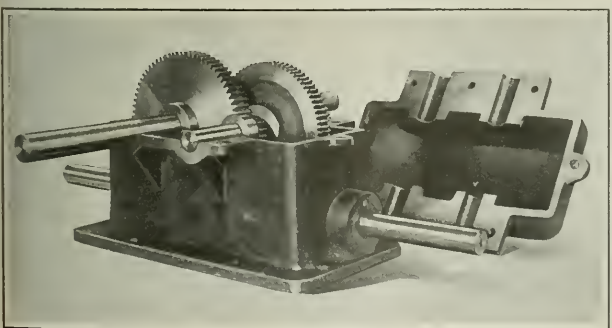
Riveting Machine which is a Recent Product of the Blomquist-Eck Machine Co.

down with it. This movement automatically turns on the air, the hammer then continuing to operate until the pressure on the foot-treadle is released. When that is done, the hammer is immediately returned to its upward position by a weight so attached that it counteracts the pressure of the foot-treadle.

As the hammer returns to the upward position, the air is automatically turned off. The air supply can be regulated by tilting the cam at the right-hand side of the machine, which controls the air throttle. The hammer slides within the carriage and is backed up by a spring at the top which absorbs the shock. While operating, the hammer is rotated by means of a belt passing over a pulley at its lower end. The machine illustrated has a pedestal designed with a special anvil or horn, but the anvils may be made to suit any condition and may be provided with vertical adjustment.

NATISCH GEARED SPEED TRANSFORMER

The speed of a driven shaft can be greatly reduced in relation to that of the driving shaft by the interpolation of a combined spur- and worm-gear transformer, which is made in various ratios between 1 to 75 and 1 to 1000, and for transmitting up to 5 horsepower, by the Natisch Gear Works, 451 Hudson Ave., Brooklyn, N. Y. The transformer illustrated is arranged to transmit ½ horsepower at a ratio of 1 to 600. The case is an iron casting of strong construction, and when the cover is assembled, is oil-tight and dust-proof. The design of all sizes of the transformer is similar, and for some ratios the same case is used, the change in ratio being accomplished by varying the number of teeth in the gears and the pitch of the worm and worm-wheel.



Combined Spur- and Worm-gear Speed Transformer built by the Natisch Gear Works

GENERAL ELECTRIC DIRECT-CONNECTED PLANER DRIVE

The General Electric Co., Schenectady, N. Y., has developed a new form of control which employs dynamic braking to prevent over-travel of direct-connected motor-driven planers either on reversal, through failure of voltage, or from other causes. The apparatus consists of a control panel on which are mounted the necessary rheostats and contactors, a resistance, a master switch or push-button, and a standard direct-current reversing adjustable-speed motor. The control is of two styles, one with a resistance selecting contactor and the other without. The remainder of the equipment, consisting of forward, reverse, and accelerating contactors, is the same in both cases.

The selective resistance contactor is connected to control the dynamic brake resistance in each direction of rotation, so that the resistor can be adjusted for one direction without affecting the adjustment in the other. A machine supplied with this control and geared for a table feed of from 25 to 50 feet per minute on the cutting stroke and from 50 to 100 feet per minute on the return stroke, with motor speeds of from 250 to 500 revolutions per minute on the cutting stroke and from 500 to 1000 revolutions per minute on the return stroke, can have the dynamic brake adjusted to give a maximum stopping effort at 500 revolutions per minute on the cutting stroke without regard to the return.

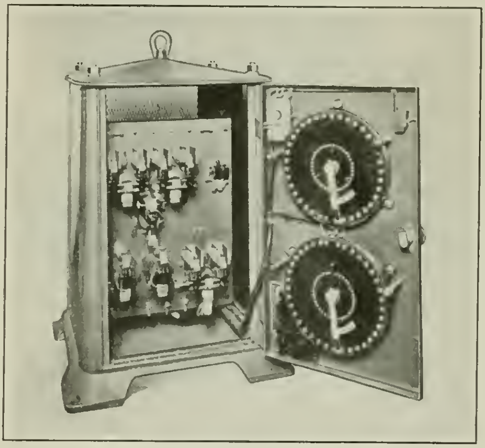


Fig. 1. Controller employed in Planer Drive developed by the General Electric Co.

Otherwise, if the resistance is adjusted for the maximum speed of 1000 revolutions per minute, the braking effort at 500 revolutions per minute will not be sufficient to stop the planer quickly on the return stroke.

One of the chief difficulties met with in planer drives is over-travel on reversal due to the contactor tips welding together under severe service conditions. In this new control the difficulty has been avoided by an arrangement whereby the welding of the contacts causes the planer to stop and will not allow it to over-run its set limits. Over-travel due to voltage failure and on reversal is taken care of by having the motor always connected to the dynamic brake. The utilization of dynamic braking, with a further refinement of the selective resistance contactor, makes it possible to jog the planer effectively by means of either the master switch or a push-button station. The switch or button, in jogging, can be operated in one direction, and when brought to the off posi-

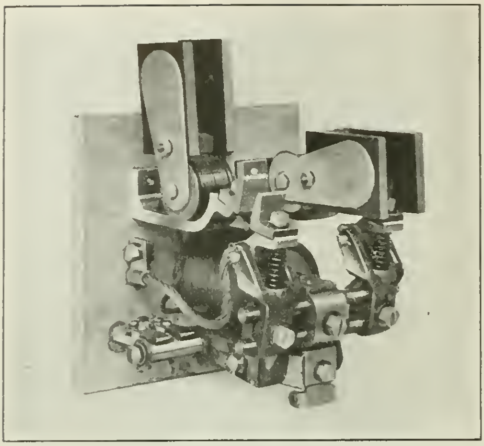

Fig. 2. View of Contactors showing Method of attaching Shunts

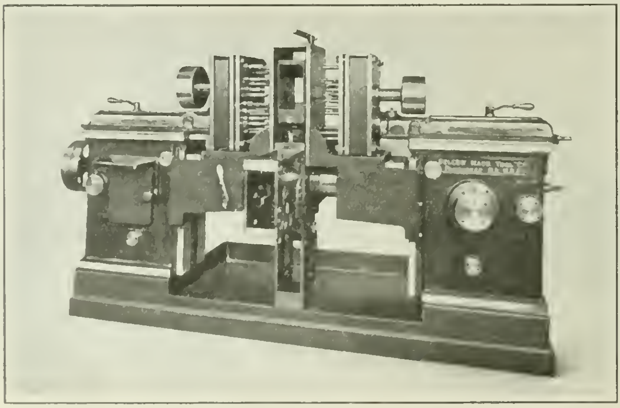
tion, the machine will stop. A machine equipped with the selective resistance contactor can be used on jobs having a small tool clearance, where the load varies from no load to full load and where cuts are made to the end of the planer travel.

SELLEW AUTOMATIC DRILLING MACHINE

An automatic drilling machine of the station type, having two horizontal heads, each of which contains a multiple number of drilling spindles, is a recent development of the Sellew Machine Tool Co., Pawtucket, R. I. In the accompanying illustration the machine is set up for drilling sixty holes in machine castings, 24 by 18 by 6 inches in size; however, it is also adapted for many classes of light drilling. Both heads are fed toward the jig and away from it simultaneously, the operation of the machine being continuous and automatic. The operator merely changes the work at the front station of the work-holding fixture and indexes this fixture through the stationary jig. An indexing takes place each time the drill heads are withdrawn from the jig.

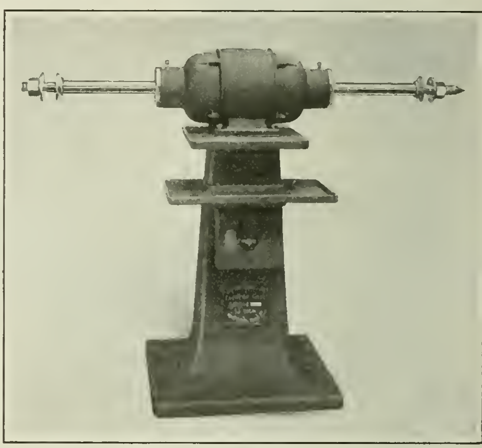
The drill spindles are mounted in radial and thrust ball bearings, and the individual spindles are run at speeds proportionate to the diameters of the drills attached to them. The feed of the drills, instead of being at a continuous rate, is eased as the drill enters the work and as it breaks through when the drilling is at an end, similar to a hand feed. The heads have a quick return. The head slides are arranged at their front ends to take different heads, and these can be changed quickly. The saddles provided on the table for carrying the jig are adjustable to accommodate a wide range of work. The machine is about 10 feet in over-all length, and weighs approximately 5000 pounds.



Automatic Multiple-spindle Drilling Machine built by the Sellew Machine Tool Co.

BLOUNT MOTOR-DRIVEN BUFFING MACHINES

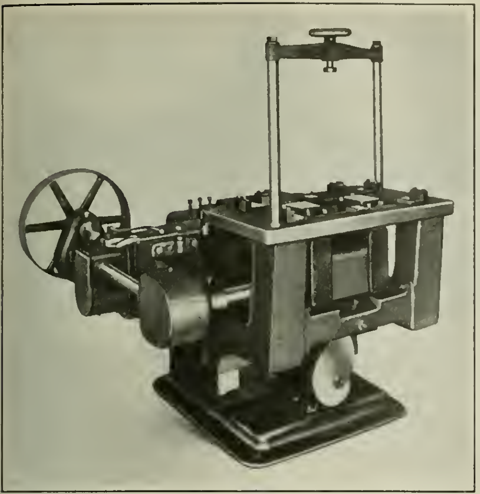
A line of alternating-current motor-driven buffing machines of the type shown in the accompanying illustration has been recently developed by the J. G. Blonnt Co., Everett, Mass. These machines are built in four sizes as follows: ½ horsepower, for 6- by ½-inch wheels; 1 horsepower, for 8- by 1-inch wheels; 2 horsepower, for 10- by 1½-inch wheels; and 3 horsepower for 12- by 2-inch wheels. Each machine is equipped with S K F ball bearings mounted in dustproof housings, and a snap switch having thermal cut-outs to afford protection for the motor. The spindle is made of high-carbon steel, and a taper point is fitted to the right-hand end so that the machine can accommodate small wheels. The head or motor unit is regularly mounted on a column with a pan, but it may also be supplied with a bench base when such a construction is preferable. The safety snap switch is placed on the column beneath the tool tray which serves to protect it from the buffing compounds used and from breakage or abuse. Westinghouse motors are supplied on this line of equipment.



Direct-connected Motor-driven Buffing Machine built by the J. G. Blount Co.

NEWTON STRADDLE-MILLING MACHINE

A recent development of the Newton Machine Tool Works, Inc., 23rd and Vine Sts., Philadelphia, Pa., is the cycle-feed Model C-75 straddle-milling machine here illustrated. The particular machine shown was built for facing the crankshaft bearings of automobile cylinders. It may be driven by a belt connecting either to a motor or a countershaft, the drive being transmitted through gears enclosed to permit their running in oil. The machine has two spindles which are mounted in housings having individual end adjustment to permit regrinding of the milling cutters. The table motion includes a rapid advance downward, a slow feed while



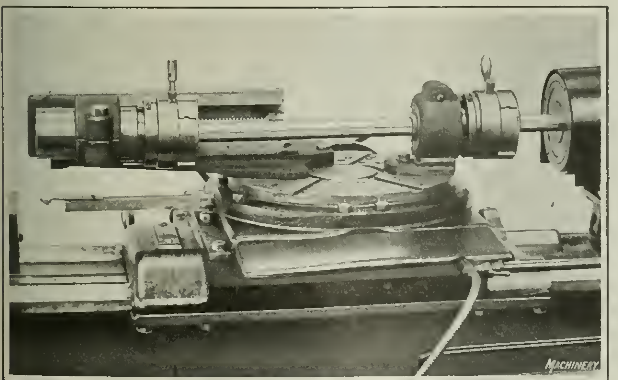
Model C-75 Straddle-milling Machine which has been recently designed by the Newton Machine Tool Works, Inc.

the cut is taking place, and an upward quick return. It automatically stops at the loading position which may be on a level with the conveyor rolls. Provision is made so that the rate of feed or the time required for the cycle of one operation may be increased or decreased to suit the material being machined. The table is provided with hardened steel jig plates. The work is clamped from above by a double-post beam clamp that is hinged at one end and supplied with a central clamping screw operated by a handwheel.

CINCINNATI-ACME TURRET LATHE STAYBOLT ATTACHMENT

Of particular interest to the railroad field is the staybolt attachment here illustrated which is manufactured by the Acme Machine Tool Co., Cincinnati, Ohio, for use on the Cincinnati-Acme flat turret lathes manufactured by this concern. The equipment has two die-heads which cut a thread simultaneously on opposite ends of the staybolt. The dies should be set from a master or staybolt tap to insure that the two threaded portions will have one continuous lead. The rear die-head can be adjusted to accommodate various lengths of staybolts.

When using bar stock, a roller back-rest multiple-turner is employed to turn the bolt to the proper diameter for the threads, a recessing slide being used in turning the relief. Both die-heads are used to cut the thread, the staybolt being finally severed from the bar by a cutting-off tool. When threads are to be cut on forged staybolts, the bolts are forged to the correct thread and recess diameters and length, when a continuous lead is desired, and both die-heads are used simultaneously, as when threading bar stock. The attachment is made in three sizes for staybolts from 1¼ to 1½ inches in diameter. The maximum length of staybolt which can be turned and threaded at one chucking varies with the sizes from 25 to 36 inches. When the staybolts can be threaded without a thread-lead relation, it varies from 48 to 71 inches.



Staybolt Attachment for Flat Turret Lathes built by the Acme Machine Tool Co.

PRATT & WHITNEY DIE-SINKING MACHINE

A new die-sinking machine incorporating unique features in its design that particularly adapt it for handling large dies, has been brought out by the Pratt & Whitney Co., Hartford, Conn. Through the medium of two "Bayrer's" compensating arms, dies up to 4 tons in weight can be suspended by elevating screws, and readily placed in position on the table. These arms also make it easy for the operator to swivel, tilt, or turn large work on edge. The hand feeds are thereby rendered sensitive to light cuts, and the die may be fed over to extreme limits for cutting gates, without cramping. In Fig. 1, the compensating arms are folded back against the sides of the column. The arms are carried on roller bearings supplemented by ball bearings, and are therefore sensitive to any movement of the die.

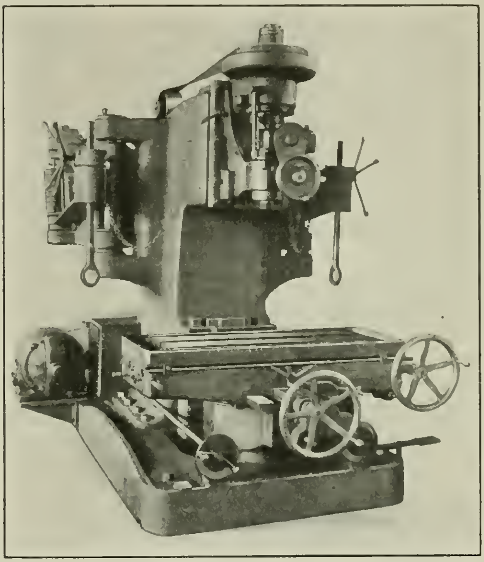


Fig. 1. New Large-size Die-sinking Machine brought out by the Pratt & Whitney Co.

Fig. 2 is another front view of the machine, showing the arms extended to support a die that has been swiveled on the table and moved into position for taking a cut near the end of the die. Both carrying arms are provided with balance beams and adjustable weights by means of which the weight of the die can be approximately balanced and relieved from the table. The holding members attached to the ends of the die act as trunnions on which it may be readily tipped on its side for edge cuts. When the die is being tipped on its side, the table is dropped clear of it, and consequently the arms sustain the entire load. Dies of various thicknesses may be adjusted to a convenient level for the operator

The cutter-spindle is mounted in a counterweighted vertical head having a hand feed with a graduated dial. A rapid traverse enables the head to be adjusted quickly. Power is transmitted to the cutter-spindle through a quarter-turn belt connected to the gear-box at the rear of the machine. All changes of speeds and feeds are effected by levers placed at the front of the machine for the convenience of the operator. Both hand and power feeds are supplied for the longitudinal and cross feeds of the table and, in addition, a rapid power movement is provided for all table traverses, including elevating and lowering. The mechanism that actuates the power movements operates from a friction clutch that prevents injury to parts in case the members are fed too far.

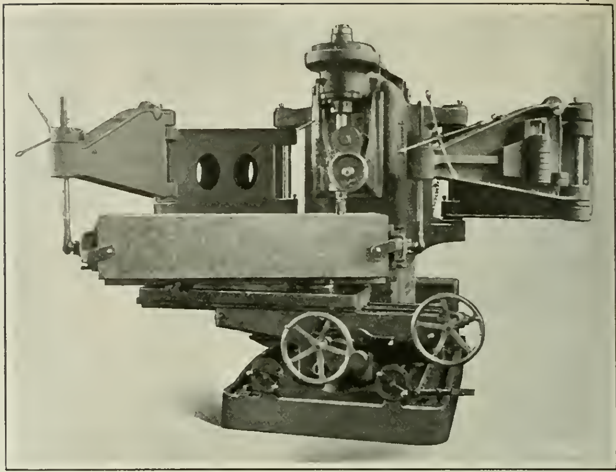

Fig. 2. The Pratt & Whitney Die-sinking Machine with the Arms extended

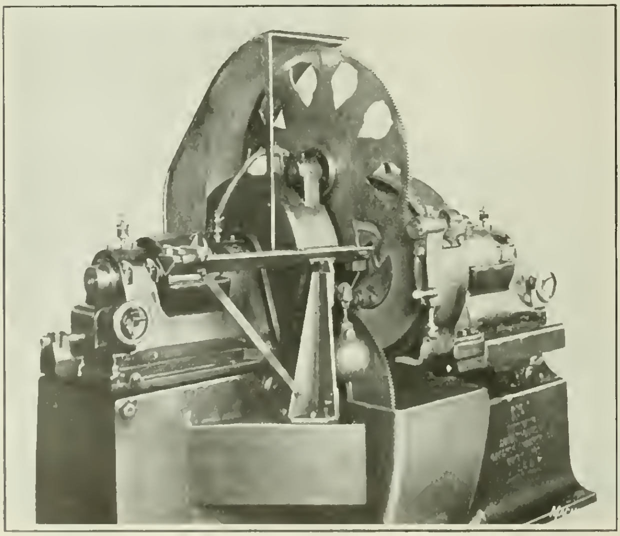
A cherrying attachment may be readily applied to the cutter-head and driven through gearing connected to the nose of the spindle. When not in use, the cherrying attachment may be swung out of the way so as not to interfere with the use of the machine on other work. This die-sinking machine may be equipped for either a constant-speed drive direct from a lineshaft or from a motor mounted on the machine. It is also built without the die-carrying arms when these are not required. The main dimensions are: Size of table top, 22 by 48 inches; longitudinal feed of table, 48 inches; cross-feed of table, 17 inches; vertical feed of table, 15 inches; and vertical feed of cutter-head, 12 inches. The weight of the machine is approximately 16,000 pounds.

GARDNER AUTOMATIC DOUBLE-SPINDLE GRINDING MACHINE

A machine designed for the rapid and simultaneous grinding of two opposite parallel sides of a piece, which differs from ordinary double-spindle disk grinding machines in a number of respects, is here illustrated. This machine is of the continuous-feed type, and has been developed and placed on the market by the Gardner Machine Co., 414 Gardner St., Beloit, Wis. The two spindles are offset in relation to each other, and for wet grinding the driving members consist of 24-inch diameter abrasive ring-wheels which are carried in chucks designed particularly for this type of machine. For dry grinding 24-inch steel disk wheels faced with abrasive disks, are used.

The parts to be ground are carried to the cutting position by a carrier that passes between the grinding wheels. For the purpose of accommodating a wide range of work, from pieces having a large surface requiring the removal of considerable stock to pieces with small areas over which only a slight cut is to be taken, the carrier is provided with a feed varying from six to forty pieces per minute. This carrier has a number of openings to receive the work. As the work approaches the grinding position one of the grinding wheels automatically advances until it reaches a positive stop. It approaches the work under an adjustable stroke pressure, and, consequently, advances only as rapidly as stock is removed. Thus constant pressure is maintained against the work. The wheel is returned to the open position by a cam, and the work is automatically unloaded as it passes from between the wheels. The cam referred to also governs the spring pressure feed. Provision is made for aligning the two spindles and an adjustment of the grinding members is obtained by a handwheel operating through worm-gearing and a screw, this handwheel being graduated to 0.0001 inch to permit close adjustments.



Gardner No. 1 Automatic Double-spindle Grinding Machine

When grinding work of a size that permits operation of the machine at the higher rates of feed, the automatic feeding device is of material assistance in keeping the work-carrier loaded at all times, as it practically eliminates all hand labor. However, in cases where larger work necessitates the operation of the machine at the lower feeds, it is usually more economical to feed the carrier by hand. Devices for truing the grinding members are an integral part of the machine. Although these are so located that they are ready for use at all times, they do not interfere with the operation. Among the parts for which this machine is particularly adapted, are piston rings, ball and roller bearing races, adding machine parts,

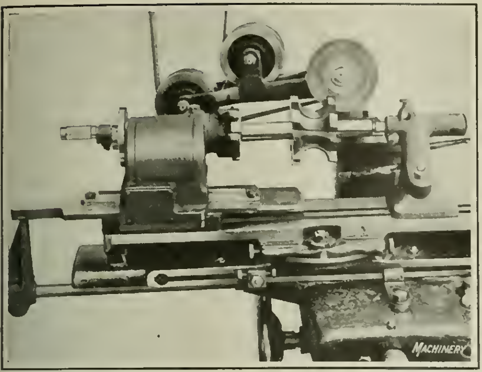


Fig. 1. "Curvex" Cutter and Hob Grinding Attachment made by the R. K. LeBlond Machine Tool Co.

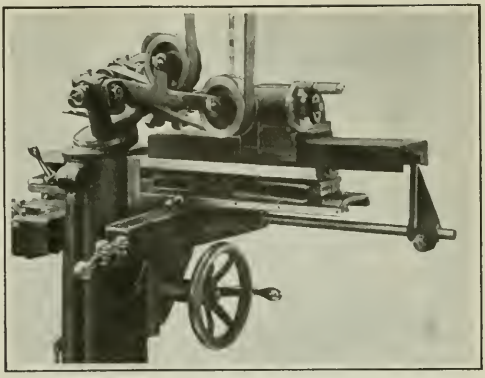

Fig. 2. Rear View of Cutter and Hob Grinding Attachment, showing Angular Raising Block

thrust washers, gear blanks and similar pieces. The openings in the work-carrier may be made to conform to the shape of practically any such piece. The holes in the particular carrier shown were made for ball bearing races, but by means of metal inserts they have also been used for conveying other pieces.

BLACK & DECKER PORTABLE DRILL

A half-inch portable electric drill having the familiar pistol grip and trigger switch used on other portable drills manufactured by this concern, which have previously been illustrated and described in MACHINERY, is being placed on the market by the Black & Decker Mfg. Co., Towson Heights, Baltimore, Md. The grip is placed beneath the housing, and the current connection is at the lower end of the grip. A three-jaw chuck for holding straight-shank drills up to ½ inch is provided with the equipment. The switch cover plate may be quickly removed to expose the terminal block to which the electric cable and motor leads are attached by means of screw terminals. The net weight of this tool is approximately 15 pounds.

LEBLOND CUTTER AND HOB GRINDER ATTACHMENT

An attachment lately developed by the R. K. LeBlond Machine Tool Co., Cincinnati, Ohio, for use on the universal tool-room grinding machine built by this firm, facilitates the grinding of "Curvex" milling cutters made by the Pratt & Whitney Company, and of spiral hobs. In grinding a "Curvex" cutter, the cutter is mounted on an arbor between the centers of the attachment, as shown in Fig. 1, the table is set to zero, and, from a chart of leads and angles, the taper guide bar of the attachment is set to the required angle. Although this guide bar is shown exposed in this illustration, it is ordinarily protected by a cover, as will be seen in Fig. 2. As the table of the grinding machine is fed horizontally, the cutter-spindle is automatically revolved in the proper relation to the lead and spiral angle. The cutter is indexed by the plunger and index-plate to bring each tooth to the grinding plane.

The wheel-head is mounted on an angular raising block, as shown in Fig. 2, to bring the wheel-spindle to an angle of 15 degrees from the horizontal. A special grinding wheel is used, the front face of which is dressed vertically to insure a single line of contact between the wheel and the work. This enables the work to be fed vertically to the wheel. The knee is swiveled to an angle corresponding to the helix angle of the cutter, and the table traversed past the wheel by the rack and pinion. The grinding plane is always on a true radial line from the center of the cutter, and the wheel always clears itself in the work.

The wheel is dressed on the face by clamping a diamond on the table and using the vertical feed. Fig. 2 also shows the belt sheaves provided for aligning the belt when using an angular raising block; this equipment is not required in grinding spiral hobs.

MURCHEY NIPPLE REAMING AND CHAMFERING MACHINE

The front view of a nipple reaming and chamfering machine, and a close-up view of the chuck and reaming and chamfering tools are shown in Figs. 1 and 2. This machine is a recent product of the Murchey Machine & Tool Co., 34 Porter St., Detroit, Mich. The piece of pipe being operated upon is held in the chuck jaws, which are opened by the manipulation of a foot-lever, and automatically closed when pressure is released from the lever. The jaws are hardened and ground. The chuck unit slides on wide bearings, and centers itself as the tools begin to cut. After a nipple has been machined, the operator pushes it from between the jaws as he inserts a

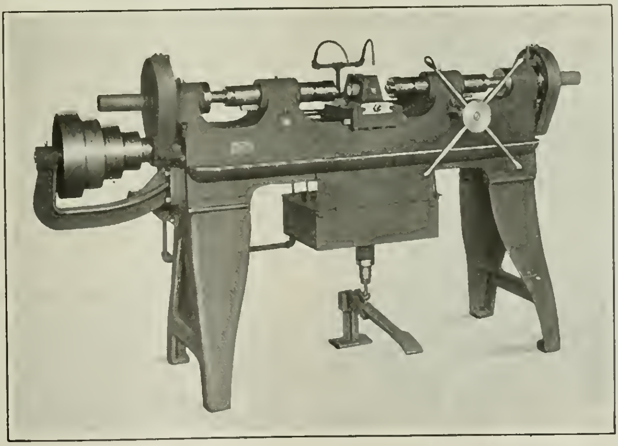

Fig. 1. Nipple Reaming and Chamfering Machine made by the Murchey Machine & Tool Co.

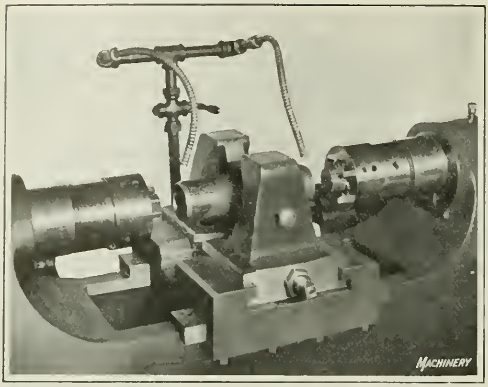

Fig. 2. Close-up View of Chuck and Reaming and Chamfering Tools

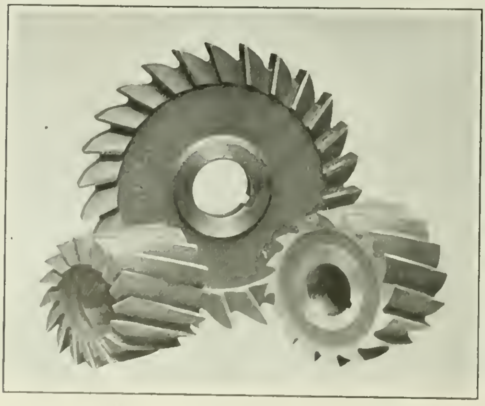
new piece, the finished nipple dropping into a receptacle. The countershaft of the machine is arranged with right- and left-hand pulleys, while four-step cone pulleys give a selection of four speeds. A pump provides for an adequate supply of lubricant to the work. The machine is suitable for pipe of all sizes from ½ inch to 2 inches, and will handle lengths up to 12 inches. It weighs about 1200 pounds.

While primarily designed for the reaming and chamfering of nipples, the machine can also be equipped with die-heads for threading nipples made from ⅛- to ¾-inch pipe. It may also be employed for threading tees, valves, studs, and other parts requiring a thread on both ends. The opening and closing of the die-heads is automatic.

"PARABOLIC" MILLING CUTTERS

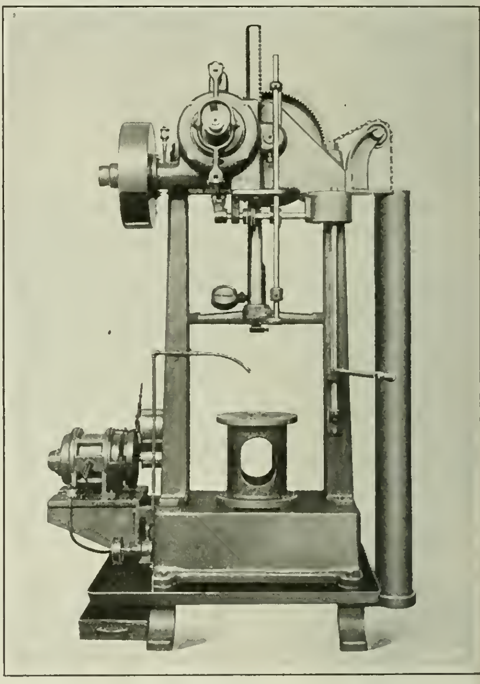
As the result of several years of research, the National Twist Drill & Tool Co., Detroit, Mich., has placed on the market a new type of milling cutter known as the "Parabolic," three examples of which are here illustrated. This name was selected to characterize the distinctive construction of the teeth. The tests indicated that in order for a milling cutter tooth to be of uniform strength throughout its length, its shape should be that of a parabola, slightly modified at the small end, and so this shape was adopted for these cutters. The number of teeth is nearer to that of the conventional fine-tooth cutter than to that of the coarse-tooth type. In order to obtain an efficient chip thickness per tooth without an excessive peripheral speed, a fairly large number of teeth was found desirable. This cutter is made in plain side and end-mill types, as well as for special purposes.



"Parabolic" Milling Cutters manufactured by the National Twist Drill & Tool Co.

LUCAS VERTICAL BROACHING PRESS

The machine shown in the accompanying illustration is a modification of the general-purpose power forcing press which has been manufactured by the Lucas Machine Tool Co., Cleveland, Ohio, for a period of more than twenty years. The utility of the machine for repetition work has been enhanced by an increase in the speed of the stroke and the addition of a quick-power return and lever control. The machine is especially adapted for vertical push-broaching operations. The working elements consist of a ram to which motion is transmitted by gearing controlled by a friction clutch which engages a worm-wheel driven by a worm on the pulley shaft. The operating lever for controlling the clutch is adjustable vertically on the rod in front of the right-hand column so that it is within convenient reach of the operator, whether he is standing or sitting. Movement of this lever to the left engages the clutch and causes the ram to start on the down or pressure stroke. The ram



Vertical Press of Modified Design placed on the Market by the Lucas Machine Tool Co.

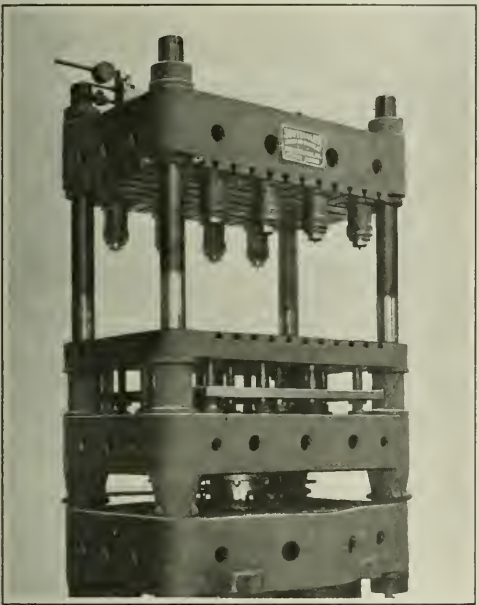
descends until the upper trip on the rod in front of the ram strikes a dog on the horizontal shaft. This shaft is connected by bevel gears with the vertical shaft to which the operating lever is attached, and thus stops the downward movement of the ram.

Movement of the operating lever to the right causes the ram to start on its return stroke at a quick rate of speed, which continues until the lower trip strikes the dog on the horizontal shaft. Both trips are adjustable vertically on the rod so as to stop the ram at predetermined points. The number of strokes the ram makes in any given time, therefore, depends upon the length of the stroke. A graduated gage registers the pressure in tons up to the rated capacity of the machine. The friction drive can be adjusted to any pressure up to the maximum capacity of the press. The machine is made in two sizes of 15 and 30 tons capacity. The net weight of the 15-ton machine is approximately 2900 pounds, and that of the 30-ton machine, 3800 pounds. The 15-ton press is driven by a 7½-horsepower constant-speed motor, and the 30-ton press by a 10-horsepower motor.

SOUTHWARK HYDRAULIC AUTOMOBILE-BODY PRESS

The Southwark Foundry & Machine Co., Philadelphia, Pa., has recently developed a press for the production of all-steel automobile bodies. The general construction of this machine will be apparent by reference to the illustration. The press has a capacity of 450 tons. The main ram is located in the lower base to which are secured four columns. The press is provided with clamping and stripper platens. The stripper platen carries four hydraulic cylinders acting upon a forged steel plate which, in turn, has sixty stripper pins, 1½ inches in diameter. These pins project through the clamping platen, which is a solid steel casting and is provided with T-slots.

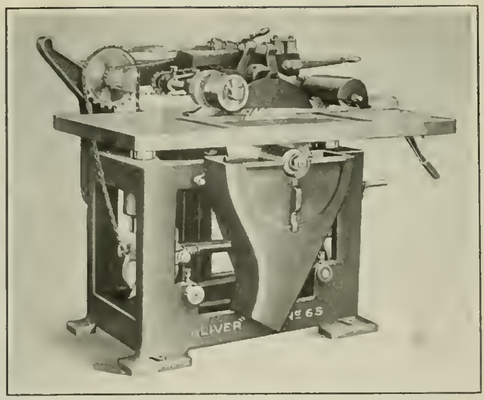
The top platen carries eight hydraulic jacks having 5-inch diameter rams and strokes of 5 inches, these jacks being employed to accomplish the clamping. This platen is adjustable to accommodate the various sizes of dies which it may be desired to employ with the press. The machine operation is controlled by a single lever; this lever operates a valve which subjects the four hydraulic cylinders and the main ram to a low pressure, and as soon as the dies have come together, high pressure is applied through the steam operating valve to complete the operation. The clamping cylinders are automatically controlled from a low-pressure filling tank, and are capable of standing a pressure of 5000 pounds per square inch. The press has a die space of 7 by 5 feet, a minimum vertical opening between the platens of 18 inches, and a maximum opening of 4 feet.



Hydraulic Automobile-body Press made by the Southwark Foundry & Machine Co.

OLIVER SELF-FEED RIP SAW

Safety provisions and a dust chute are the principal new features on the No. 65 self-feed rip saw brought out by the Oliver Machinery Co., Grand Rapids, Mich., which is an improved design of other machines sold by this company. The machine is intended for ripping all kinds of lumber and may be used for rough as well as for finished stock. The saw arbor is mounted on a frame having a vertically adjustable table with an in-feed roller which may be either corrugated or smooth, according to the requirements of the work. This roller carries the stock through the saw and across the table. A gang of six saws separated by 1-inch spacing collars may be used at one time. Three rates of feed are provided, 80, 110 and 140 feet per minute, respectively.



Self-feed Rip Saw now being placed on the Market by the Oliver Machinery Co.

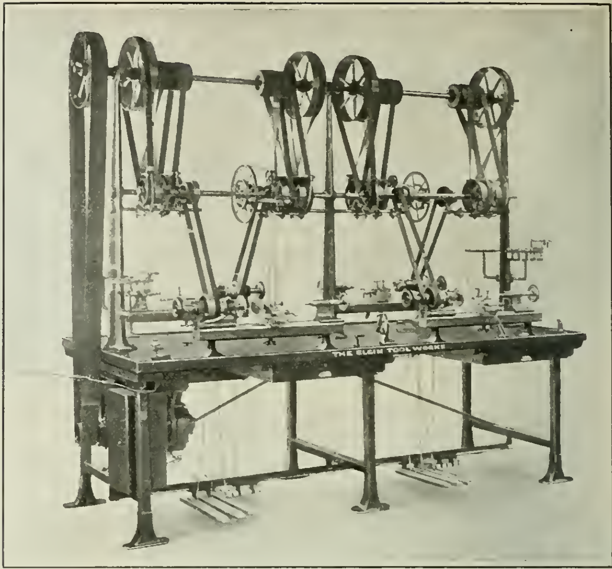
The features of the machine include a quick adjustment for the feed rollers, quick adjustment and locking of the ripping fence, and quick vertical table adjustment. The machine has a mechanism that absorbs shocks on the feed rollers and overcomes any jerks produced in starting the stock through the machine. The lower portion of the saw is adequately guarded by means of the dust chute and a cover, while the upper portion runs in another guard. The feed rollers are also covered by metal guards to eliminate accidents while feeding the machine. This saw may be arranged for either a motor or countershaft drive. It will accommodate saws up to 18 inches in diameter, will cut lumber up to 5 inches in thickness, and rip pieces up to 24 inches in width.

"PAKFULL" SECTIONAL FILING EQUIPMENT

Two five-drawer sections of a filing case made by the Economy Drawing Table & Mfg. Co., Adrian, Mich., for filing tracings and blueprints are shown in the accompanying il-

Sectional Filing Case made by the Economy Drawing Table & Mfg. Co.

lustration. Between each drawer is a frame, on the under side of which is a piece of heavy paper that is flush with the bottom of the frame so that the drawer enters a pocket. The sides of the drawer extend upward into the frame a sufficient distance to keep the contents from sliding over the top of the drawer on either side, while two dowels at the back, which protrude upward into the frame, keep the contents from sliding over the back and into the rear of the cabinet. When the drawer is closed the front comes up against a groove in the frame, so that it is dustproof. The cabinet can be furnished with drawers either 26 by 38 by 2 inches or 32 by 44 by 2 inches, inside measurements.



Four-machine Bench-lathe Unit built by the Elgin Tool Works, Inc.

ELGIN BENCH-LATHE UNIT

The accompanying illustration shows a unit consisting of four bench lathes, countershafts, jack-shaft, driving motor, and bench, which is being introduced to the trade by the Elgin Tool Works, Inc., Elgin, Ill. This unit may be supplied with either the regular No. 4 or No. 4 by 5 lathes manufactured by this concern and two- or three-speed countershafts. The motor can be furnished for operation on either alternating or direct current. The belt-shifters are operated through foot-treadles. The bench is made of kiln-dried hardwood and furnished with a tool drawer and collet rack for each lathe. Although the machine illustrated is equipped with four lathes, it can be provided with a larger or smaller number.

HARRINGTON MULTIPLE-SPINDLE DRILLING MACHINE

A No. 19 multiple-spindle drilling machine of the rail type, on which the spindle heads have not only a longitudinal movement on the cross-rail but also an in-and-out movement on arms mounted on the rail, has been added to the line of machines built by Edwin Harrington Son & Co., Inc., 17th and Callowhill Sts., Philadelphia, Pa. An advantage of this design is that it enables irregularly located holes to be drilled, permits close center distances, and has a relatively large in-and-out movement. The machine illustrated in Fig. 1 has three spindles, although four are usually provided. The machine is designed to transmit 25 horsepower which is considered ample for driving four 2-inch drills at ordinary speeds and feeds.

The in-and-out movement of each spindle head is independent of the others, and is effected through a ratchet-operated screw. Each spindle is provided with a counterweight, and a clutch on the driving gear allows any spindle to be stopped independently of the others. The heads are moved along the cross-rail by revolving a pinion that engages a rack on the rail, this pinion being rotated by turning the squared end of a shaft extending to the outer end of the arm. Another shaft located above this traversing shaft operates the arm-clamping device. Simultaneous feeding of the different spindles is controlled from the right-hand end of the machine, while separate feeding of any spindle is governed at the end of its corresponding arm. The feeding mechanism is driven by a belt from the top shaft, through change-gears and worm-gearing. By turning a handwheel, quick vertical movements of the spindles are obtainable. The several spindles are fed together through the medium of a clutch located at each arm. A handwheel provides for moving the spindles up and down independently or for setting them to the proper height when the universal feed is used. Automatic stops that disengage the spindles at any predetermined point are provided for use with the individual feed.

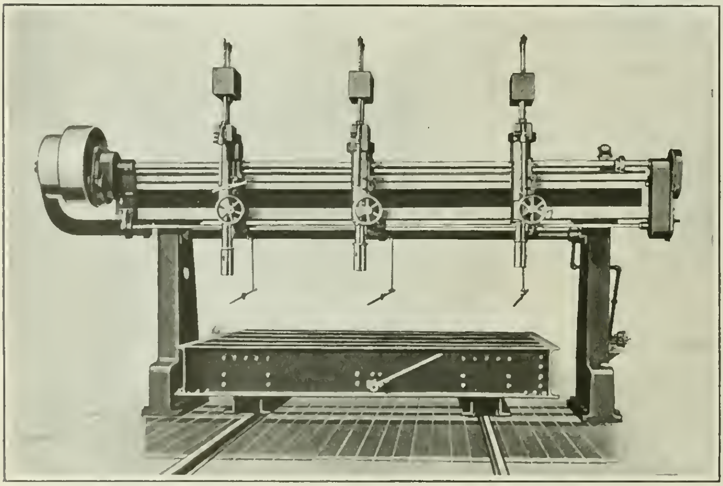


Fig. 1. No. 19 Multiple-spindle Rail Drilling Machine built by Edwin Harrington Son & Co., Inc.

When the machine is driven from a countershaft, two-step cone pulleys and back-gears provide four spindle speeds. When an adjustable-speed motor is employed for driving the machine, a single pulley is supplied, and when a constant-speed motor is used, the motor is placed on top of the machine and the countershaft mounted in a frame fastened to one upright. A speed-gear box can also be furnished in place of the countershaft. For large work a truck table made of structural steel, as illustrated, is generally considered best. This table is fitted with wheels to travel on tracks placed on the floor level, and can be readily moved by the use of a ratchet lever, although a power movement through an individual motor can also be provided. For other work a stationary table of structural steel may be preferable. Cast-iron tables with finished surfaces of various areas and arranged either to slide or roll are also applicable by providing the uprights with proper guides. A pump and distribution manifold furnish a continuous supply of cutting lubricant to the drills through universal-joint outlet pipes.

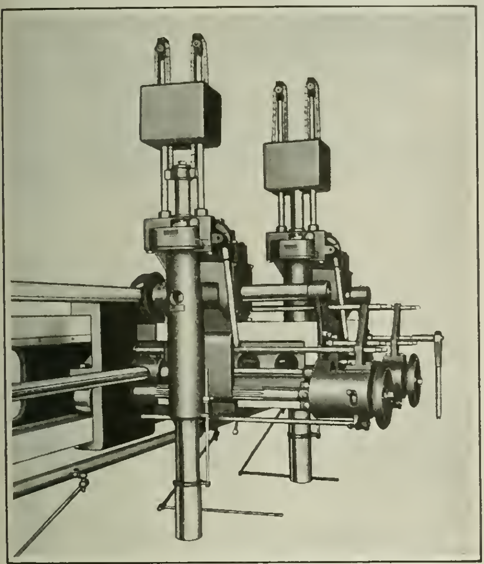

Fig. 2. Close-up View of Spindle Heads showing Construction of Mechanism governing In-and-out Movement

---

ECLIPSE INTERCHANGEABLE SPOT-FACER AND COUNTERBORE

The accompanying illustrations show assembled and disassembled views of an interchangeable spot-facer and counterbore known as the "Junior," which is manufactured by the Eclipse Interchangeable Counterbore Co., 7410 St. Aubin Ave., Detroit, Mich. The complete tool consists of a nickel-steel holder, an externally and internally threaded nut, a high-speed steel spot-facer having milled flutes, and a machine-steel pilot. The cutter is aligned accurately with the holder by means of a ground boss that snugly fits a hole in the holder. The nut is screwed into the holder by means of its external threads, and serves two purposes. First, it enables instant removal of the pilot in case of breakage, and second, by quickly changing it for one with a smaller internal thread, the same holder may be used with different pilots and cutters. The end of the pilot head is provided with a slot to receive the end of a screwdriver, and flats to facilitate its removal by means of a plier or wrench. The spot-facing tool may also be used with standard Eclipse holders and pilots through the use of an adapter. The spot-facer is made in various sizes, from ½ to 3 inches in diameter, and the shank of the holder is made with a No. 2, 3, or 4 Morse taper. Spot-facers can also be supplied without the pilot.

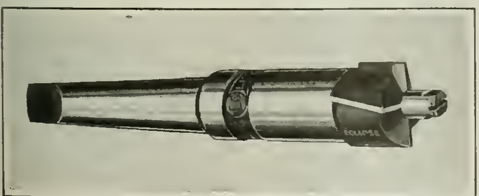

Fig. 1. Spot-facer and Counterbore made by the Eclipse Interchangeable Counterbore Co.

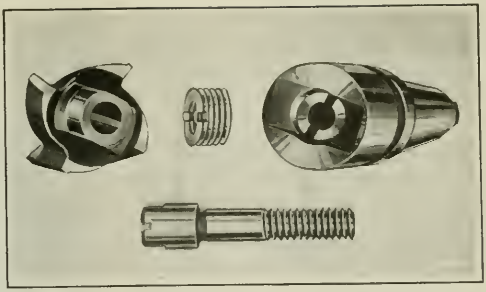

Fig. 2. Disassembled View of the Tool illustrated in Fig. 1

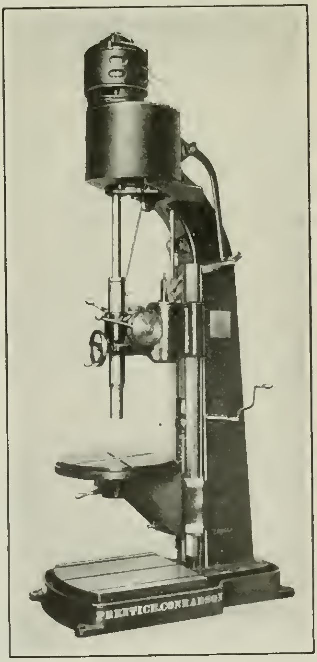
CONRADSON UPRIGHT DRILLING MACHINE

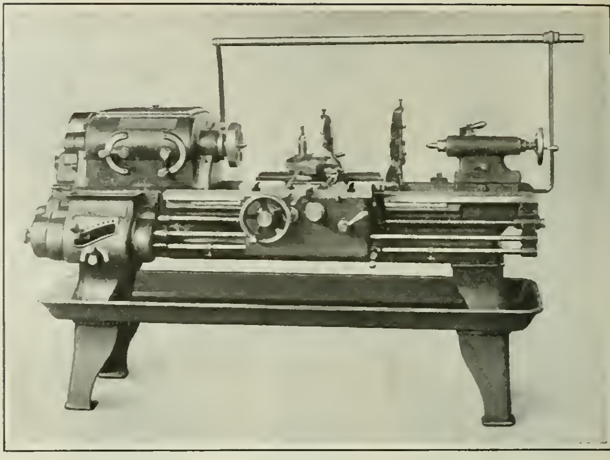
A 32-inch upright drilling machine driven from a motor mounted at the top of the column and connected to the spindle through gears is built by Prentice Conradson, Green Bay, Wis. The armature shaft of the motor consists of a hollow sleeve into which the upper end of the spindle extends, but the spindle is not fastened to this shaft. On the lower end of the armature shaft is mounted a gear from which the drive is transmitted to the spindle through the plain and sliding cluster gears contained in the column just beneath the motor. Nine speed changes are obtainable, while the feeding mechanism provides for six feeds ranging from 0.006 to 0.035 inch per spindle revolution.



Upright Drilling Machine built by Prentice Conradson

The table has the usual adjustments, and a rectangular or sliding table can be supplied instead of the circular table shown, if desired. A reversing motor is provided for tapping. Alternating- or direct-current motors can be supplied, a 3-horsepower motor being recommended for ordinary work, and a 5-horsepower motor running at 1800 revolutions per minute for rapid work. The controller furnished with the machine protects the motor against accidental over-loads. Some of the specifications are as follows: Maximum distance from base to spindle nose, 56 inches, and minimum distance, 15½ inches; vertical traverse of table, 16 inches; and maximum distance from table to spindle nose, 37 inches. The machine has a capacity for driving a 3-inch high-speed drill through steel, and weighs about 3700 pounds.

SUNDSTRAND TOOL-ROOM LATHE



New 14-inch Tool-room Lathe built by the Rockford Tool Co.

A 14-inch tool-room lathe driven either through a cone pulley or a geared headstock is a recent product of the Rockford Tool Co., 2400 Eleventh St., Rockford, Ill. The machine illustrated is equipped with the geared headstock. All gears in the headstock are submerged in oil, and sliding gears are used exclusively. The spindle speeds range in geometrical progression from 13 to 326 revolutions per minute, and all speed changes can be made while the machine is in motion. The headstock has a friction clutch designed to stop the spindle immediately when the clutch is disengaged. Oiling of the spindle bearings is accomplished from a reservoir.

The quick-change gear-box has a tumbler and a cone of eight gears, which can be set to run at different speeds by the lower lever on the feed-box. By this arrangement forty-eight different threads and feeds are obtainable. By shifting the position of an intermediate slip gear located beneath the spindle, the feed-box may be disengaged. A number of special threads can be obtained without the use of extra gears; however, the design of the feed-box is such that any special thread may be cut by furnishing the proper gears.

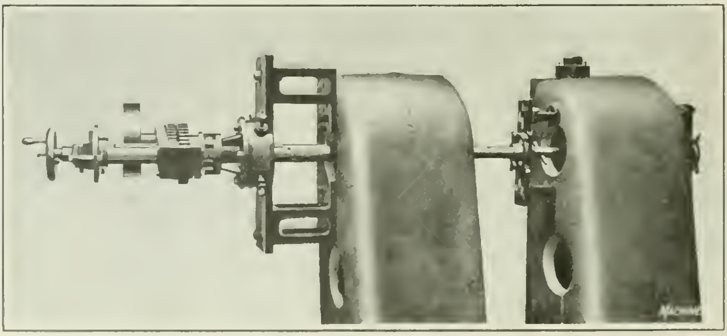
The apron is of box construction with all gears enclosed by a plate on the rear side. The rack pinion may be disengaged from the rack when desired. The apron is provided with a sensitive clutch for throwing in both the longitudinal and the cross feeds. A separate feed-rod and a reversing rod are provided. Reversing of the feeds is effected by a lever conveniently located on the right-hand end of the apron. With this construction it is convenient for the operator to set the feed instantly to neutral or reverse. Collars can be placed at certain positions on the reversing rod for stopping the carriage automatically at desired points. This possibility is especially convenient in cutting threads.

The lead-screw is connected directly to the cone of gears in the feed-box and has end thrusts taken up by ball bearings at the tailstock end of the lathe. Micrometer stops are regularly furnished for the cross-slide. The tailstock is clamped by a device at the back having a handle which is conveniently operated from the front. Boring and counter-boring operations are facilitated by the provision of a collar on the tailstock which is graduated to 0.001 inch. The relieving attachment is operated through a knuckle-joint connection. The taper attachment is located close to the cross-feed screw extension block which receives all strains on the attachment. This attachment is graduated both in taper per foot and degrees, and is provided with a micrometer adjustment. On a motor-driven lathe the motor is supported on a bracket attached to the back of the left-hand leg, thus eliminating the necessity of an idler pulley.

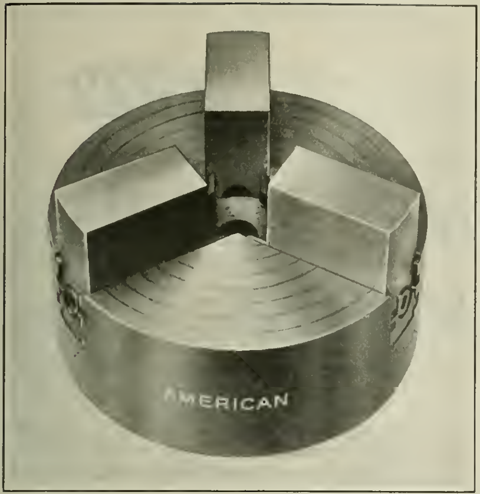
PEDRICK BORING UNIT

In December MACHINERY was published a description of a taper boring-bar placed on the market by the Pedrick Tool & Machine Co., 3639 N. Lawrence St., Philadelphia, Pa. Another boring unit somewhat similar in design and which may also be driven by belt, electric motor, air drill or by hand, is here shown applied to large housings for boring the bearings in line with each other. The unit consists of a boring-bar, feeding and driving mechanisms, and the cross-head. The bar is a steel forging having a square-thread feed-screw located in a groove that extends almost the full length of the bar. The bar is 3 inches in diameter by 3 feet long and affords a travel of 18 inches. In the illustration the device is shown provided with an extension for the particular job in hand.

The feed-case is attached to one end of the bar, and by blocking the handwheel, this mechanism will be automatic in operation. Two changes of feeds may be thrown in or out of operation by the movement of a slip-pin. When a larger range of feeds is required, a three-change feed-case may be furnished. It will be seen that the unit is attached to the work by means of the cross-head, which also serves as a guide for the boring-bar. This cross-head is provided with a convenient means of accurately setting the boring-bar for an operation. The latter may also be used in vertical positions.



Boring Large Housings with a Boring Unit made by the Pedrick Tool & Machine Co.



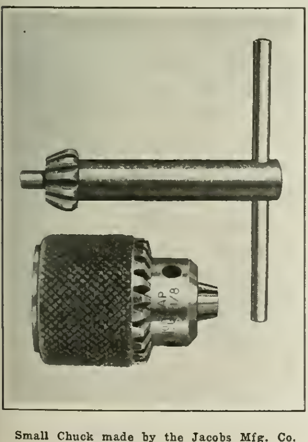
Three-jaw Air-operated Combination Chuck made by the S-P Mfg. Co.

AMERICAN IMPROVED AIR-OPERATED CHUCKS

The line of air-operated chucks formerly manufactured by the American Air Chuck Co. has been redesigned and is now being made by the S-P Mfg. Co., 872 E. 72nd St., Cleveland, Ohio. The capacity of the standard chucks in this improved line ranges from 6½ to 18 inches. The accompanying illustration shows a three-jaw combination chuck designed to hold the work by either internal or external surfaces and intended for general manufacturing purposes. Special jaws or master slides having false jaws can also be furnished for quantity production work. Sector levers operate the chuck slides for the universal movement, these levers being fastened to steel blocks fitted to the rim and center part of the chuck. A patented feature permits shutting off the air from the cylinder without releasing the grip on the work. The chuck can be quickly arranged for use as an ordinary lathe chuck in the event that the supply of air fails.

JACOBS DRILL CHUCK

A small chuck designed for use on watchmakers' lathes and jewelers' drilling machines, and in the multiple drilling, and tapping of work on which the holes have close center distances, has been brought out by the Jacobs Mfg. Co., Hartford, Conn. This chuck is of the same design as the "Super" drill chuck described in May MACHINERY, but is intended for holding drills as small as No. 80, which is 0.013 inch in diameter, and for operation at a speed of approximately 20,000 revolutions per minute. The body of the chuck is machined within a tolerance of 0.0005 inch, this degree of accuracy being essential to obtain a correct balance in operation on account of the high speed at which the chuck is employed. The chuck is ⅞ inch outside diameter, 1 5/16 inches maximum over-all length, and weighs about 2 ounces.



Small Chuck made by the Jacobs Mfg. Co.

NEW MACHINERY AND TOOLS NOTES

Nipple-holder: Armstrong Mfg. Co., 297 Knowlton St., Bridgeport, Conn. Two sizes of holders intended for use in making both right- and left-hand nipples. The No. 20 holder is suitable for nipples from ¼ to 1 inch in size, while the No. 30 holder is for nipples ranging in size from 1 to 2 inches.

Bending, Forming, and Shearing Machine: Bussel Machine Co., El Paso, Texas. A hand-operated machine which requires no extra dies to bend any size of stock within its capacity to any angle. The machine will bend right- or left-hand work without adjustment. The bending posts have four bending edges and make less than one-quarter turn in producing a 90-degree angle which is obtained without the use of a square.

Drilling and Tapping Machine: W. Gaterman Mfg. Co., Manitowoc, Wis. A drilling and tapping machine known as the "Electro-magnetic." The tap is held in a floating spindle driven through two coil springs in such a manner that shocks and jars on the tap are eliminated. On the top of the machine is a device which automatically reverses when the torque transmitted to the tap is too great. Electromagnets are employed in the reversing mechanism.

Portable Electric Rivet Heater: U. S. Electric Co., New London, Conn. A portable electric rivet heater built with two, four, or six electrodes for manual operation. The larger sizes can also be furnished with an automatic movement for carrying the rivets between the electrodes and discharging them when heated. In a machine of the latter design, two intermittently rotating members carry the rivets forward in pairs. Cams open and close the electrodes with the movement of the carriers.

Drilling Fixture: Hartman Mfg. Co., 308 Pearl St., Hartford, Conn. A device intended for use on drilling machines to take the place of the many parallel strips and pieces of blocking required when much drilling of irregular shaped pieces is done but where a quantity of any one kind does not warrant making a special jig. The fixture consists primarily of a base block and two adjustable angle-plates that may be placed in any position relative to each other and securely fastened.

Hot-pressed Nut Machine: Acme Machinery Co., Cleveland, Ohio. A machine for making hot-pressed nuts from a bar of special section. In the first operation the bar is indented on both sides to form the sides at angles equal to those of the sides of two abutting nuts. As the indenters withdraw, the blanks are sheared off and carried to the die box, where two punches advance from opposite sides and pass part way through each blank, compressing it in the center so that the surrounding metal flows and fills all parts of the die. The core is finally punched out.

Bolt-cutting and Nut-tapping Machine Operating Device: Key Boiler Equipment Co., 27th St. and McCasland Ave., East St Louis, Ill. An air-operated automatic device which controls the operation of bolt-cutting and nut-tapping machines. When applied to a bolt-cutting machine, the device clamps the work, feeds it into the dies, opens the dies after the thread has been cut, returns the carriage to its starting position, and sets the dies for the next cut. When applied to a nut-tapping machine, the spindles are held up by an air-operated piston when the taps are full, the rising and falling of the spindles is controlled, and the blanks are automatically fed.

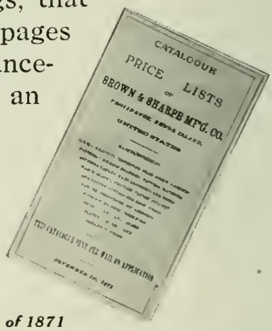
1833 1922

Eighty-Nine Years Of Progress

Since the foundation of the business in 1833

Brown & Sharpe Products

have met with increasing favor throughout the entire mechanical world. One of the earlier catalogs, that of 1871 for example, contained only sixteen pages but this small pamphlet carried its announcements of high grade Machines and Tools to an ever-widening mechanical field.



Sixteen page Catalog of 1871

General Catalog No. 137
The 1922 Buyer's Guide
for Mechanical Equipment

The demand for products of uniformly high quality has so increased that today, in 1922, the General Catalog describing Brown & Sharpe Products contains over six hundred pages and lists a quantity and variety of equipment unthought of in the earlier years. 1922 marks the eighty-ninth year since the origin of the business and the fiftieth year since the moving of our plant to its present location. Our customers have the benefit of a rare fund of accumulated knowledge and experience which is reflected in the design and manufacture of our products and is at the disposal of customers seeking practical solutions of their mechanical and manufacturing difficulties.

The Industrial Machinery Division of the Department of Commerce

THE reorganization of the Department of Commerce, which was taken in hand by Mr. Hoover when he became Secretary of the Department, has now proceeded to a point where the various bureaus and divisions are actually engaged in the work for which each one was created. The division to which the machine tool industry belongs is known as the Industrial Machinery Division. According to the 1919 census, there are more than 4000 factories in the United States producing industrial machinery, the value of these factories exceeding $2,200,000,000 a year. These 4000 factories have more than 400,000 employes in normal times, providing a support for probably 1,500,000 people. Seventeen per cent of the products of these factories, or nearly $400,000,000 a year is exported, and it is evident that an export business of such a volume is of great importance both to the owners and the employes of the factories employed in making industrial machinery.

The Industrial Machinery Division of the Bureau of Foreign and Domestic Commerce was developed in order to promote the export trade of the machine-building industries, and it is believed that the foreign trade in this field can be materially increased by the work that will be done by the Bureau under Mr. Hoover's leadership. W. H. Rastall, chief of the Industrial Machinery Division, believes that while present export figures equal approximately an export of $1000 a year per employe, this figure can be doubled by the application of American salesmanship and good business methods, aided by the Government through a properly organized and conducted Department of Commerce. The work of the Machinery Division will be directed toward this end.

Purpose and Aim of the Industrial Machinery Division

The Industrial Machinery Division covers, in addition to machine tools and metal-working machinery, mining machinery; paper and pulp mill machinery; pumps; printing presses; refrigerating machinery; shoe machinery; sugar mill and saw mill machinery; woodworking machinery; textile machinery; typesetting machinery; road-making machinery; air compressors; concrete mixers; engines and railway cars; excavating machinery; laundry machinery; flour mill machinery; gas and water meters; and elevators. Briefly described, it may be said to include every kind of machinery used in factories, power plants, mines, railways, and engineering construction work, but it does not take in agricultural and farm machinery, or electrical machinery or equipment. The Division of Industrial Machinery has been placed in the hands of qualified engineers, who have actually sold a great variety of machinery in different parts of the world, and who are therefore familiar with conditions existing abroad. They are experienced exporters of American machinery, and have faced world-wide competition in foreign markets.

The Division is anxious to have American manufacturers in the machinery field realize that it aims to be of the greatest possible service to them, and feels that the best way to accomplish this is by establishing close contact with the industries. There are 600 representatives of the Government in foreign countries who can be called upon to obtain specific trade information when required, and should circumstances justify, arrangements can be made to send special investigators into the foreign trade fields. No problem is too large or too small for this service. As an indication of what the Department of Commerce actually accomplishes, it may be mentioned that the Department as a whole answers more than 1000 inquiries daily, or approximately 350,000 a year.

Services Offered by the Industrial Machinery Division

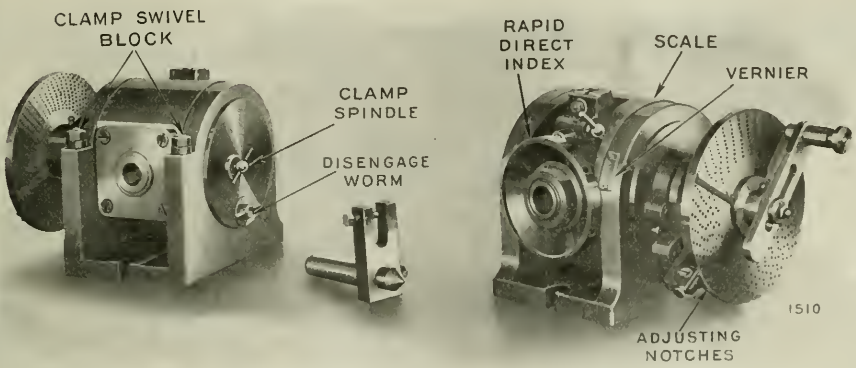
The men in charge of the Industrial Machinery Division are familiar with the different sales methods used in the various markets of the world in marketing machinery. Where it is wisest to sell through agents or dealers, the Division has reasonably complete lists of available dealers which will be furnished to manufacturers who are interested. When the manufacturer is able to visit Washington, he can also obtain much additional information relating to these dealers, which has been collected by the Bureau from time to time, to make it possible to select suitable agents for any specific product.

Through its overseas' representatives the Government is now receiving information relating to new engineering enterprises. Manufacturers who wish to obtain such information quickly should communicate with the Industrial Machinery Division so as to be placed on its list for this kind of information. The Division is also making studies of the various foreign markets and export problems, and these studies are published in Commerce Reports, the newspapers, and the trade press, according to circumstances. A report on the machinery markets of Asia is now being prepared, which is the result of a special investigation made by Mr. Rastall personally, who visited every important city between Yokohama and Bombay, thirty months having been spent in this investigation. The Division is also in a position to answer questions relating to foreign tariffs, patents, trademarks, agency agreements, and legal matters, through the cooperation of the Commercial Law Division and the Foreign Tariffs Division. The Bureau of Foreign and Domestic Commerce has frequently been able to assist in adjusting disputes, and, if necessary, the cooperation of the Department of State may be obtained through the Bureau.

Present Work of the Division of Industrial Machinery

One of the present activities of the Industrial Machinery Division is to collect the laws and regulations of all foreign countries covering the inspection, construction, and operation of steam boilers and air- and gas-containers. These will be available to American manufacturers and exporters of machinery. A general survey of the railway mileage and rolling stock all over the world is in preparation. A collection of the electrical regulations covering the whole world will be made.

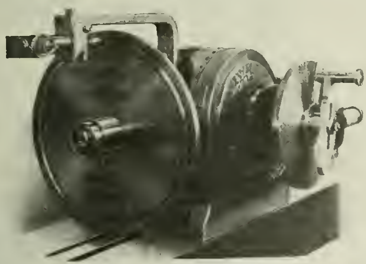
Briefly, it is the object of the Department of Commerce, through the Industrial Machinery Division, to collect any information that American manufacturers deem necessary for extending their foreign trade. The cooperation of the industries is requested as regards suggestions for the extension of the work of the Department. In making plans for the future work of the Industrial Machinery Division, advice from manufacturers is needed. The Division wishes to aid manufacturers in securing actual sales in the widely distributed markets of the world, and welcomes advice and suggestions from manufacturers in preparing its plans. Furthermore, the Department of Commerce invites manufacturers to use the information stored up in the Department to the fullest extent, and to present any problem relating to foreign commerce to the Department.



Cincinnati Tool-room Millers

When you talk about the Tool-room Miller, you think first of the Dividing Head. This is a feature that you depend most upon. You want it to be accurate and reliable. We believe we can show you that CINCINNATI UNIVERSALS, both MILLERS and DIVIDING HEADS, come closest to meeting your requirements.

There is not space to give details here. Ask for them.

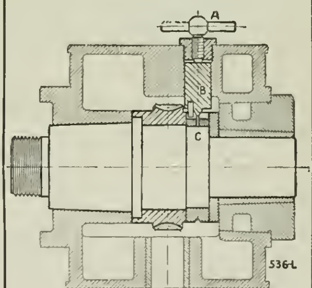


The Indexing Test

The 12 in. disk contains an accurately graduated silver ring. By means of a microscope with a micrometer adjustment, we can read the errors in the wormwheel and also those in the worm to one-fortieth of a thousandth (.000025) of an inch; not only the errors in pitch, but also the inaccuracies of the tooth face.

The maximum indexing error allowed is .001 in. in 12 in.

Let Us Send You the Catalog



HORIZONTAL SECTION OF CINCINNATI DIVIDING HEAD

The spindle clamp consists of a split ring, C, which is spread by the wedge B by tightening the screw A, thus clamping the spindle endwise, securely, without crowding it out of alignment.

The Cincinnati Milling Machine Co.

CINCINNATI, OHIO, U. S. A.

BRITISH MACHINE TOOL EXPORTS AND IMPORTS

In a review prepared by W. H. Rastall, chief of the Industrial Machinery Division of the Bureau of Foreign and Domestic Commerce, at Washington, some very interesting figures and charts are presented that will prove of value to all engaged in the export of machine tools. A chart is shown in Fig. 1, illustrating comparative British and American exports of metal-working machinery, as well as German exports

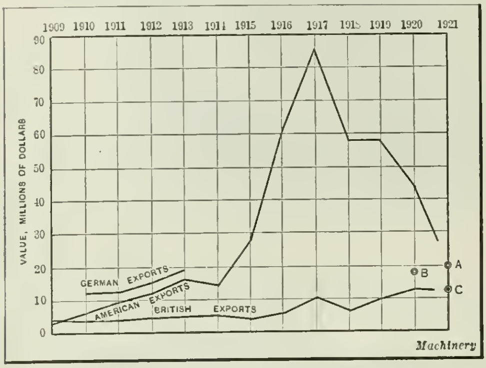


Fig. 1. Exports of Metal-working Machinery since 1909 by the United States, Germany, and Great Britain

for the years 1910, 1911, and 1912. It will be noted that, while in the four years preceding the war American exports increased rapidly, the exports of Great Britain made but little progress. During the war period American exports increased in an unprecedented manner, but show a rapid falling off in 1920 and 1921, while the British exports at the end of 1920 reached a higher level than they had ever attained before. The line representing German exports in pre-war years is somewhat deceptive, because the classification employed by the German customs authorities includes a great deal of metal-working machinery and tools not included in the British and American returns. The estimated exports of America for 1921 are denoted by circle *A*; those

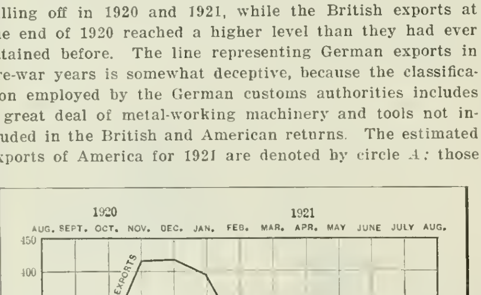

Fig. 2. British Exports and Imports of Machine Tools from August, 1920 to August, 1921

of Germany for 1920, by circle *B*; and those of Great Britain for 1921, by circle *C*.

The diagram Fig. 2 shows details of recent British exports and imports prepared from data published by MACHINERY, London. This chart shows that at the present time the British exports are falling off, though not in as marked degree as the imports. The chart also contains a line for exports of lathes from Great Britain, showing that the general tendency in regard to decreased exports is practically followed by the decreased exports in this type of machine tool. Complete details showing the exports of machine tools from Great Britain for each month beginning August, 1920, and including August, 1921, have also been compiled by Mr. Rastall, giving in detail both the number of machines and the value for the following groups: Lathes, drilling machines, grinding machines, milling machines, planing and shaping machines, punching and shearing machines, and all other machine tools. The imports of machines into Great Britain for the same classes of machines are also covered. This information may be obtained by individual manufacturers through application to the Industrial Machinery Division, Department of Commerce, Bureau of Foreign and Domestic Commerce, Washington, D. C.

PERSONALS

CHARLES ADDAMS, formerly a sales engineer with the Standard Roller Bearing Co., Philadelphia, Pa., is now connected with the Bearings Co. of America as sales engineer in the eastern territory.

J. M. MCNEAL, sales engineer of the Landis Machine Co., Inc., Waynesboro, Pa., manufacturer of bolt and pipe threading machines, has returned to this country after spending a year and three months traveling in England and on the Continent.

C. F. MEYER, assistant secretary of the Landis Machine Co., Waynesboro, Pa., manufacturer of bolt and pipe threading machines, has recently returned from a year's trip around the world, having visited India, Java, China, Japan, and the Hawaii Islands.

JAMES HARTNESS, president of the Jones & Lamson Machine Co., Springfield, Vt., and governor of the state of Vermont, has been awarded the Edward Longstreth medal by the Franklin Institute, acting through its Committee on Science and the Arts, for the development of the Hartness screw thread comparator.

WILLIAM S. DICKSON has been appointed assistant manager of the Crane Machinery Co., Buffalo, N. Y. Mr. Dickson was identified for many years with the Cincinnati Planer Co. Later he became sales engineer of the Acme Machine Tool Co. and general manager of the Greaves-Klusman Tool Co. During the last two years he has been connected with the Cleveland office of W. K. Stamets.

EARL B. STONE has been appointed advertising manager of the Cleveland Tractor Co., Cleveland, Ohio, to take the place of G. B. Sharpe, who has resigned. Mr. Stone has been connected with the company for two and a half years, serving as sales representative, assistant advertising manager, and district sales manager. His former advertising experience included work with the General Fireproofing Co., Youngstown, Ohio, and the National Acme Co., Cleveland.

MARTIN G. SPERZEL has been made sales manager of the Royersford Foundry & Machine Co., Royersford, Pa., succeeding John D. Sells, who is retiring from active business. Mr. Sperzel has been connected with the company for the last six years as sales engineer, and was connected with the Standard Roller Bearing Co. for almost the same length of time. The Royersford Foundry & Machine Co. will continue to make and market the Sells roller bearings, which it has done since the latter part of 1904, when Mr. Sells became identified with the company.

HJALMAR G. CARLSON, of Worcester, Mass., was awarded a gold medal—the annual prize of the American Society of Mechanical Engineers—December 7, at the meeting of the society in New York. The medal is awarded to the engineer who is responsible for the most noteworthy development in mechanical engineering practice that has been called to the attention of the society during the past year. Mr. Carlson won the prize for the work that he did in connection with a process for the production of 30,000,000 drawn steel booster casings used as component parts in high-explosive shells. The method developed is not one confined to the production of war material, but may also be applied to drawn steel parts for industrial purposes in general. In awarding the prize, it was stated that Mr. Carlson's invention, according to the Army Ordnance Department, was of the greatest importance during the war, in enabling the military authorities to secure adequate artillery ammunition for the American Expeditionary Forces.

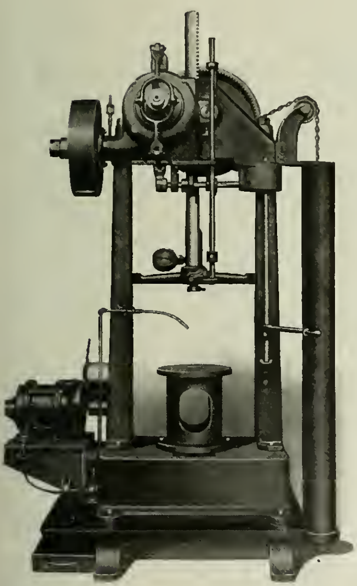
ANNOUNCEMENT

SOMETHING NEW

Yet tested and tried

The Lucas Vertical Push-Broaching Machine

(A modification of the Lucas Power Forcing Press)



Has been in successful operation for over two years on *vertical push-broaching* and *production assembling.*

ADVANTAGES:

Shorter, and therefore less expensive broaches.
Better lubrication of cutting edges.
Easier setting of work, easier manipulation of broaches.
More production.
A choice of fixed positions for the operator.
Lever Control (adjustable for height).
Less Floor Space Required.

WE ALSO MAKE THE
"PRECISION"

BORING, DRILLING AND MILLING MACHINE

Send for Special Circular C-26-M.

LUCAS MACHINE TOOL CO. NOW AND ALWAYS OF **CLEVELAND, OHIO, U.S.A.**

FOREIGN AGENTS: Alfred Herbert, Ltd., Coventry. Societe Anonyme Belge, Alfred Herbert, Brussels. Aux Forges de Vulcain, Paris. Allied Machinery Co., Turin, Barcelona, Zurich. Benson Bros., Sydney, Melbourne. V. Lowener, Copenhagen, Christiania, Stockholm. R. S. Stokvis & Zonen, Rotterdam. Andrews & George Co., Tokyo.

NEW BOOK ON SHOP MATHEMATICS

SHOP ARITHMETIC FOR THE MACHINIST. By Erik Oberg. 116 pages, 6 by 9 inches; 92 illustrations. Published by THE INDUSTRIAL PRESS, 140-148 Lafayette St., New York City. Price, $1.

This treatise is intended for men in machine shops and tool-rooms whose training has been chiefly along practical lines, and also for students of mechanical subjects who desire a book featuring the problems commonly encountered in shop work. All subjects have been treated as simply as possible, and many examples are used to show exactly how different arithmetical processes are applied to practical shop problems. The advantages and use of formulas are explained, and most of the formulas are written out or expressed in words to show the student just what each formula actually means. In fact, a special effort has been made to explain all methods in plain, simple language.

Many text-books deal with principles rather than with specific examples, but the shop man not used to solving problems often finds it difficult to apply these principles. The purpose of this treatise, therefore, is to present the most common machine shop and tool-room problems and show clearly, by carefully selected examples, how the principles are applied in each case. It is assumed that the student understands such elementary subjects as addition, subtraction, multiplication, and division of whole numbers and fractions, and that he is familiar with the use of common mathematical signs for indicating the different operations referred to. If the student is not entirely familiar with the elementary arithmethical processes mentioned, it is advisable for him to study a text-book on arithmetic before attempting the solution of the problems given.

COMING EVENTS

January 11-14—Annual meeting of the Society of Automotive Engineers in New York City. Secretary, Coker F. Clarkson, 29 W. 39th St., New York City.

April 19-20—Annual meeting of the National Metal Trades Association in New York City; headquarters, Hotel Astor. Secretary, Homer D. Sayre, Peoples' Gas Bldg., Chicago, Ill.

April 24-29—Annual convention and exhibit of the American Foundrymen's Association in Cleveland, Ohio; headquarters, Cleveland Public Hall, Lakeside Ave. and E. 9th St. Secretary, C. E. Hoyt, 140 S. Dearborn St., Chicago, Ill.

May 8-11—Spring meeting of the American Society of Mechanical Engineers in Atlanta, Ga. Assistant Secretary (Meetings), C. E. Davies, 29 W. 39th St., New York City.

NEW BOOKS AND PAMPHLETS

Ninth Annual Report of the Secretary of Commerce Covering the Fiscal Year Ended June 30, 1921. 149 pages, 6 by 9 inches. Published by the Department of Commerce, Washington, D. C.

Results of Some Tests of Manila Rope. By Ambrose H. Stang and Lory R. Strickenberg. 11 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Technologic Paper No. 198 of the Bureau of Standards. Price, 5 cents.

A Course in Mechanical Drawing. By Louis Rouillion. 92 pages, 8 by 9½ inches. Published by the Norman W. Henley Publishing Co., 2 W. 45th St., New York City. Price, $1.50.

The fifteenth edition of this book has now been issued in revised and enlarged form. It explains the art of making working drawings, lettering, and dimensioning, and is intended either for school use or for self-instruction. This course was originally issued in blueprint form with accompanying typewritten notes, and has been in use at the Pratt Institute and Y. M. C. A. classes for a number of years. The course covers a period of two school years of about twenty-four weeks each. Because of the interest in isometric drawing evinced by students, this subject has been added to the present edition. A parallel course, in the form of supplementary exercises, is presented at the end, so that the book may be used as a text-book in class work.

Railroad Shop Practice. By Frank A. Stanley. 331 pages, 6 by 9 inches. Published by the McGraw-Hill Book Co., Inc., New York City. Price, $4.

This book deals with shop practice in railroad repair shops, including large, medium and small shops, and describes typical methods and appliances adapted to the class of work handled in these shops. The material in the book is presented in twenty-three chapters. An idea of the operations dealt with will be obtained from the following list of chapter heads: The Work of the Railroad Repair Shop; Operations on Locomotive Cylinders; Machining Pistons and Piston-rings; Piston Valves, Cages and Rings; Tools for Crossheads and Guides; Connecting-rod Operations; Making Driving-boxes; Machining Shoes and Wedges; Eccentrics, Links, and Tumbling Shafts; Locomotive Frame Work; Driving Wheels and Axles; Wheel Shop Equipment and Methods; Machining Pipe Joints and Other Parts; Brass Tools for Locomotive Valves and Fittings; Some Portable Tools and Appliances; Special Tools, Cutters and Tool-room Methods; Air Pump, Hose Coupling, and Miscellaneous Devices; Blacksmith Shop Equipment and Work; Boiler Shop and Flue Work; Tools and Methods Used on Steel Car Work; Welding Operations on Locomotives and Cars; Reclamation Work; and Handling Materials in the Railroad Plant.

Hendrick's Commercial Register of the United States. 2324 pages, 8½ by 11½ inches. Published by the S. E. Hendricks Co., Inc., 70 Fifth Ave., New York City. Price, $12.50.

This is the thirtieth annual edition of this well-known commercial register of producers, manufacturers, dealers, and consumers. The new edition appears in a slightly larger size, with a type face of 7 by 10 inches. The text matter has been opened up, leaving a space between columns, thus making it more readable and giving ample space for checking and memoranda. The larger page, taking more matter, naturally makes a smaller book, which is easier to handle. Although the increased size of the page takes 25 per cent more matter and would normally reduce the number of pages from 2800 to 2100, new matter has been added to make more than 2300 pages. The book covers the engineering, machinery, electrical, building, chemical, hardware, iron and steel, mining, quarrying, railroad, architectural, constructional, contracting, mill, and kindred industries throughout the United States. It contains over 100,000 names of individuals and firms, comprehensively classified by trades or products and thoroughly indexed and cross-indexed. The first and main section of the book is the classified trades section, covering 1552 pages, in which are classified alphabetically all the trades in the various fields mentioned. There are over 3000 classifications in the mechanical industries which include the names and addresses of the manufacturers of practically every kind of machine and operating supply used in the production of raw materials and in the manufacture of finished and semi-finished products. A special list of over 15,000 machine shops and foundries, classified according to the exact type of work done, is included. The second section contains a list of trade names or special brands of the products included in the classified directory, and covers 190 pages. This is followed by the alphabetical section, including 403 pages, in which are given the names and addresses of all manufacturers in the fields covered, as well as the main industry of each firm. The address of the head office or works only is given, the branch office and work addresses being included in the various classified lists. A complete index to the trade classifications is included, which covers 132 pages.

NEW CATALOGUES AND CIRCULARS

Lovejoy Tool Works, Chicago, Ill. Circular illustrating the Lovejoy No. 3 portable electric drill with a capacity for drilling ¼ inch in steel.

Atlas Vise Co., Inc., Lowville, N. Y. Circular containing illustrations and specifications covering the line of "Nutyp" vises for machinists and pipe fitters.

Gas Producer & Engineering Corporation of New Jersey, 115 Broad St., New York City. Leaflet containing a list of representative users of "Galusha" gas generators.

Turner Machine Co., Danbury, Conn. Circular showing typical examples of Turner spur and bevel cut steel gears. This company makes a specialty of replacement gears for Ford cars.

New Departure Mfg. Co., Bristol, Conn. Loose-leaf sheets Nos. 141 and 142FE, illustrating and describing the application of New Departure ball bearings in portable electric drills and pneumatic corner drills.

Jones Machine Tool Works, Philadelphia, Pa. Circular containing illustrations and dimensions of the Jones motor-driven slotting machines, which are made in five sizes of 12, 16, 20, 25, and 32 inches, respectively.

Monitor Controller Co., Baltimore, Md. Circular illustrating an installation of the Monitor system of controllers operating diamond polishing machines, which require a positive drive, free from vibration and fluctuation.

Pratt & Whitney Co., Hartford, Conn. Circular 269, describing the distinctive features and details of construction of P & W vertical shapers, which are made in 6- and 10-inch sizes, for tool-room work on a production basis.

Brown & Sharpe Mfg. Co., Providence, R. I. Leaflet containing a chart showing the growth of the Brown & Sharpe plant from 1872, when it included 55,000 square feet of floor space, to its present size of 1,471,400 square feet.

Universal Boring Machine Co., Hudson, Mass. Circular illustrating and describing the Universal horizontal boring machine made by this concern, which is equipped with a boring-bar 4½ inches in diameter for performing heavy work, such as is done in railroad shops.

American Spiral Pipe Works, Chicago, Ill. Circular showing installations of American spiral-riveted pressure pipe, lap-welded steel pipe, and corrugated boiler furnaces. Examples of special fittings and forged steel pipe flanges are also illustrated.

Pawling & Harnischfeger Co., 38th and National Aves., Milwaukee, Wis. Bulletin 4F, describing the details of construction of the P & H No. 4F horizontal, boring, milling and drilling machine of the floor type, which is designed to drive high-speed tool steels to capacity limits.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., is distributing small vest-pocket blotters (No. 57), illustrating the Westinghouse Type LC crane safety switches. A larger size blotter, No. 56, telling how to insure against loss by stocking renewal parts, is also being distributed.

Hisey-Wolf Machine Co., Cincinnati, Ohio. Bulletin 105-A, descriptive of Hisey "Super" universal motor drills, designed for operation on direct current or single-phase alternating current, for any frequency from 25 to 60 cycles. These drills may be used for drilling in either wood or metal.

Triplex Machine Tool Corporation, 18 E. 41st St., New York City. Catalogue 1, illustrating the uses of the Triplex No. 1 combination bench machine tool for turning and boring; horizontal, angular, and vertical milling; thread cutting; and drilling. Specifications of the machine are included.

United States Blueprint Paper Co., 201 S. Wabash Ave., Chicago, Ill. Circulars descriptive of several drafting instruments, including the "Draftsquare" for use in drawing nuts, circumferences, radii, screw threads, and for lettering; the Ames lettering instrument; and sets of drawing instruments.

Harrisburg Corporation, Harrisburg, Pa. Bulletin A, containing an illustrated description of the Rainsford type of radial drilling machine made by this concern. These machines are made in seven sizes, with capacities for drilling to the center of circles 7, 8, 10, 10, 12, 14, and 16 feet in diameter, respectively.

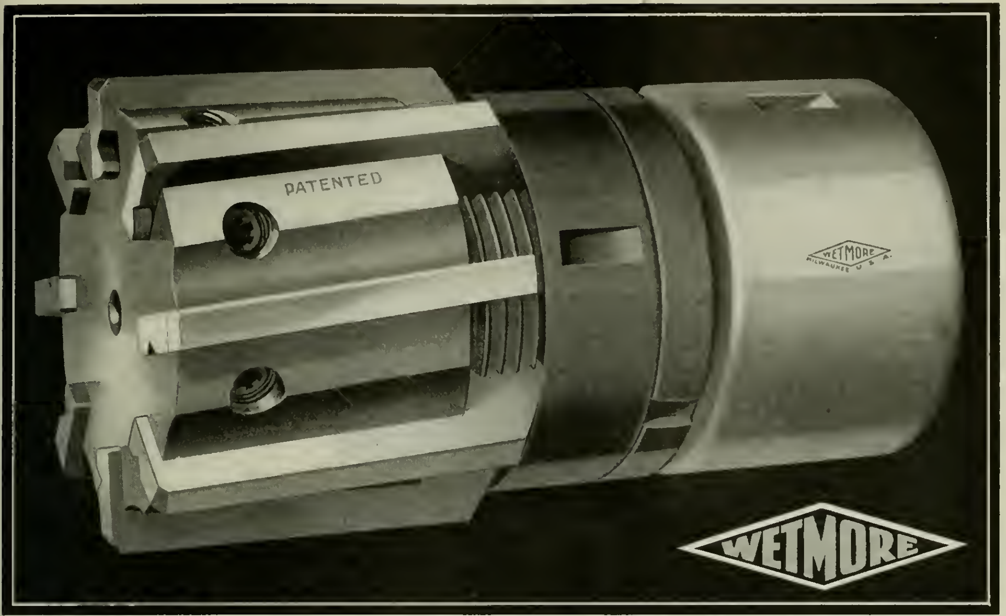
Pangborn Corporation, Hagerstown, Md. Pamphlet giving data on the Pangborn Type GF industrial barrel sand-blast intended for the manufacturing plant, small foundry, or shop doing small work in limited volume. The company is also distributing a blotter illustrating the Type DC sand dryer and the Type HC moisture and oil separator.

Ingersoll Milling Machine Co., Rockford, Ill. Circular showing examples of standard Ingersoll inserted-tooth milling cutters, which are adapted for face-milling steel, aluminum, or cast iron. This line of cutters also includes arbor mills, solid mills, and special inserted-tooth profile cutters. The field of application of the types illustrated is outlined.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Folder 4474, treating of lead-base babbitt metal for use in motor and generator bearings. This metal, which has been used for years in the motors made by this company, has just been placed on the market. The pamphlet contains instructions for using this metal so as to obtain the best results.

Howe Chain Co., Muskegon, Mich. New 100-page catalogue No. 121, illustrating and describing the Howe complete line of chains for elevating, conveying, and power transmission. The catalogue contains full-size illustrations, complete information and data, and price lists for all standard chains. Copies of the book will be sent to those interested upon request.

Eck Dynamo & Motor Co., Bellville, N. J. Bulletins 1300, 1500, 1600, and 1900, descriptive of Eck direct-current motors, vertical motors, back-geared motors, and Types 1 and I-B induction motors, respectively. Each of the bulletins gives complete specifications for the different sizes of motors, in addition to a general description covering the features of construction.



Announcing

The New Wetmore "Bull-dog"

Combining all the advantages of both solid and adjustable reamers, this new Wetmore Expanding Heavy-duty Reamer (6, 8 or 10 blades) represents the highest development of quantity-production precision tools.

No huskier or more enduring reamer has ever been produced for heavy duty work than this Wetmore "Bull-dog". The body is *guaranteed* against breakage, even under severest reaming tests. Its new tongue drive relieves the strain on the coupling nut. Assures perfect alignment between arbor and body. Large adjustment provides for wear and regrinding, so that the "Bull-dog" with its original blades will outlast several solid, non-adjustable reamers.

In every detail—design, quality of materials, workmanship, finish—the "Bull-dog" is typical of Wetmore standards of manufacturing. And the more carefully you compare it with other good reamers, the more you will appreciate these advantages of Wetmore Expanding Reamers:

Left-Hand Angle Cutting Blades that prevent digging in, chattering, and scoring of the reamer while backing out.

Solid, heat-treated alloy steel body—guaranteed against breakage.

Adjustments to the thousandth of an inch can be made in less than a minute. In fact, the Wetmore is the quickest and easiest adjusting reamer made. Cone expansion nut keeps blades always parallel with axis.

No grinding arbor required for regrinding. Wetmore Reamers can be reground on their original centers.

The above are but a few of many features of Wetmore Expanding Reamers. Let us send you our 1922 Catalog—just off the press. No better "hand-book" on reamers was ever published, we believe. Write for *your* copy.

WETMORE REAMER COMPANY., Milwaukee, Wisconsin

(Manufacturers of Expanding Reamers and Cylinder Reaming Sets, Arbors and Thread Gauges)

WETMORE REAMERS

EXPANDING

G. A. Gray Co., Cincinnati, Ohio. Catalogue 37, containing a detailed description and illustrations of Gray planers, which are made in three types known as standard planers, maximum service planers and switch and frog planers, and in a variety of sizes. The various details of construction are made clear by a liberal use of illustrations in connection with the text.

Gould & Eberhardt, Newark, N. J. Bulletin 90, containing a description of a new system of automatically hobbing worms, utilizing a hob which has a broaching action and is so designed that worms having shoulders at both ends may be cut. These hobbing machines will cut either single or multiple threaded worms. Copies of the pamphlet will be sent to those interested upon request.

American Bronze Corporation, Berwyn, Pa. Engineering data sheets 107, 108, 109, 110, 111, 112, containing data on running clearances allowed for different classes of bearings; permissible angular deflection of journals in plain bearings, with chart; relation of rubbing speeds to revolutions per minute; allowances for press fits of hard bronze bushings; and design of water pump for automotive engines.

Eclipse Interchangeable Counterbore Co., 7410 St. Aubin Ave., Detroit, Mich. Circular D, containing data covering Eclipse "Junior" interchangeable spot-facers, which are so made that many different sizes may be used with each holder, the tool being made of high-speed steel and the holder of nickel steel. Adapters are provided for these tools so that they can be used with standard Eclipse holders and standard pilots.

Hadfield-Penfield Steel Co., Bucyrus, Ohio. Catalogues descriptive of this company's Diesel type horizontal and vertical standard fuel oil engines, which are built on the two-cycle principle. The horizontal engine is made in three sizes of 50, 75, and 100 brake horsepower, the latter two sizes being built as twin units giving 150 and 200 brake horsepower. The vertical engine is built in two- to six-cylinder units, developing 50 and 125 brake horsepower per cylinder.

Electric Furnace Co., Alliance, Ohio. Folder showing a large number of typical installations of Bailey electric furnaces in the eastern states, Pennsylvania region, Ohio, Ohio valley, Michigan, Middle West, and Canada. The furnaces selected as examples are those that handle a wide range of non-ferrous alloys and a diversity of brass products, and the illustrations show the various sizes that have been built to meet the needs of different melters of non-ferrous metals.

W. S. Rockwell Co., 50 Church St., New York City. Bulletin 240, entitled "Heat-treatment of Springs with Stationary and Continuous Furnaces," containing an outline of the fundamental principles of heating and handling, with illustrations of their practical application in the manufacture of a wide variety of springs. This pamphlet is not merely a furnace catalogue, but contains general information which should be of interest to those engaged in this class of work.

Ingersoll-Rand Co., 11 Broadway, New York City. Pamphlet containing a reprint of a paper entitled "Steam Condensing Plants," by Paul Bancel, read before the Baltimore Section of the American Society of Mechanical Engineers. This paper presents a study of power plant conditions and discusses new phases of the fixed and operating charges of power plant equipment. A new Ingersoll-Rand surface condenser is described in the article, as well as the barometric and low-level, multi-jet types made by this company.

Seifreat-Woodruff Co., 20 S. Canal St., Dayton, Ohio. Circular announcing an industrial exhibit of machine tools in operation which was shown at the company's Dayton show-rooms in December. Among the tools exhibited were an American Tool Works Co.'s lathe, shaper, and radial drilling machine; Barnes drilling machine; Colburn manufacturing drilling machine; Gooley & Edlund manufacturing milling machine; LeBlond universal milling machine and universal cutter grinder; Libby turret lathe; Lumsden tool grinder; Springfield Machine Tool Co.'s lathe and straightening press; and Wood turret screw machine.

Fafnir Bearing Co., New Britain, Conn. Catalogue 21, of Fafnir ball bearings. The first section of the book contains descriptive material on types of Fafnir ball bearings and how to mount them; cleanliness and lubrication; types of closures; cross-sections of mountings; and Fafnir double ball bearing hanger boxes and transmission ball bearings. The construction is made clear by a liberal use of both halftone and line illustrations. The second part contains tables of sizes, dimensions, load ratings and prices of Fafnir ball bearings, as well as tables of standard fits for ball bearing mountings, and decimal equivalent tables.

American Broach & Machine Co., Ann Arbor, Mich., has published a broach handbook which has been compiled for the purpose of placing information on broaching, broached fittings, and the use and care of standard broaches before engineers, superintendents, draftsmen, purchasing agents, and others who come in contact with broaching operations. The first few pages are devoted to S A E broached fittings. In the following pages are discussed the method of setting up, grinding, care and use of keyway broaches, round broaches, square broaches and spline broaches. A number of illustrations are included showing interesting broaching operations. The last part of the book contains illustrations and specifications of American rack-operated broaching machines.

National Tube Co., Pittsburg, Pa. National Bulletin No. 17B, containing detailed information on the mechanical uses of Shelby seamless steel tubing. The material is divided into seven subjects as follows: Properties and general characteristics of Shelby steel tubing; use of tubing in place of solid stock or forgings; advantages of tubing in mechanical services; special operations on mechanical tubing; forming and machining mechanical tubing; mechanical tubing for specific purposes; and a survey of the uses of mechanical tubing. The section dealing with special operations on mechanical tubing contains a large number of line illustrations showing examples of parts for which seamless tubing is especially suitable. An idea of the wide application of this product will be obtained by referring to the alphabetical list of applications of seamless steel tubing.

Hunter Saw & Machine Co., Pittsburg, Pa. Catalogue E, illustrating and describing the Hunter complete line of solid and inserted-tooth metal-cutting circular saw blades, inserted-tooth setting device, serrating device for friction disks, slate saws, pipe cutters, circular knives, rotary shear blades, saw sharpening machines, pneumatic hammer rivet sets, chisel blanks, and hardened steel specialties. Tabulated matter giving sizes and prices for each of the products is included. One of the sections of the book contains instructions for the care and operation of Hunter inserted-tooth saws, and the heavy work which can be handled with these saws will be understood by reference to the illustrations. The book concludes with a section of useful information, containing milling saw specifications for different types of machines, tables of number of teeth in milling saws for a given diameter and pitch, approximate weights of circular blades, etc.

R. K. LeBlond Machine Tool Co., Cincinnati, Ohio. Catalogue illustrating and describing the LeBlond line of heavy-duty milling machines. The catalogue contains 111 pages, 8½ by 11 inches, and gives a detailed description of the construction of the cone type and geared drive milling machines. Specifications are given for the different sizes in both types. This line of machines is made in both plain and universal styles, and attention is called to the fact that there has been a complete regrouping and rearrangement of sizes and ranges, the heavy-duty machines having been made considerably heavier and supplemented by a lighter line. The section on dividing heads and milling attachments for LeBlond milling machines includes tables for spacing on plain dividing heads and on LeBlond dividing heads, as well as tables for cutting spirals. The book concludes with instructions for oiling, adjusting, and setting up these machines.

TRADE NOTES

Eastman & Co., 63 E. Adams St., Chicago, Ill., has been organized by D. T. Eastman, formerly advertising manager of the Eagle Picher Lead Co. of Chicago, to engage in technical advertising.

Rich Tool Co., 513 A, Railway Exchange, Chicago, Ill., manufacturer of drills, reamers, etc., has appointed the Busch Corporation of St. Louis representative of the company in the St. Louis territory.

Ford Chain Block Co., Second and Diamond Sts., Philadelphia, Pa., has opened a branch office and warehouse at 85 Walker St., New York City, where a complete stock of chain blocks and trolleys will be carried.

Pennant Tool & Engineering Co., Springfield, Ohio, is now located in its new building at North and Isabella Sts. The company handles tool and die work and special machine work. H. H. Swope is president and general manager.

Rockford Milling Machine Co., Rockford, Ill., has appointed the Charles A. Strelinger Co. of Canada, Ltd., Windsor, Ontario, Canada, exclusive distributor for its products. The products of the Rockford Tool Co. will also be handled exclusively by this company.

Harrold Tool & Forge Co., Columbiana, Ohio, manufacturer of mechanics' hand tools, screw-drivers, and drop-forgings, has recently changed its corporate name to the Colonial Tool & Forge Co. Wiebusch & Hilger, Ltd., of New York City, will continue to be the selling representative of the company.

Manning, Maxwell & Moore, Inc., 119 W. 40th St., New York City, has moved its Philadelphia office from the Lincoln Building, to larger and better quarters in the Pennsylvania Building at 15th and Chestnut Sts., occupying rooms 905 and 906. This concern also moved its Boston office on December 1 from 10 High St. to the Textile Building at 99 Chauncey St., rooms 802 and 803.

J. B. Engineering Sales Co., Hartford, Conn., has recently moved from 60 Prospect Ave. into larger quarters at 54 Church St. The company specializes in power plant equipment, and is a distributor for Sells roller bearings and other products of the Royersford Foundry & Machine Co., as well as for the products of the Oriscom-Russell Co., and the Conveyor Corporation of America.

Rivett Lathe & Grinder Co., Brighton District, Boston, Mass., has recently opened a sales office in Detroit, Mich. The new office is located with the Reed-Prentice Co., at 408 Kerr Bldg. It is requested that prospective purchasers of Rivett machinery in the Detroit district communicate with the Detroit sales office, as facilities have been provided for furnishing information promptly and for filling orders with dispatch.

Greenfield Tap & Die Corporation, Greenfield, Mass., announces that it has consolidated the small tool and drill divisions of the company, and has placed P. T. Irvin, former manager of the drill division, in charge of the consolidation, which will be called the small tool division. Mr. Irvin has had considerable experience along these lines, having been sales manager of the Lincoln Twist Drill Co., Taunton, Mass., for the last three years, and prior to that sales manager of the Wells Bros. Co. of Greenfield.

Cincinnati Shaper Co., Elam St. and Garrard Ave., Cincinnati, Ohio, and its subsidiary the Cincinnati Gear Cutting Machine Co. have arranged to open a branch sales office at 940 Lemcke Annex, Indianapolis, Ind. T. C. McDonald has been appointed local manager. This office will supervise the sale of machine tools for these companies in the Indianapolis and Louisville district, as well as in certain states in the southwest. Mr. McDonald will also continue as local representative of the Reed-Prentice Co.

Leonard Machine Works, Philadelphia, Pa., moved on January 1 to their new plant, Baltimore Ave. and Hirst St., Lansdowne, Pa. The new plant was built according to plans made by Mr. Leonard. It is a one-story building, of steel framework and brick construction, with all-steel sash and a monitor roof. The manufacturing floor space is approximately 50 by 100 feet. The company will continue its contract manufacturing, and in addition will develop further and manufacture its line of pipe-bending machines, as well as a line of special machinery.

Whiting Corporation, Harvey, Ill., manufacturer of cranes and foundry equipment, has purchased a controlling interest in the Grindle Fuel Equipment Co., manufacturer of powdered coal plants for use in connection with steam boilers, malleable furnaces, annealing ovens, and other types of furnaces. The Grindle Fuel Equipment Co. has moved its offices to Harvey, and will continue its business under the same name. The Whiting Corporation will manufacture all Grindle equipment. The following officers have been elected: President, B. H. Whiting; vice-president and general manager, A. J. Grindle; and secretary and treasurer, T. S. Hammond.

Diamant Tool & Mfg. Co., Inc., 95 Runyon St., Newark, N. J., has appointed Russell, Holbrook & Henderson, Inc., 30 Church St., New York City, its exclusive sales representatives, handling Diamant standard punch and die sets in the territory covering New Jersey north of Trenton, all of New York City, New York state south of Kingston, and all of Connecticut west of the Connecticut River. The company has also appointed H. M. Bush, 16 S. Third St., Columbus, Ohio, sales representative for central Ohio, and Russell Propes, 1025 Cherry St., Norristown, Pa., sales representative for southeastern Pennsylvania, including the Philadelphia section.

Wetmore Reamer Co., 60-64 Twenty-seventh St., Milwaukee, Wis., manufacturers of a line of expanding reamers, including cylinder reaming sets, and the Wisconsin Tool & Supply Co., of Milwaukee, manufacturer of special tools, jigs, dies, fixtures, and thread gages, have been consolidated and will hereafter be operated under the name of the Wetmore Reamer Co. The company will specialize in the manufacture of expanding reamers for high-speed and quantity production work, as well as expanding machine reamers under one inch in size, which are a recent development. It will also continue to build tools and dies, fixtures and special thread gages. The officers of the consolidated corporation are as follows: President and general manager, Edward J. Waltzer; vice-president, Charles G. Forster; secretary, Carl A. Forster; and treasurer, Edward D. Johnson. The direct management of the company will be under the supervision of the Wisconsin Tool & Supply Co. organization.

Atlas Vise Co., Lowville, N. Y., has been incorporated, with a capitalization of $25,000, by Foster M. Strickland of Champlain, N. Y., and E. W. Fulton, G. L. Fulton, Henry Petrie, and H. W. Green of Lowville, for the purpose of manufacturing, buying, selling, importing, and exporting vises and tools of all kinds. Executive and sales offices have been opened in the Bowen Block, Lowville. Manufacturing and selling rights under patents owned by E. W. Fulton, former president and general manager of the Fulton Machine & Vise Co. of Lowville, have been secured, as well as similar rights to the trade name and patents of the Velox Vise Co. The vises are now being manufactured for Mr. Fulton by the Porter-Cable Machine Co. of Syracuse, N. Y., and it is expected that the new organization will continue the arrangement and that all shipments will be made from Syracuse. The line of vises acquired includes a new type of combination vise especially designed for garages, and a Velox steel bar quick-action vise more especially adapted to the needs of industrial plants. Standard bench vises will also be carried.

Commercial Gear-cutting Practice

First Article of a Series Dealing with the Use of Different Types of Gear-cutting Machines for Cutting Various Classes of Gearing

This Installment Covers the Cutting of Spur Gears on Automatic Machines of the Formed-cutter Type

By FRANKLIN D. JONES

A COMPLETE history of all machine tools and mechanical processes used in machine shops would contain no part more fascinating than that dealing with the origin and development of gear-cutting machines. The necessity of utilizing positive means for transmitting rotary motions in machines accounts for the fact that the general subject of gearing has engaged the attention of engineers for generations, and since gearing of some type is in common use on almost every kind of mechanism, it is not surprising that gear-cutting is a subject of unparalleled interest among machine shop processes.

This article and others to follow will deal with the different methods and machines now used for cutting gears of various types and sizes, from small precision gears up to very large, heavy designs. In this general review of the subject, the object will be to show (1) how gears of different kinds are cut; (2) what types of machines are used under different conditions; (3) what factors affect production and quality; (4) commercial rates of production for cutting gears by different processes; and to give other important facts for the user or prospective user of gear-cutting machines. The development of the highly specialized gear-cutting machines now employed has required a vast amount of experimenting, and the designing and redesigning of many different types of machines and cutters to obtain equipment capable not only of cutting accurate gearing but also of working on a commercial basis. The modern gear-cutting processes to be described will include the cutting of spur, straight-tooth, bevel, spiral bevel, helical (or spiral), double-helical or herringbone, and worm gearing.

General Classification of Gear-cutting Processes

The gear-cutting processes commonly utilized for producing different types of gears may be divided into three general classes. One includes the use of tools or cutters which form gear teeth by reproducing the shape of the cutter itself; in another class are the generating processes whereby the proper tooth curves are formed through relative motions of the tool and work, as when a straight-sided cutting tool generates the required tooth curves due to the rotary motion imparted to the gear blank. The third general classification includes the use of templets or master formers, which control the path followed by the cutting tool, and consequently the curvature of the gear tooth. This method is applied chiefly to the cutting of very large gears, and like the other processes referred to will be illustrated later by examples from practice.

The tool which cuts or forms the gear teeth may either revolve or have a reciprocating motion. When the shape of the cutter is directly reproduced on the gear, a revolving or disk type of cutter is generally used, the gear teeth being formed by milling operations. In some cases, a formed tool having a reciprocating motion may be employed, as, for example, when a gear is cut on a shaper or slotter because a regular gear-cutting machine is not at hand. Many machines of the generating type have revolving cutters, whereas other classes of generating machines operate with a planing or reciprocating motion. Machines of the templet or form-copying type are in the planer class. The forms of cutters used on different machines and the methods of applying these machines to various classes of gearing are to be illustrated by examples representing a wide range of practice.

Different Methods of Cutting Spur Gears

The cutting of spur gears will be dealt with first, since this type is used much more than any other. Spur gearing, in common with other classes, may be cut by a number of different methods, each of which is satisfactory when applied under favorable conditions. These gear-cutting methods include (1) milling the teeth with cutters conforming to the shape of the spaces between the teeth; (2) milling the teeth with a cutter of the hob type, which represents a rack in the axial plane and is used in generating the tooth curves; (3) planing with a circular cutter which has teeth like a gear and serves to generate the tooth curves as the cutter and gear blank revolve

---

This series of articles will form a complete treatise on the cutting of spur gears, straight-tooth bevel gears, spiral bevel gears, helical and herringbone gears, internal gears, worm-gears, and worms. There will be numerous examples from practice ranging from small instrument gears up to very large spur and bevel gears. Recent developments in gear-cutting machinery will be included, together with specific information covering operating principles, methods of setting up machines, time required for cutting gears of different types and sizes, and other essential points.

---

in unison; (4) planing with a tool that takes a series of cuts across the side of the tooth and is guided by a templet or former as it is gradually fed inward; (5) planing with a tool that conforms to a single rack tooth and generates the tooth curves as it moves laterally after each stroke, while the gear blank receives an indexing movement that causes each tooth to mesh properly with the traversing tool; (6) planing with a tool which is similar to a short section of a rack and is used in generating tooth curves as the gear blank rotates relative to the rack cutter; and (7) planing the teeth of the gear by the use of a formed tool which is of the same shape as the tooth spaces.

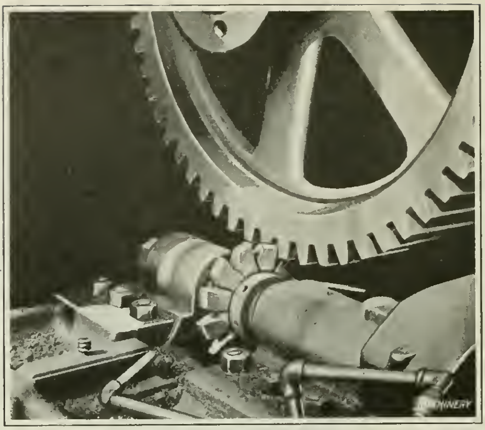

Fig. 1. Cutting a Spur Gear with a Formed Cutter

These various processes are utilized in manufacturing plants of different kinds, because the method of cutting gears, in common with other shop processes, depends upon such factors as the quantity of work to be done, its size, and the degree of accuracy necessary. For instance, the gear-cutting practice in a general repair shop would ordinarily differ from the methods used in the average plant manufacturing, say, machine tools; and still other variations are found in automobile plants, particularly where production is on a very large scale. The manufacturers of gear-cutting machines have developed types to meet these different conditions. For example, there are machines designed for general gear-cutting operations, and other highly specialized types intended solely for cutting large numbers of duplicate gears.

An example of specialization is found in the automotive field where machines of special design are used exclusively for roughing bevel gears preparatory to finishing in other machines. In this instance, it is essential to combine high production with accuracy, which is obtained by using the special machines for rapid roughing and other machines for accurately generating the tooth curves. While these very special types of gear-cutting machines are not found in many shops—considering the machine-building field as a whole—they illustrate what has been done by gear-cutting machine manufacturers to meet different commercial requirements. Just how various gear-cutting processes and types of machines are applied both in plants requiring high production as well as in shops where the variety of gear sizes is large in proportion to the number of gears cut, will be illustrated by many diversified examples of gear-cutting practice.

Cutting Spur Gears by the Disk or Formed-cutter Method

The disk or formed-cutter method is utilized in a great many shops, especially for cutting spur gears. This is a non-generating method, the shape of the gear tooth being a reproduction of the shape of the cutter. It has been applied successfully to a wide range of work, including very small precision gears as well as large heavy spur gears. A close-up view of a formed cutter at work is illustrated in Fig. 1. It will be seen from this illustration that this is merely a milling operation.

When gears of small or medium size are required in small quantities or odd sizes, formed cutters are often used in standard types of milling machines, particularly in repair and jobbing shops, but this and other articles to follow will deal only with machines designed expressly for gear-cutting.

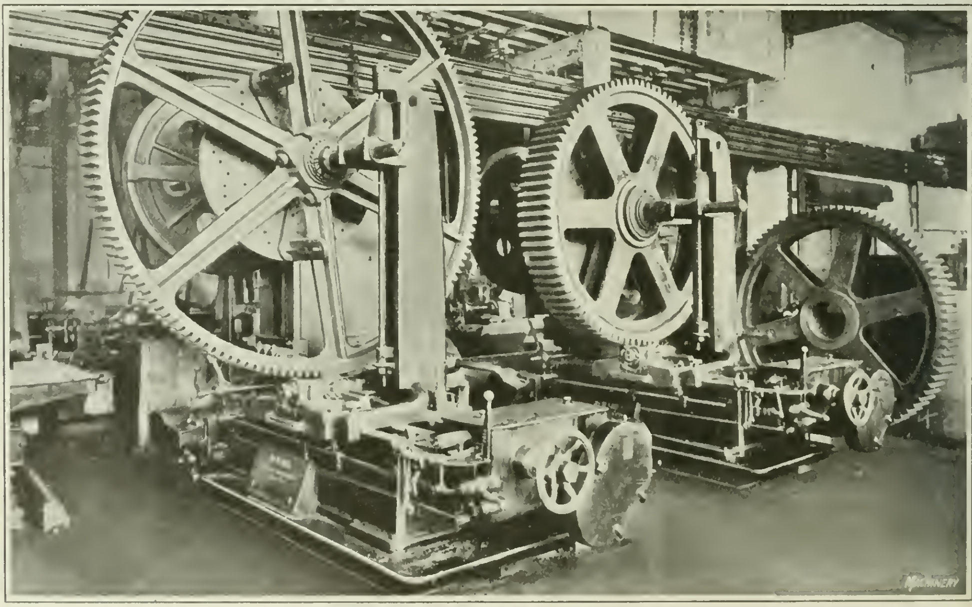

Fig. 2. Examples of Gear-cutting on Machines of the Formed-cutter Horizontal-feeding Type

The machines of the formed-cutter type are commonly known as automatic gear-cutting machines because, after the gear blank or blanks are in the cutting position and the machine is properly adjusted, all the gear teeth are cut automatically without further attention on the part of the operator. Certain other types of gear-cutting machines also operate automatically except for the insertion and removal of the work, although the term "automatic" is not used in designating them to the same extent as in the case of spur-gear machines.

The general characteristics of these automatic spur-gear machines include a main spindle for holding and driving the work-holding arbor; a cutter-slide arranged to move parallel with the axis of the work-spindle; a mechanism for feeding the cutter-slide at a suitable rate and returning it to the starting point; and a mechanism for indexing the gear blank after each tooth space is milled. The arrangement of different makes of these machines varies somewhat. For instance, the cutter-slide of some machines has a horizontal feeding movement along the main bed, as in the example shown in Fig. 2, and the work-spindle is carried by a slide having vertical adjustment along a column, to suit the gear diameter. The cutter-slides of other machines feed vertically along the face of the column, as in Fig. 4, and the work-spindle is held in a vertical position on a slide or table mounted on horizontal ways formed on the main bed. The details of indexing and feeding mechanisms as well as other parts also vary in design, as will be seen by a comparison of illustrations to follow; this series of articles, however, will deal chiefly with gear-cutting processes and the methods of *using* different types of machines rather than with their design, especially as the latter is related to constructional details.

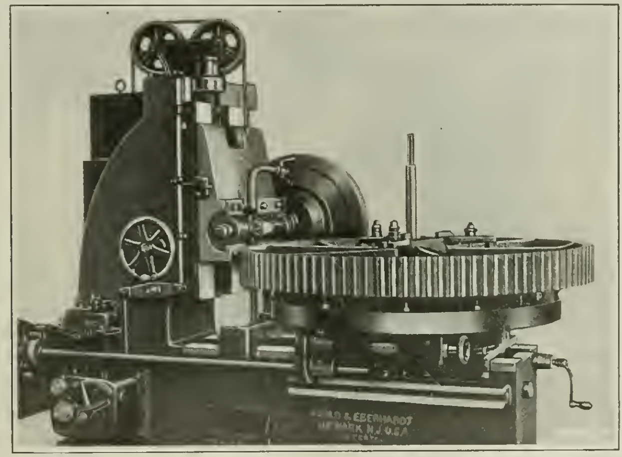

Fig. 4. Cutting a Cast-steel Spur Gear on a Machine of the Vertical-cutting Type

Centering Cutter Relative to Gear Blank

While the exact method of setting up or adjusting automatic gear-cutting machines varies somewhat for different makes, the general procedure will be reviewed briefly and later some of the more important features will be more fully described. After selecting a cutter of the right pitch and number, this cutter with its arbor is placed in the working position. The cutter-spindle bearing is then adjusted to locate the cutter central with the work-spindle so that the center line of each tooth space cut in the gear blank will be radial. This is usually done by means of a centering gage or indicator supplied with the machine. The type of gage used on Newark gear-cutting machines is illustrated in Fig. 3. It consists of a steel straightedge *A* having a vee formed in one end. This straightedge or gage, when in use, is placed on a horizontal surface in contact with the raised edge *B* which holds the gage in alignment. The gage-supporting surface is located on the cutter-slide. The cutter is set in the central position by simply adjusting the spindle laterally until one of the cutter teeth is in contact with both sides of the V-shaped notch when the gage is held firmly against the raised aligning edge *B* of the support.

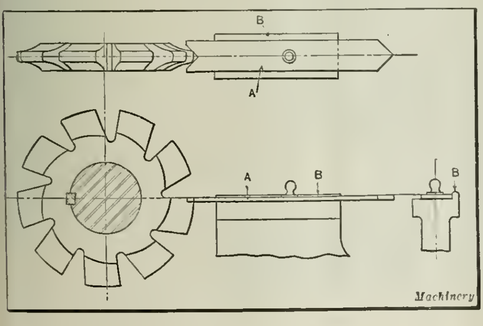

Fig. 3. One Type of Gage used to center Cutter Relative to Gear Blank

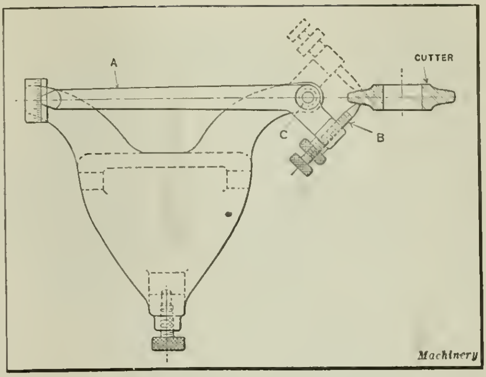

Fig. 5. Another Type of Cutter-centering Gage

The type of indicator used on Brown & Sharpe machines is illustrated in Fig. 5. This indicator is clamped to the ways of the bed in front of the cutter-slide. The cutter-spindle is adjusted until indicating lever *A* shows that it is in a central position. The point of screw *B* should come in contact with the cutter approximately at the pitch line. The position of the indicating lever is then reversed on pivot *C*, as indicated by the dotted lines. If the zero line on lever *A* is equidistant from the zero line on the gage, for the two positions of contact point *B*, this shows that the cutter is in a central position. If preferred, screw *B* may be so adjusted that the lever *A* stands at the zero position and both zero lines will coincide when the cutter is central.

While the indicator just described enables the cutter to be set accurately enough for ordinary purposes, the method of centering recommended when very accurate quiet-running gears are required is as follows: First turn a blank to the same size as the gears to be cut; then, after centering it as accurately as possible, take a single cut through this blank. Without changing the position of the cutter, remove the blank from the work-arbor and reverse its position. Next, with the blank free to turn on the arbor, feed the cutter into the slot previously milled and revolve it by pulling the

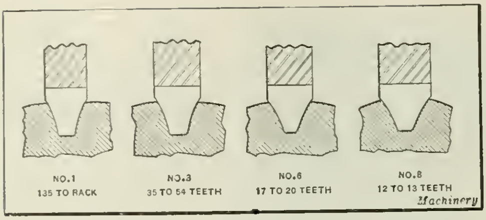

Fig. 6. Diagram showing Variations in Shapes of Gear-cutters of the Same Pitch but intended for Small, Medium, and Large Size Gears

belt so as to mark its position relative to the slot. If the second cut follows the outline of the first, the cutter is exactly central, but if the cutter removes some stock from the top of the space on one side and the bottom of the other, this indicates an inaccurate setting. When such an error is detected, the cutter should be adjusted away from that side of the tooth from which stock was removed at the deepest part of the cut. After this has been done, a second cut is taken in the blank, and the procedure described in the foregoing is repeated to check the adjustment again.

Other Adjustments when Setting up Machines

Another important point to consider when setting up a machine is the method of supporting the work. An arbor inserted in the main spindle is generally used, and frequently this arbor is additionally supported by an arm or outer bearing. It is good practice to test the accuracy of the arbor when setting up a machine. This may be done by placing a dial indicator in contact with it; the worm of the indexing mechanism is disengaged from the index-wheel to permit revolving the spindle and arbor by hand, and then the indicator shows whether the arbor is concentric with the machine spindle. The gear blank or in some cases two or more blanks are placed on the arbor, the number depending upon the width and general proportions of the blanks. The indexing mechanism is geared to agree with the number of teeth to be cut, the proper combination of gearing for a given number of teeth being shown by the chart accompanying the machine. The cutter speed and rate of feed are regulated by means of change-gears, according to the pitch of the gear to be cut, the kind of material, and the kind of steel used in making the cutter. Speed and feed plates attached to the machine show the speeds in revolutions per minute, and the feeds either in inches per minute or per revolution of the cutter. The slide supporting the gear blank is adjusted to mill teeth of the proper depth and thickness, usually by means of a graduated dial on the machine, reading to thousandths of an inch.

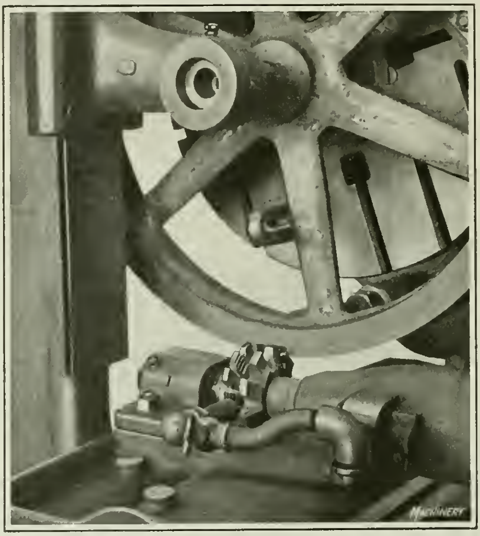

Fig. 7. Machine equipped with Two Cutters for taking Roughing and Finishing Cuts simultaneously

The usual practice is to finish each tooth space by one passage of the cutter, although two cuts are sometimes required. The rim rest, which is used whenever possible to take the thrust of the cut, is adjusted so as to support the gear blank without interfering with the indexing movement. Before bringing the indexing worm in mesh with the wheel, it is well to turn the spindle by hand to make sure that the rim rest does not bind tightly against the work.

As any error in the adjusting of the indexing mechanism would be very serious, the indexing movement is sometimes tested before cutting the gear. One method is to nick the blank in one place and then index by hand to correspond to the number of teeth to be cut in order to see if the nick in the blank is in alignment with the cutter after the work has been indexed one revolution. Another method is to start two grooves or tooth spaces, cutting far enough into the blank to give the tooth its full form for a short distance. The chordal thickness at the pitch line is then measured by using a vernier gear-tooth caliper.

Before the machine is ready for use, the dogs that control the stroke of the cutter-slide must be adjusted to give the slide a movement sufficient to allow the cutter to pass through the blank and then return far enough to permit indexing. One dog is set so that the feeding movement of the slide is reversed after the center of the cutter passes the end of the work. The other dog is then set to stop the return movement when the cutter clears the blank, at a distance of, say, about 1/4 inch, or enough to provide clearance for the indexing movement. This clearance should not be excessive, as this simply increases the idle time, thus decreasing the rate of production.

Selecting a Formed Cutter for Spur Gears

Formed cutters for cutting spur gears must not only be of the required diametral pitch, but they must also be selected with reference to the number of teeth in the gear to be cut. For example, a cutter for a gear having 28 teeth of 8 diametral pitch differs in shape from a cutter for a gear of the same pitch having, say, 60 teeth. The variations in the shapes of cutters Nos. 1, 3, 6, and 8 are illustrated by the diagrams in Fig. 6. The involute cutters commonly used are made in series of eight cutters for each diametral pitch. Cutter No. 1 is intended for gears ranging from 135 teeth to a rack; No. 2 from 55 to 134 teeth; No. 3 from 35 to 54 teeth; No. 4 from 26 to 34 teeth; No. 5 from 21 to 25 teeth; No. 6 from 17 to 20 teeth; No. 7 from 14 to 16 teeth; and No. 8

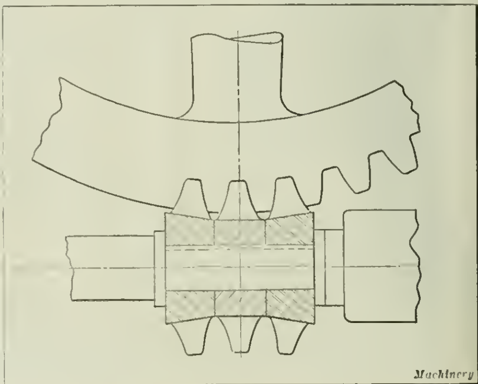

Fig. 8. Gang Cutter for finishing Two Teeth simultaneously

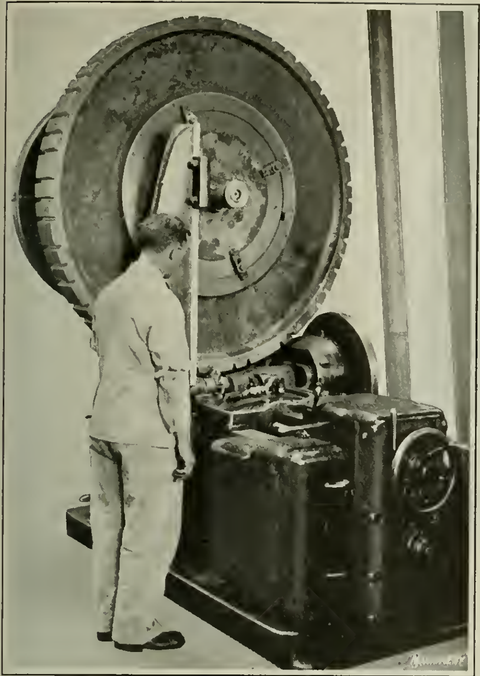

Fig. 9. Example illustrating Application of Intermittent Indexing

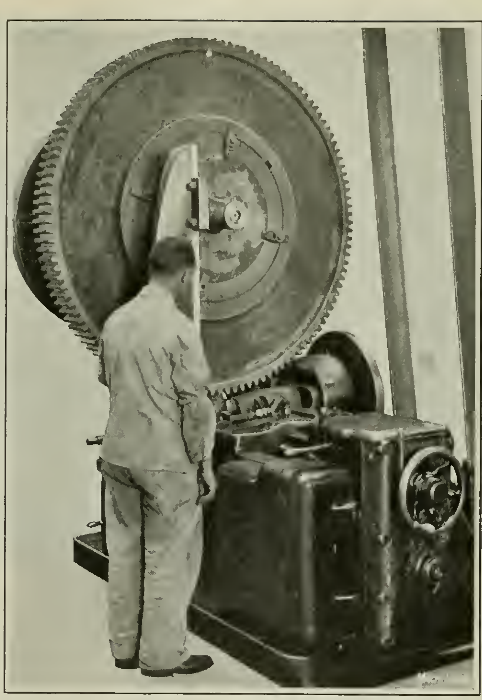

Fig. 10. Finishing the Gear roughed out as illustrated in Fig. 9

for 12 and 13 teeth. The shape of each cutter in this series is correct for a certain number of teeth only, but it can be used for other numbers within the limits given. For instance, a No. 6 cutter may be used for gears having from 17 to 20 teeth, but the tooth outline is correct only for 17 teeth or the lowest number in the range, which is also true of the other cutters listed. When this cutter is used for a gear having, say, 19 teeth, too much material is removed from the addenda of the teeth, although the gear meets ordinary requirements.

These cutters are so formed or relieved that the faces of the teeth may be ground for sharpening without changing the outline of the tooth curve. It is essential when grinding to keep the face of each tooth radial or in a plane intersecting the axis. All teeth must also be of the same height, so that the work of cutting will be distributed uniformly, instead of having one or two high teeth do all the work. Another important point is to keep the cutters sharp, because this increases production, decreases the power required for driving the machine, and produces a smoother and also a better wearing tooth surface on the gear.

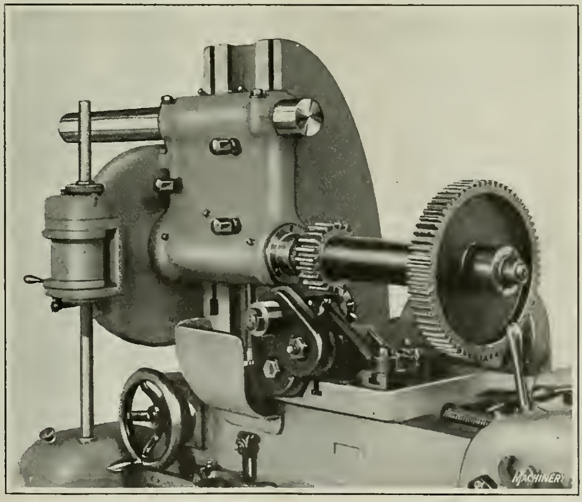

Fig. 11. Gear-cutting Machine equipped with Special Attachment for cutting Quill Gears

Intermediate Series of Cutters to Obtain Greater Refinement

When greater accuracy of tooth shape is desired to insure smoother or quieter operation, an intermediate series of cutters having half numbers is used. The half numbered cutters made by the Brown & Sharpe Mfg. Co., Providence, R. I., are for the following ranges of tooth numbers: Cutter No. 1½, 80 to 134 teeth; No. 2½, 42 to 54; No. 3½, 30 to 34; No. 4½, 23 to 25; 5½, 19 and 20; 6½, 15 and 16; and 7½, 13 teeth. There are seven cutters in this series, No. 8½ being omitted since this would be for a pinion with less than 12 teeth. What has been said about cutter selection applies particularly to spur gears. When bevel gears are cut by the milling process, as will be explained in one of the articles to follow, the method of determining what cutter number to use is different from the method employed in the case of spur gears.

Formed Cutters for Spur Gears with Stub Teeth

Involute gears having a 14½-degree pressure angle are generally considered standard, and are ordinarily cut by gear manufacturers unless otherwise specified, although the stub-tooth gear having a 20-degree pressure angle might be considered standard in the automobile field, as applied to transmis-

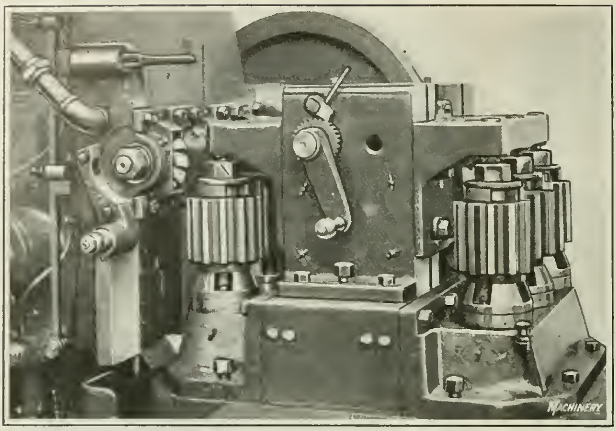

Fig. 12. Example of Gear-cutting on Machine of Multiple-cutter Revolving-turret Type

sions and for certain other applications requiring exceptionally strong gear teeth. Because of the increased pressure angle of a stub-tooth gear, the change in tooth outline is more pronounced for different numbers of teeth than with a 14½-degree pressure angle; hence, in order to secure the same degree of refinement, a larger number of cutters is required for each pitch. While the series of eight cutters referred to may be used for each pitch, a set of fifteen cutters is recommended by the Brown & Sharpe Mfg. Co. to obtain the accuracy ordinarily expected in gears of smaller pressure angle. This set of cutters includes the eight regular numbers plus the seven half numbers or intermediate shapes referred to. To obtain the best results, the cutter should be made special to suit the exact number of teeth required.

RATES OF FEED, IN INCHES PER MINUTE, FOR CUTTER-SLIDE

Diametral Pitch	2	2½	3	4	5	6	7	8	10	12	16
Cast iron ..	3½	3½	4	4½	4½	5	6	6	7	8	9
Steel	1½	1½	2	2½	2½	3	4	4	4½	5	6

Machinery

Number of Cuts Necessary for Gears of Different Pitches

As a general rule, each tooth space is finished by one passage of the cutter when the teeth are formed by milling, although two cuts are frequently taken, especially when cutting large pitches. The degree of accuracy and finish desired may also have a bearing upon the number of cuts necessary. Ordinarily, when the teeth of cast-iron gears are coarser than 2 diametral pitch, it is good practice to take roughing and finishing cuts. When the gears are made of steel or hard bronze, roughing and finishing cuts are preferable for 4 diametral pitch or coarser. While cast-iron gears up to 2½ diametral pitch can usually be finished satisfactorily with one passage of the cutter, it will be understood that the condition of both machine and cutter might change the conditions decidedly. When a second cut is taken for finishing, it is important to have the roughed-out tooth spaces central with the cutter to avoid removing unequal amounts of metal on the sides, since this tends to wear the cutting edges unevenly and produce inaccurate teeth. If roughing cuts are taken, the stocking cutter should be set to mill the teeth the full depth, the allowance for finishing being on the sides. Stocking cutters having ridges to break up the chips are commonly used.

Using Cutters in Gangs to Reduce Time for Cutting Gears

A gang of two or more cutters is sometimes mounted on an arbor, so that all the cutters operate simultaneously. One method is to place a stocking cutter in advance of the finishing cutter, as illustrated in Fig. 7, the finishing cutter being in the central position. This plan is also followed in cutting rack teeth, a common method being to place a stocking cutter and a finishing cutter side by side.

Another arrangement of gang cutters is illustrated in Fig. 8, which shows how two teeth may be finished at each indexing by using a gang of three cutters. It will be noted that the end cutters are of special shape, which is one disadvantage of this method. When accurate gears are required, the gang-cutter method is not advisable; when used, it is generally applied to cutting gears of small pitch, especially when required in large quantities. In general, the use of gang cutters is not recommended for the best classes of work. Ordinarily when the finishing cutter is preceded by a stocking cutter, the teeth are not milled as accurately as when these cutters are used separately; moreover, gang cutters for finishing two or more teeth simultaneously are inferior to the single-cutter method as regards accuracy.

Determining Cutter Speed and Rate of Feed for Cutter-slide

Actual tests are necessary to determine the most effective combinations of cutter speed and feed, because in addition to the pitch of the gear and the cutting qualities of the metal, speeds and feeds are decidedly affected by the kind of cutter used, its condition, especially in regard to sharpness, rigidity of both machine and work, the provision for cooling the cutter, and other variable factors. The following figures obtained from the Brown & Sharpe Mfg. Co. are given as a guide only, and other speeds and feeds should be substituted whenever actual tests show that they will give better results and higher production. When average conditions exist, high-speed steel cutter speeds may vary from 80 to 125 feet per minute for cast iron, and from 65 to 100 feet per minute for machine steel. When carbon steel cutters are used, the speeds for cast iron are ordinarily from 60 to 70 feet per minute, and for machine steel from 30 to 40 feet per minute.

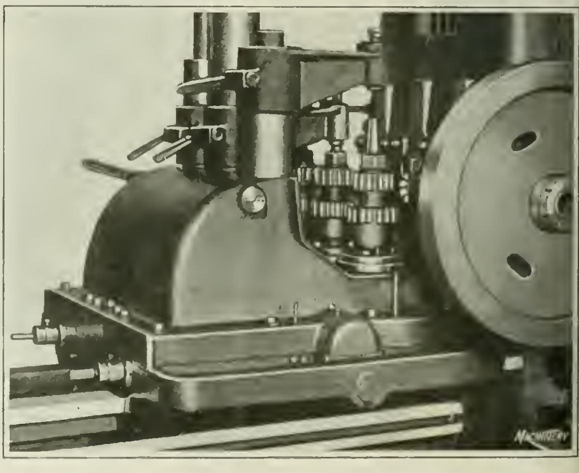

Fig. 13. Another Example of Multiple Gear-cutting

Rates of feed for the cutter-slides, in inches per minute, are given in the accompanying table, which applies to high-speed steel cutters and covers diametral pitches from 2 to 16. In determining the proper rate of feed by actual test, it is necessary, of course, to consider the amount of time the cutter may be used without regrinding, because the highest rate of feed that may be used for a short period is not necessarily the most economical rate.

Changing Rate of Feed when Using Double Cutters

The use of double cutters (one for roughing and the other for finishing) is considered advantageous in many shops when a large number of gears are to be cut, although this method is sometimes employed even when cutting a single gear. When taking the first cut, as illustrated in Fig. 7, both cutters must cut a tooth space through solid stock, whereas for the following cuts the finishing cutter simply removes what has been left by the roughing or stocking cutter. Because of this heavy cutting at the start, a slower feeding movement should be used, and to avoid feeding by hand or changing the gears, the Brown & Sharpe machine (Fig. 7) is equipped with a feed-changing mechanism, which automatically changes the slow feed used for the first cut to a feeding movement twice as fast for the remaining cuts. The feed is again reduced for taking the first cut on the next blank, by means of a hand-lever.

The cast-iron gear shown in Fig. 7 is to have 75 teeth of 2½ diametral pitch; the face width is 3½ inches. Cutters of 5¾ inches diameter operate at a speed of 66 revolutions per minute, or about 90 feet per minute at the pitch line, and the feeding movement after the first cut is 2¼ inches per minute. The time per gear is 3¾ hours.

Additional examples illustrating the use of roughing and finishing cutters at the same time are illustrated in Fig. 2, which shows two gear-cutting machines made by the Newark Gear Cutting Machine Co. of Newark, N. J. When taking the first cut through the solid rim, a relatively slow feed is used, and for all succeeding cuts, where only one cutter is cutting into the solid rim, a faster rate of feed is obtained simply by pulling the triple-geared feed knob out another notch. The large gear on the machine at the left has 150 teeth of 1¾ diametral pitch, and the gear at the right has 86 teeth of 1¼ diametral pitch. Both of these gears are made of cast steel.

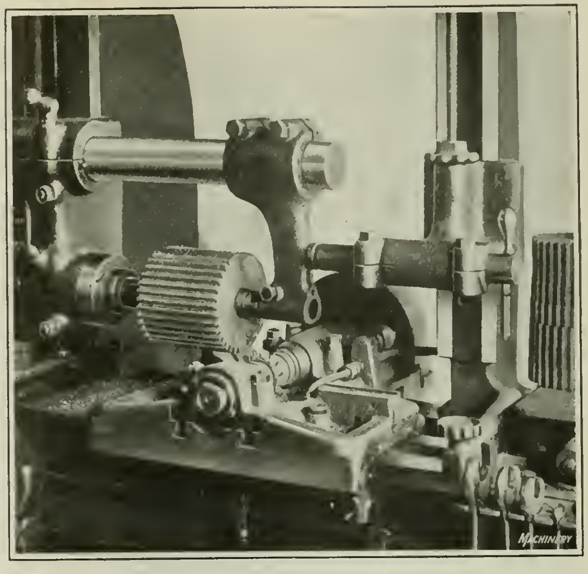

Fig. 14. Stack of Five Gears mounted on an Arbor

Adjustment for Tooth Depth, and Methods of Gaging

Adjustment for depth of cut is made by changing the position of the work-holding slide until the cutter (which should be revolving) just grazes the blank; the cutter is then withdrawn to clear the blank, and the slide carrying the work-spindle is adjusted an amount equal to the whole depth of the tooth, as shown by the graduated dial of the adjustment screw. The whole tooth depth equals 2.157 divided by the diametral pitch. In using this method, care should be taken to safeguard against errors which might result from lost motion between the adjusting screw and nut. The outside diameter of the gear blank should also be measured carefully, and an allowance made if it is not the correct size. The outside diameter of a spur gear is found by adding 2 to the number of teeth and dividing this sum by the diametral pitch.

A good method of checking the position of a cutter relative to the blank is by measuring the tooth thickness with a vernier gear-tooth caliper. This caliper measures the chordal thickness of the tooth at the pitch line. In order to use the caliper, it is necessary to know what the chordal thickness should be and also the perpendicular distance from the chord to the top of the tooth. These dimensions may be determined by formulas or by referring to tables to avoid calculations. (See formulas and tables in MACHINERY'S HANDBOOK, pages 589 to 591.)

Another method of gaging tooth depth is by first cutting two spaces in the blank diametrically opposite (assuming that the gear has an even number of teeth) and a little less than the correct depth. The root diameter is then measured, and

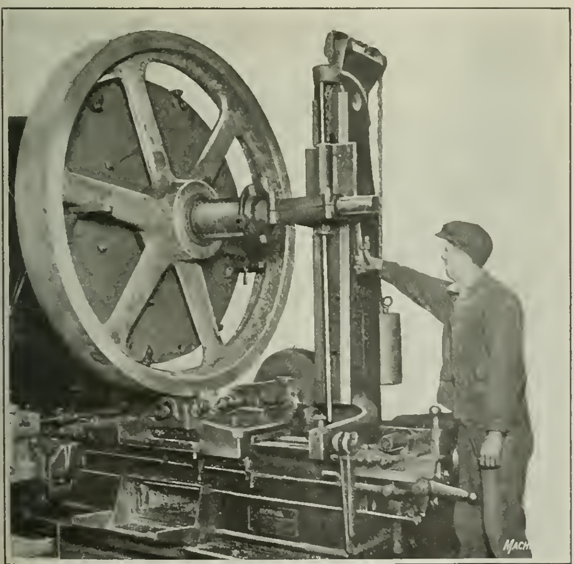

Fig. 15. Method of supporting a Fairly Large Gear

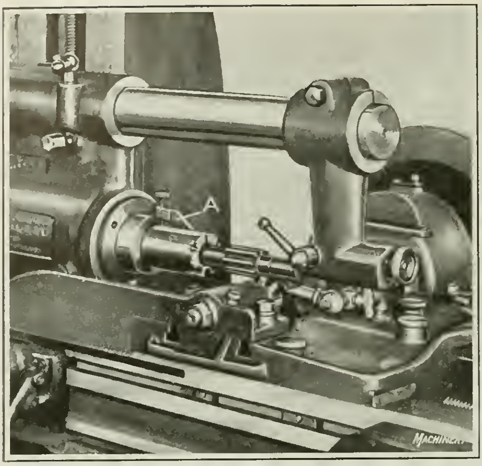

Fig. 16. Pinion held between Centers and aligned by Lever A engaging Keyway

the spaces are recut accordingly; the root diameter is again measured to check the accuracy of the adjustment. A special gage applied to the work-arbor is sometimes used for testing the depth of the cut, especially when cutting a number of duplicate gears.

Single and Block Systems of Indexing

Most gears are cut by indexing from one tooth to the next, but sometimes the index mechanism is arranged to rotate the blank an amount equal to two or more tooth spaces. This "block indexing" is done when using a gang of cutters, which finishes two or more teeth at one time. Block indexing may also be employed with a single cutter, as, for example, when every seventh tooth space is cut in a gear having 100 teeth. When this method is employed, the gear must make two or more complete revolutions in order to finish all the teeth. The object of this system of indexing is to distribute the heat generated by the gear-cutter, and secure greater accuracy and more rapid production. When the teeth are cut by indexing one tooth at a time, the tendency is toward local heating of the gear rim, especially if there is no provision for cooling the cutter and the work. Some compound is ordinarily used, however, for steel gears, and compressed air has been utilized when cutting cast-iron gears, although this is not the general practice. With block indexing, the total number of teeth in the gear must not be a multiple of the number of teeth indexed.

An example of intermittent or block indexing is shown in Fig. 9, which illustrates a roughing operation. A Brown & Sharpe machine is being used and also the improved stocking cutter made by this company. The stepped and plain teeth alternate, the stepped teeth projecting beyond the outline of the plain teeth just enough to break up the chips. This cutter enables comparatively heavy cuts and coarse feeds to be employed, and the intermittent indexing is adopted to prevent errors which might arise from local heating when taking the stocking cuts. This is a cast-iron gear having 124 teeth of 2 diametral pitch, and 6 inches face width. The cutting speed is 90 feet per minute, and the feed 3½ inches per minute. The roughing cuts are taken in six hours. Fig. 10 shows a machine finishing the same gear. The rate of feed for finishing is reduced to 1½ inches per minute.

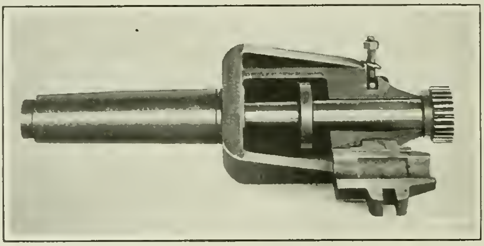

Fig. 17. Special Device for holding a Turret-driving Sleeve when cutting Gear Teeth

Attachment for Cutting Quill Gears

Automatic gear-cutting machines are sometimes equipped with special attachments to adapt them for gear-cutting operations which otherwise could not be performed. One type of attachment is shown in Fig. 11. This attachment, which is for a Brown & Sharpe automatic gear-cutting machine, is clamped on the cutter-slide in place of the regular cutter-spindle bearing. The cutter-spindle of the attachment is elevated enough to permit cutting the teeth of the smaller member of the quill gear. This cutter is driven from the main spindle through a train of steel spur gears. Fig. 11 illustrates the cutting of a gear having 22 teeth of 4 diametral pitch and 2¼ inches face width. The cutter speed for roughing is 100 revolutions per minute, or 78 feet per minute, and the feed 2½ inches per minute. The time required for roughing varies from thirty-eight to forty minutes per gear. On the finishing cut the speed is reduced to 80 revolutions per minute, or 62 feet per minute, and a feed of 2 1/16 inches is used. The time required for the finishing operation on this job is forty-five minutes per gear.

Cutting Spur Gears on Machines of the Multiple Type

Multiple types of gear-cutting machines are sometimes used when the production of duplicate gears is large enough to warrant installing a machine designed for multiple operation. Fig. 12 shows one of the vertical-cutting machines made by Gould & Eberhardt, Newark, N. J., which is arranged for cutting three steel pinions at the same time. In this particular instance, the pinions are roughed out on this machine and afterward finished on a gear-hobbing machine, but this type of machine is used also for finishing certain classes of gears.

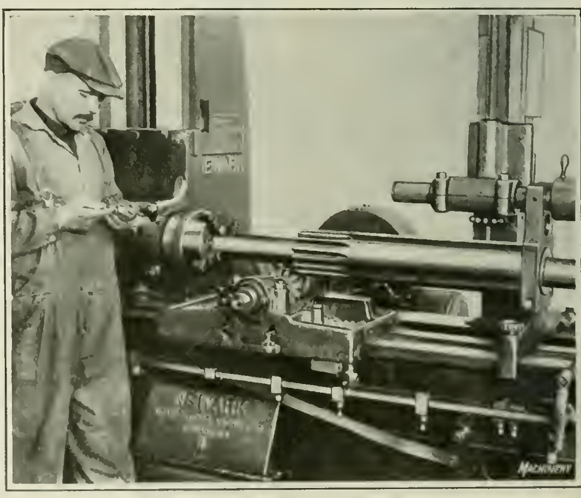

Fig. 18. Cutting a Pinion Integral with a Long Shaft

The pinions are held on a turret which is arranged to hold three on each side. As soon as the pinions on one side are cut, the turret is turned a half revolution, thus locating the uncut blanks opposite the cutters, which are at work while the operator is removing the finished pinions and replacing them with blanks. The support for the upper ends of the work-spindles is in one piece, and is raised for removing the pinions by turning the hand-lever seen in the illustration.

Another multiple gear-cutting operation on a Gould & Eberhardt machine is shown in Fig. 13. This machine is used for cutting three pinions simultaneously. These are double pinions, having twelve and sixteen teeth respectively of 3–4 pitch. Each work-spindle has independent adjustment toward or away from the cutters to compensate for any variations in the cutter diameters. Machines of this kind are intended especially for cutting the coarser variety of spur gears used in trucks and tractors.

Arbors and Fixtures for Holding Gear Blanks

The results obtained with gear-cutting machines may be decidedly affected by the method of holding and supporting gear blanks while cutting the teeth. Many inaccurate gears have been due entirely to poor chucking practice. The aim should be to hold the blanks rigidly but without distortion due to clamping stresses. If there is chattering, the cutter is dulled rapidly, the rate of production lowered, and the quality of the work affected. The size of the blank, its shape, and the shape of any section which may be cast integral with it, largely determine the method of chucking, which should be arranged to permit inserting and removing work readily.

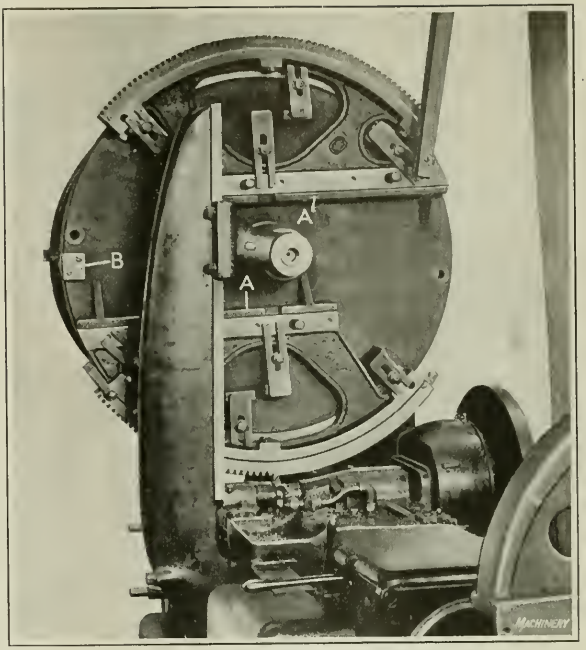

Fig. 19. Cutting Segment Gears which are held on a Special Fixture

The means regularly employed on automatic spur-gear cutting machines include the use of solid arbors, expanding arbors, arbors having stepped flanges or adapters for accommodating bores of different diameters, and special fixtures for large gears or odd shapes. The faceplate of the machine may be put on the spindle and used in conjunction with small jacks or supports placed at different points. The most important support, however, is the rim rest, which is so located as to prevent deflection due to the thrust of the cut, and should always be used if possible. A gear rim should run true to prevent binding against the rim rest, and it is well to apply a little oil to that side of the rim.

Gear Blanks Mounted on Arbors

When cutting small and medium-sized gears it is common practice to cut two or more at the same time by clamping the blanks together in the form of a gang or stack. Fig. 14 shows five gears mounted on an arbor. This arbor has a taper shank which enters the hole in the machine spindle, and the outer end of the arbor is held by the overhanging supporting arm, which is also braced (in this particular instance) by the vertical box column support. The work-holding part of this arbor is straight, and the gears are clamped against the shoulder by a nut at the outer end of the arbor. When gears are held in this way, the rims should be faced true, because inaccuracies will tend to distort the arbor when the clamping nut is tightened. This illustration shows a Newark machine cutting cast-iron gears having 36 teeth of 6 diametral pitch and 1⅛ inch face width. By cutting the gears in gangs of five, a production rate of four minutes per gear is obtained. One cut is taken, and a high-speed steel cutter used. This cutter makes 142 revolutions per minute, and the feed of the carriage is 15 inches per minute.

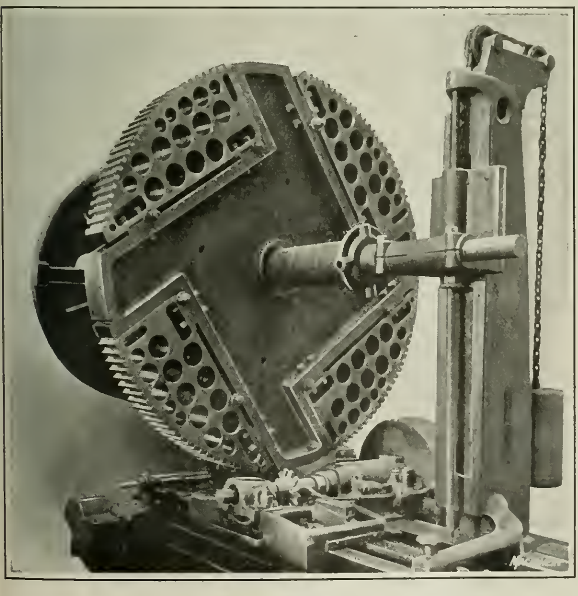

Fig. 20. Another Example of Segment Gear-cutting

Sometimes a gear is mounted on an ordinary lathe arbor, which is supported between centers. The arbor has a dog at one end so that it indexes around with the work-spindle. When cutting larger and heavier classes of gearing, the outer end of the arbor is frequently supported by a bearing instead of using a center. Fig. 15 shows a machine set up in this way. The outward bearing is adjustable along the vertical face of the supporting column, so that it can be set in alignment with the arbor or work-spindle, the height of which varies, of course, for different sizes of gears.

The tractor pinion shown in the Brown & Sharpe machine in Fig. 16, is held between centers, the work being centered at each end. It was necessary in this case to align the teeth relative to a keyway, which is done by engaging the keyway with lever *A* pivoted to a sleeve into which one end of the pinion-shaft extends. Incidentally this stub-tooth pinion has 9 teeth of 7–9 pitch, and a face width of 2¼ inches. It is made of low-carbon steel and one pinion is finished in five minutes, only one cut being taken for each tooth space. The high-speed cutter makes 166 revolutions per minute, or 120 feet per minute, and the feed is 9½ inches per minute.

Fig. 18 shows how a steel spur pinion was cut on a shaft 6 feet long in a Newark machine. On account of the length of this shaft, it would ordinarily have to be cut in a milling machine unless a gear-cutting machine were available with a large enough hole in the work-spindle to take the shaft. In this particular instance, a gear-cutting machine was used by holding one end of the shaft in a chuck screwed on the work-spindle, and the outer end by a bearing attached to the box column support. The feeding movement of the cutter-slide was reversed because the work was too long to feed the cutter forward.

A special holding device used when cutting the teeth on a turret-driving sleeve is shown in Fig. 17. The work is held in place by the hinge cover, which is shown in the open position. This fixture has a taper shank which fits into the spindle of the machine.

Fixtures for Holding Segment Gears

The special fixture shown in Fig. 19 applied to a Brown & Sharpe machine is used for holding two segment gears used in the elevating mechanism of anti-aircraft guns. Great accuracy was required for these parts, and the fixture is designed to hold each of the segments in the same relative position. As the illustration shows, each segment not only fits around the periphery of the fixture or faceplate, but is also located against a projecting ledge or shelf *A* extending along the side of the fixture. The block *B* is used for locating purposes to insure obtaining segment gears which are as near exact duplicates as possible. These segments each have 60 teeth of 4 diametral pitch, and 3 inches face width. Roughing and finishing cuts are taken. The speed for roughing is 57 revolutions per minute or 75 feet per minute, and the feed 1½ inches per minute. The roughing time is seven hours for the two segments. The cutting speed for finishing is the same as for roughing, but the feed is reduced to one inch per minute, and the time is ten hours for finishing the two segments.

Another example of segment gear work is shown in Fig. 20. These segment gears are for the elevating mechanism of 9.2-inch howitzers. As will be seen by referring to the illustration, four segments are mounted on the fixture and are accurately located by bolting them against finished seats. The teeth in this case were cut to a special pitch, and the work was performed at the plant of the Earle Gear & Machine Co. in Philadelphia, Pa.

THE DeLAMATER-ERICSSON MEMORIAL

The DeLamater-Ericsson Tablet Committee announces that it has had a communication from the Association of Swedish Engineers, Stockholm, Sweden, stating that the association will hold a celebration of the sixtieth anniversary of the battle of the *Monitor* and *Merrimac* simultaneously with the celebration which will be held in New York and Washington on March 9, when tablets in commemoration of the work of Ericsson and DeLamater will be unveiled at four different places in New York City, as mentioned in the December number of MACHINERY, page 312.

ANNUAL MEETING OF AMERICAN ENGINEERING COUNCIL

The American Engineering Council, the governing body of the Federated Engineering Societies, at its first annual meeting at Washington, January 5 and 6, made plans for the coming year. Dean Mortimer E. Cooley of the University of Michigan, president of the Federated Societies, presided. Dexter S. Kimball, dean of the College of Engineering, Cornell University, who is also president of the American Society of Mechanical Engineers, was elected one of the vice-presidents of the Federated Societies. Among the questions discussed was the principle of licensing or registering engineers. The secretary's report showed that the membership of the society is now composed of eight national and twenty state and local engineering societies.

The council voted to continue its support of the legislation for the relief of the United States Patent Office as reported in the Lampert bill. A report of the committee described conditions in the Patent Office as alarming. It was brought out by this report that one of the leaders of the House opposed the bill on the ground that it carried salaries higher than those paid for similar service in other departments of the Government. The chairman of the council's patent committee showed that there were many government positions involving legal or scientific knowledge that carried salaries above those requested for the Patent Office examiners, and demonstrated that the Patent Office examining force would be disintegrated if the matter were not soon adjusted.

* * *

SAFETY AND HEALTH WORK IN THE INDUSTRIES

A constructive article on the importance of safe and healthy working conditions in the industries appears in the December number of *The Nation's Health*, written by Otto P. Geier, M.D., of Cincinnati, Ohio, in charge of the health and safety work at the plant of the Cincinnati Milling Machine Co. The article points specifically to the value of hygienic and safe working conditions in producing better workers and better citizens. It is urged that safely guarded modern machinery, education in safety, clean working conditions, adequate ventilation and lighting, reasonable comforts and conveniences, and a fair wage system make for better efficiency, teamwork, and individual responsibility. On the other hand, Dr. Geier points out that unsafe and unclean working conditions, frequent accidents, careless treatment of employes, driving rather than leading, and slipshod wage systems produce constant dissatisfaction and irritability, affecting both the mental and physical state of health of the individual.

A health exposition was recently held in Cincinnati, which showed the work of the industrial physician. The article referred to places the information gathered relating to industrial relations, health and safety work at this health exposition at the disposal of executives in the industries in an interesting and instructive form. Reprints of the article, which should prove of great value to manufacturers in general, may be obtained from the Cincinnati Milling Machine Co., Cincinnati, Ohio, upon request. The article is distinctly constructive in its tendencies, and should prove helpful to many manufacturers who are realizing the importance of constructive work to counteract the pleas of agitators who are endeavoring to produce strife and discontent.

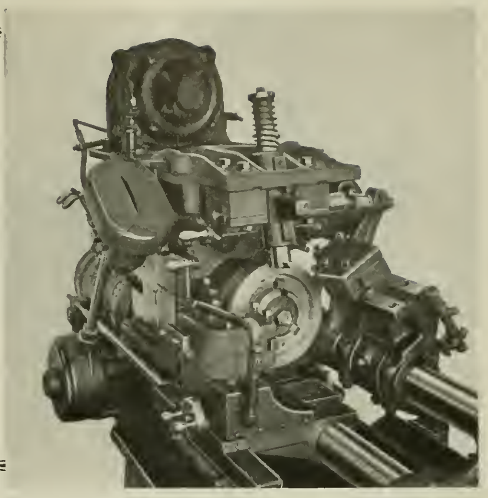
* * *

Building construction in Germany has increased steadily since 1919, according to an item in a Commerce Report. Figures for the first quarter of 1921 show that 5402 buildings were completed during that period, as against 1063 in the same period of 1919. The larger proportion of the buildings constructed were dwellings.

Tooling Equipment for Automobile Gears and Ball Races

Second of Two Articles Dealing with the Production of Automobile Gears

By RALPH E. FLANDERS
Manager, Jones & Lamson Machine Co., Springfield, Vt.



IN the preceding article on the machining of automobile gears, published in January MACHINERY, the operations dealt with were those in which Fay automatic lathes and double-spindle production lathes were employed. In the present article, the examples will include jobs performed on Fay automatic lathes and, in addition, operations on double-spindle flat turret lathes and Hartness automatic lathes.

Operations on a Camshaft Gear

The tooling equipments employed in machining a camshaft gear are shown in Figs. 2 and 3. Although the part is simple in construction, the example will serve to illustrate two or three points of importance. The first operation is performed on a double-spindle flat turret lathe provided with the tooling equipment shown in Fig. 2. The drilling and rough-boring are done in the first position. The rough- and finish-facing steps performed by tools in the second and third positions are effected by the use of the cross-sliding head. In the rough-facing step, the head feeds away from the operator, while in the finish-facing step it is returned. By this arrangement, there are no idle movements of the cross-sliding head. This is a principle of universal application to work of this kind, and it should always be observed.

The reamer shown in the fourth position carries a back-facing tool through its center. The inner side of the hub is faced with this tool for a short distance before the reamer reaches the work. The production on this operation is from thirty-four to thirty-six pieces per hour. The reason for back-facing the hub will be apparent by reference to Fig. 3, which shows the tool set-up used in completing the part in a Fay automatic lathe. The back-facing tool cuts slightly below the finished thickness of the hub and so provides a seat for the clamping nut of the arbor. On parts to be machined in this way, it would be well for a designer to specify back-facing on the drawing, but when this is not done, arrangements can usually be made for taking this cut.

Prior to the operation on the Fay automatic, the small holes around the hub center are drilled. These are utilized in the operation on the automatic lathe, dowel-pins being provided in the arbor which fit into the small holes for driving the part. On work of this kind, broaching, drilling, or keyseating should be done before turning, in order that adequate driving means may be obtained. There are two machines provided with the tooling shown in Fig. 3, and these are run by the same operator. One machine roughs the work and the other finishes it. The output is thirty complete parts per hour.

The writer is inclined to criticize this set-up on the score of having too short an arbor. While the shortness adds to the stiffness, it tends to displace the rim more for a given inaccuracy of centers or of the arbor. In general, the all-over length of an arbor ought to be at least twice the diameter of the work. The small size of the center hole, of course, makes it impossible to put two or more pieces on the arbor at a time. Camshaft gears are the most difficult to get running quietly of any of the gears used in automobile construction, and so every precaution should be taken to procure smooth running. The finishing of gears on a true arbor is a long step toward this end.

The bend in the arrow at the side of the rear tool-holder indicates the feeding movements required for this tool to prevent the hub facing tool from coming in contact with the rim of the work.

Equipments for Machining a Cluster Gear

Another characteristic gear in automobile drives is the cluster gear commonly used on the transmission jackshaft in place of a set of separate gears employed in older practice. Improved methods of forging, machining, and gear-cutting have made possible this greatly simplified construction. In the process here dealt with, the forging first has the central hole rough-drilled in a heavy-duty drilling machine and then comes to a double-spindle flat turret lathe provided with the tooling shown in Fig. 1. On this machine the hole is rough-bored and the part is rough-faced at the large end by scale-breaking tools, as shown at Position 1. A straight longitudinal feed, under a heavy cutting power, is used for this operation. The tools in the second position finish-face the end, the total cut being divided between two tools on each piece in order to shorten the operation. One tool works from the periphery of the part toward the center, and the other cuts from the center toward the outside. The tools in the third position finish-bore and chamfer the hole, and the reamer shown in the fourth position takes the final cut in the hole.

The blank has two holes drilled in the faced end for driving purposes, in a later operation, and is then mounted on a vertical arbor on a drilling machine and has the small end butt-faced. The work is now ready for the outside turning, and this is done in a Fay automatic lathe furnished with the tooling shown in Fig. 6. The arbor construction provides two driving pins to engage the holes drilled in the face of the gear blank, as previously explained. The hole of this gear does not have a keyway, and so this special means must be taken to furnish a drive which will stand the heavy torque imposed by the large number of tools used. The front tool-holder rocks in rapidly and then feeds toward the left, tool *A* turning the neck and the other tools the outside diameters. The rear tool-holder rocks in and faces and forms the various surfaces as shown. Another operation very similar to this is illustrated in Fig. 4. Two machines are used, one for roughing and the other for finishing. The production with rough forged blanks is from twelve to fifteen pieces per hour. This requires up to 15 horsepower for driving the machine.

Production of Rear-axle Drive Bevel Pinion

The machining of a separate type of rear-axle drive bevel pinion is an interesting job on account of the high production possible. The blanks are forgings and have the taper holes machined and the rear hub butt-faced in a double-spindle turret lathe furnished with the tooling shown in Fig. 8. The output of this operation is from eighty-five to ninety pieces per hour, and it should be possible to increase this somewhat with the development of a production lathe having three tool positions on a cross-slide. The blanks go next to a drilling machine to be butt-faced at the small end in the same manner as described in connection with transmission gears in the article "Cost-reducing Tooling Equipment," in January MACHINERY.

The turning operation is performed on a special double-carriage Fay automatic lathe having the tooling illustrated in Fig. 7, the two front tool-holders feeding independently in the direction indicated by the arrows. The rear tool-holders form the back of the work to the angle shown. In one automobile shop where only one cut is taken over the gears, an output of 1100 pieces in eight hours has been obtained. One machine keeps an operator busy at this rate, and he requires a helper for loading the arbors. Ordinarily, of course, two machines would be used, one for roughing and the other for finishing the work. A machine set up for a similar gear is shown in Fig. 5.

Machining a Ring Bevel Gear

The first operation on a ring bevel gear is performed on a Hartness automatic, a machine which was designed especially to embody the principle of intensive tooling. Fig. 9 shows a gear of a conventional design being produced on this machine. The operation consists of rough- and finish-facing the back and the recessed seat, and back-facing the inside of the flange. All this is done by tools in the lower holder which swings to one side for the roughing cuts and to the other side for the finishing cuts. The upper tool-holder carries cutters for rough- and finish-boring, necking, and chamfering. The hole is rough- and finish-bored by one

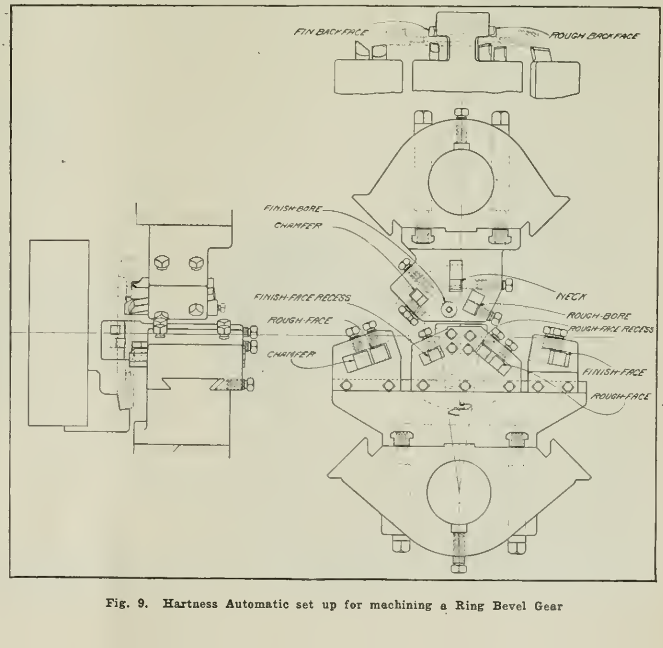

Fig. 9. Hartness Automatic set up for machining a Ring Bevel Gear

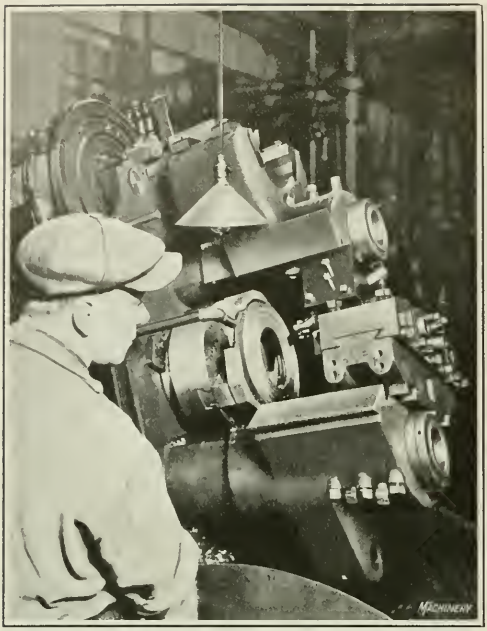

Fig. 10. Hartness Automatic provided with the Tooling for machining a Ring Bevel Gear, shown in Fig. 9

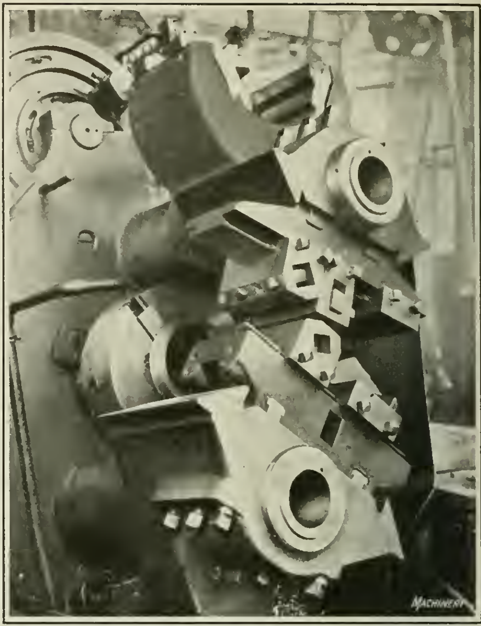

Fig. 11. Close-up View of the Equipment used in machining a Ball Bearing Race, shown in Fig. 13

feeding movement, the finishing tool following the roughing one. An accuracy of 0.001 inch can be constantly maintained in this operation. The output varies from twelve to twenty pieces per hour, depending on the size of the gear and the material from which it is made. The higher figure is obtained with a 10-inch drop-forged gear of mild steel, which is annealed, and intended to be carburized and heat-treated.

This set-up, which is also shown in Fig. 10, is an excellent example of concentrated tooling with idle movements eliminated. An operator is kept busy attending two of these machines on ordinary work. The blank next has holes drilled in the web and is then ready for an operation performed in a Fay automatic lathe provided with the equipment shown in Fig. 12 and in the heading illustration. Referring first to Fig. 12, it will be noted that the work is held in place against a hardened seat by a quick air-operated fixture, and is driven by dowels engaging the holes drilled in the web. The tools in the front holder rough- and finish-turn the outside diameter and finish-face the surface which will later be the inner end of the teeth. The tools in the rear holder rough the bevel face of the gear and round its back corner.

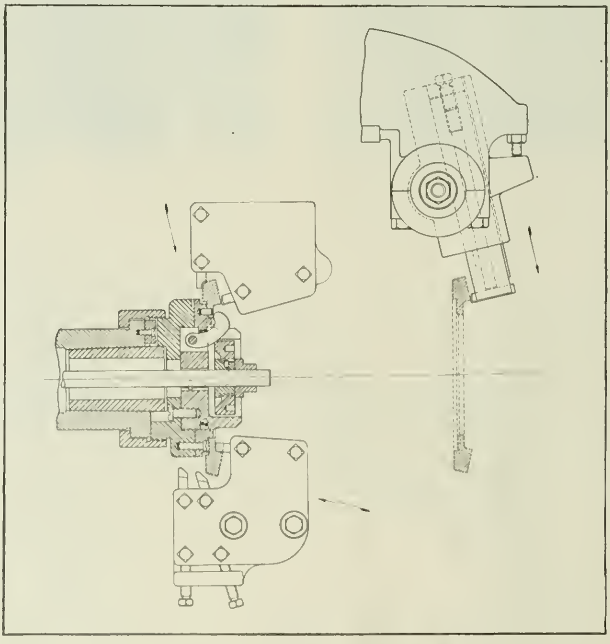

Fig. 12. Example in which the Work is held on an Air-operated Fixture and driven by Dowels engaging Holes in the Web

As plainly shown in the heading illustration, a tool is carried in an overhead slide provided for finishing the face of the gear. Since this slide is mounted independently of the arm on which the rear tool-holder is located and has a separate connection to the cam-drum, it is possible for the face finishing tool to follow right behind the roughing cut on this surface without its accuracy being affected by the heavy strains of the roughing cut. This arrangement, therefore, permits all cuts to be taken simultaneously, and in practically the time needed for the longest cut, which is that of rough-facing the bevel surface. The output per machine is from twelve to twenty gears per hour, depending upon the size and material. One operator can usually run two machines.

Tooling for Finishing Ball Bearing Races

The machining of an outside race for a large ball bearing is accomplished in Hartness automatics by the use of the tooling equipments shown in Figs. 11, 13, and 14. The blank is a forged ring made of a special steel alloy and is somewhat difficult to machine. In the first operation, the forging is held from the inside by the swivel jaws of a three-jaw chuck, as shown in Fig. 13. This gives six points of clamping in all, and makes it possible to tighten the jaws sufficiently for taking heavy cuts without distorting the work. From the tooling arrangement it will be seen that the part is bored half way through on this machine. The reason for this is that it requires no extra time, as it is done while the outside of the part is being turned, and it materially shortens the time necessary for the succeeding operation. A close-up view of this set-up is shown in Fig. 11. When the upper holder is fed in, it bores the hole and rough-turns the outside. It then swings to the left and finish-turns the outside while being fed back. The lower holder swings to the left and faces the part on one end, chamfers the hole, and rounds the outside corner. This completes the first series of operations on the part.

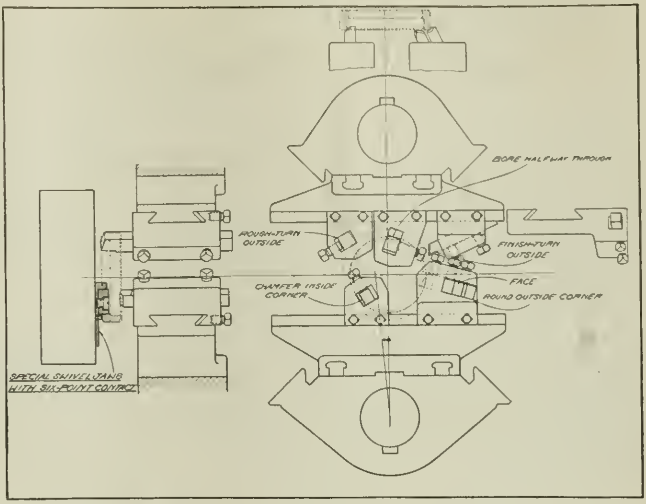

Fig. 13. Diagrammatic Illustration of the Tooling on the Machine shown in Fig. 11

Tooling for Second Series of Operations on Ball Bearing Races

Fig. 14 shows the tooling for the second series of operations. The work is held in accurately bored soft jaws which grip it on the finished outside. The lower tool-holder carries a facing tool only. The upper holder first feeds directly in and completes the boring of the unfinished half of the hole. It then swings toward the left and rough-grooves and finish-grooves the part, and chamfers and rounds the corners. The finish-grooving tool is mounted a greater radial distance from the center about which the holder oscillates than the rough-grooving tool, their relative positions being such that for a given angular swing of the holder, the finishing tool travels faster than the roughing tool and thus tends to overtake the latter. By this means, the roughing and finishing cuts are taken in one continuous movement by two separate tools mounted in the same holder.

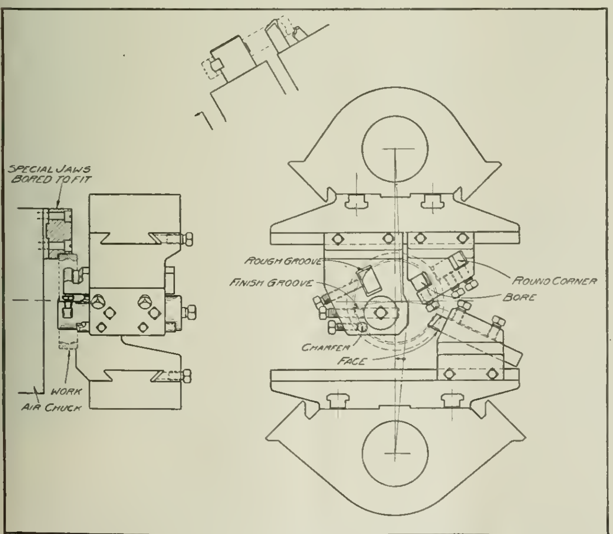

Fig. 14. Tooling employed in the Second Operation on the Ball Race which is also performed on a Hartness Automatic

MEETING OF AUTOMOTIVE ENGINEERS

At the annual meeting of the Society of Automotive Engineers held in the Engineering Societies' Bldg., 29 W. 39th St., New York City, January 10 to 13, a great many interesting papers were read. Those of especial interest to MACHINERY's readers were "Chrome-Molybdenum-Steel Application from the Consumer's Viewpoint," by C. N. Dawe; "Continuous Die Rolling," by G. R. Norton; "Drop-forging Practice," by J. H. Nelson; and "Pertinent Facts Concerning Malleable-iron Castings," by Enrique Touceda. These papers were all read at the Materials Session.

A Standards Committee meeting was held in connection with the annual meeting, at which sixteen divisions of the Standards Committee presented reports, including the committees on ball and roller bearings, chain, iron and steel, non-ferrous metals, parts and fittings, and screw threads. Other sessions of the meeting were devoted to airplane engines, body engineering, motor truck transportation, lubrication, research, fuel and engines, with a special session on passenger cars. The papers that were read before the meeting are published in the Journal of the Society of Automotive Engineers.

* * *

NEW CLASSIFICATIONS FOR EXPORT STATISTICS

Beginning January 1, the Department of Commerce will employ new classifications for its export statistics. The new classifications go into considerably greater detail as to the classes and types of machinery exported. In the metal-working machinery field, for example, the classifications will cover specifically lathes; boring and drilling machines; planers, shapers and slotters; bending and power presses; gear-cutting machines; milling machines; sawing machines; thread-cutting and screw machines; punching and shearing machines; power hammers; rolling machines; wire-drawing machines; polishing and burnishing machines; sharpening and grinding machines; foundry and molding machinery; and other metal-working machinery. In addition, there will be a sub-division for chucks; another for reamers, cutters, and drills; and one for pneumatic portable tools.

Aggressive Machine Tool Salesmen

By a Machine Tool Sales Manager

THE traveling of the machine tool salesman from shop to shop, calling upon his customers and those whom he hopes to make his customers, is the aggressive part of machine tool salesmanship—the very life of the business. The aggressive salesman realizes that the shop man buys a machine tool, not when the actual order is written out, but when he has been convinced of the desirability of acquiring a machine that he needs. Too many machine tool salesmen sit back comfortably with the thought that when their customers—their personal friends—are ready to buy, they will let them know. Such salesmen not only neglect their own personal interest, but they also fail to avail themselves of their opportunity to benefit both their customers and the manufacturers whose tools they are distributing.

A System of Successful Salesmanship

The system used by a successful machine tool salesman is an example of efficient salesmanship. This man keeps a memorandum book in which he divides his prospects into three classes: (1) Those ready for closing; (2) those active and interested; and (3) those worth cultivating. In the first list he keeps the names of all those for whom he has orders pending and who are ready for closing the sale. They receive his first attention. Every day he looks over this list, and asks himself if there is anything that he can do that day toward getting the final order; if so, he does it. He passes up other probable orders, if necessary, in order to devote himself to the actual possibilities of the day.

After the names in the first class have been attended to, he takes up the second list—the active prospects. These are concerns that he feels it will pay him to cultivate intensively, because there are machines that they should buy, because their industry is enjoying sufficient prosperity to make expansion likely, or because there is a probability of a change in the product, requiring new equipment. His efforts are devoted to bringing this second class of prospects into the first class of probabilities. If time permits, he takes up those on the third list, making a friendly call upon those that are merely prospects worth cultivating, with the aim of transferring them to his second list.

This salesman claims that his system produces very satisfactory results, and enables him to accomplish more each day than he would otherwise find time to do.

How Machine Tool Salesmen are Received

The writer of this article at one time occupied a position in which it was his duty to receive machine tool salesmen. It was the policy of the firm to receive everybody, and to answer every letter that called for an answer. Sometimes this policy becomes irksome to the man who has to receive all visitors with something to sell, and it is not carried out to the letter of the law.

The reception of a machine tool salesman depends largely upon the general condition of business. When a firm is quietly studying new methods or contemplating a change in design, the machine tool salesman is most welcome; but most of the tools bought when business is less pressing are selected because of the "missionary" calls made by salesmen at a previous time.

It is commonly stated by machine tool salesmen that when a concern issues a list, the tools are already selected, and in the experience of the writer, this is true. It may not always be true, but unless the sending out of the list develops some unexpected information, the tools in mind when the lists are circulated are generally the tools purchased. When the lists specify a 16-inch lathe of a given make, "or equal to it," it is almost certain that the prospective buyer believes that the machine made by the firm whose name he has quoted has no equal for his particular work.

Visiting New Prospects

It is the visits of the machine tool salesmen in apparently quiet times that actually build business for them. It is the "fill in" calls that start the ball rolling, and those calls require the greatest experience and diplomacy to prevent them from becoming irksome to the prospective purchaser because of their aimlessness. They are calls without an apparent reason. The salesman makes the prospective customer feel that he wants at least an inquiry, if not an order, at a time when there is no reason for either. There is no particular point to the talk. The customer is asked how his health is, how business is, and if he won't remember them when he is in the market for something.

Now, in justice to the machine tool salesman, it must be admitted that the hardest problem, when there are no immediate prospects of sales, is to find something to talk about. He sometimes will hesitate to call upon a prospect because he is unable to find the right subject to bring up, knowing that there is no immediate business. Nevertheless he should see the prospect. The average machine tool salesman makes a mistake in dealing with too many subjects at one time. It would be much better for him to stick to one theme in striving to make an impression on a prospect, considering the subject from different angles. The salesman can talk about his prospect's product. He can ask how this or that operation is performed in the customer's shop. In this way he gains much information, and he may be able to make suggestions that would prove of value. There are times when the customer does not feel like talking. It then becomes the salesman's job to arouse his interest.

Subjects of Interest to the Customer

There are many things that a salesman may speak of to interest his prospect, but he should avoid discussing all of them at one time. He makes a great many calls and can choose one subject for each call. The salesman can talk about his firm. He can explain the policy of the manufacturer he represents and the things that his firm is able and willing to do in an effort to help the customer. It is as important to impress upon the customer that the manufacturer's policy is a liberal one as that the machinery itself is of the right quality; but in order that such talk may be of value, it must be sincere and based upon the earnest convictions of the salesman. A testimonial letter from a reputable firm is a worthy means of creating a lasting impression. Automobile salesmen use such means effectively; why should not machine tool salesmen use them also? There is nothing that a customer likes to know more than that the machine he plans to buy has given satisfaction elsewhere. A point that salesmen should remember is that when they hand a prospective customer a testimonial letter to read, they should keep quiet while the prospect reads it.

Interesting incidents are often effective as a basis for an impressive interview. Back of the design or the evolution of most machine tools there is a story of how and for what reason they were designed. There is a personal interest in such incidents. Not only does one remember the tools because of the story, but one usually remembers who told the story. Hence, a double purpose is gained; the machine will be remembered and the salesman as well.

Actual increases in production effected in other plants with the machines offered for sale are always of interest, but the salesman should be careful to be accurate in all such statements and to avoid exaggerations. Reasons for the increase should be given, which leads to an explanation of the merits of the machine and special features of its design.

Briefly, a machine tool salesman, in order to make his calls worth while, must be able to use the prospective customer's time to some good purpose, and that can only be done by a thorough knowledge of the goods that he has to sell and a systematic distribution of that knowledge.

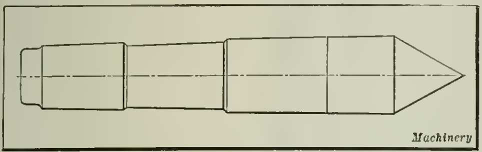
SHOULD CENTERS BE RELIEVED?

In the manufacture of "Red E" high-speed centers we are looking for improvements that will meet the needs of our customers. We have had under consideration for some time a change in design in which the centers would be relieved



Relieved High-speed Lathe Center

somewhat along the lines shown, slightly exaggerated, in the accompanying illustration. The method may have both advantages and disadvantages, and it would be of great interest to hear from the readers of MACHINERY as to their opinions of relieved centers.

THOMAS FISH
Bridgeport, Conn. President, The Ready Tool Co.

WAGES IN GERMAN MACHINE INDUSTRIES

The table below shows a comparison of hourly wages paid in the machine-building industry in Chemnitz, Germany, previous to the war and since January 1, 1922. In the present agreement on wages of workers in the metal industries, a basic hourly rate is fixed, and the worker receives a certain additional rate on account of the high cost of living. In the table these two items are added together. Furthermore, skilled workmen who are always employed at an hourly rate (not on piece-work) receive an additional amount which has also been included in the figures given. In figuring present exchange, 1 mark has been assumed to be equal to 0.6 cent.

Class of Worker	Age	1922		1914	
		Marks	Dollars, Present Exchange	Marks	Dollars, 1914 Exchange
Toolmakers, Patternmakers, Molders, Highly Skilled Operators	over 25	11.20	0.07	0.60	0.15
	21-25	9.85	0.06	0.60	0.15
	19-21	8.50	0.05	0.60	0.15
	17-19	6.29	0.04	0.60	0.15

Machinery

HAS THERE BEEN A DECLINE IN FOREIGN TRADE?

No figures are needed to show that there has been a decided decline in the foreign trade of machine tools and metal-working machinery during 1921, and it is generally believed that there has also been a decline in the foreign trade of the United States as a whole, which is thought by many to be one of the causes of the present industrial depression. The Federal Reserve Bank of Boston calls attention to the fact that for several months statements have appeared in the newspapers showing that the exports of the United States were several hundred million dollars less a month than during the corresponding month a year ago, a decline amounting to as much as 50 per cent or more. In order to ascertain whether our foreign trade actually is declining, when considered from the standpoint of volume rather than of value, an investigation was made which shows that the total volume of our exports is now actually higher than it was during the first months of 1920, although its value in dollars is considerably less. Therefore, instead of our exports actually falling off, they are really increasing, and furthermore the exports measured by physical volume have been materially higher in 1919, 1920, and 1921 than they were in 1913.

There are two factors which tend to confuse the foreign trade situation. The first is that there is a tremendous tonnage of shipping idle at the present time in our harbors. The other is that foreign exchange operates against most countries and in favor of the United States. As for the idle ships, notwithstanding the great amount of tonnage involved, the Government reports that the tonnage of vessels engaged in foreign commerce entering and leaving our ports at the present time is considerably more than a quarter greater than the average during the pre-war years of 1911 to 1913. This corresponds closely with the increase in the physical volume of both exports and imports as described in the foregoing. The reason for so many idle ships is thus seen to be not a decline in the amount of shipping actually engaged in commerce, but the fact that new tonnage came into existence during the war faster than it was destroyed; furthermore, there has been considerable construction since the armistice. There is, in fact, a greater tonnage of merchant shipping afloat today than ever before.

Increase in Volume of Exports

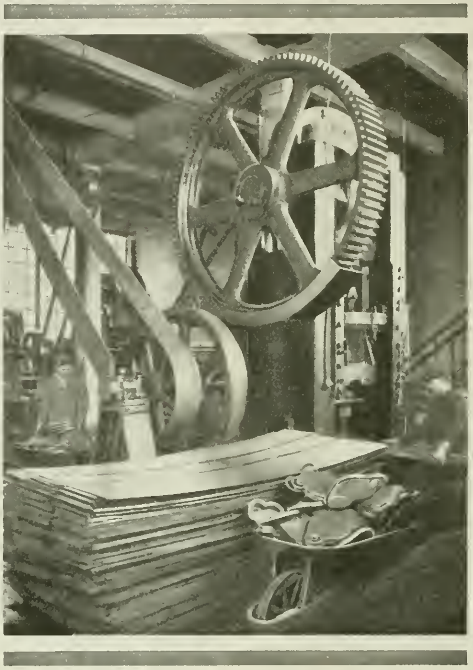
The physical volume of our exports to Germany during the year ended June 30, 1921, aggregated 66.8 per cent (two-thirds) of their pre-war total, and the tendency during the last few months has been for it to increase. An analysis of the volume of exports of specific commodities shows that Germany took 40 per cent as much cotton, 50 per cent as much copper and considerably more foodstuffs during the fiscal year of 1921 than in the corresponding year of 1913.

The United States' trade with Soviet Russia is much greater at the present time than is generally realized. The United States Department of Commerce has issued a statement based on official Soviet papers which shows that the United States supplies 16 per cent of Soviet Russia's imports, only Great Britain and Germany furnishing a larger proportion. Shoes, especially men's, represented more than half of the goods we shipped, the bulk of the remainder consisting of leather, white flour, binder twine, and agricultural machinery.

Our foreign trade situation is not discouraging when viewed broadly. Certain aspects of it, such as the decline in the exports of finished goods, have undoubtedly aggravated the depression in the manufacturing industries. The productive capacity of the latter was expanded more rapidly during the war than the normal growth of this country warranted. On the other hand, the increase in the exports of raw materials has had a tendency to relieve the stress somewhat in other fields.

Utility of Single-action Straight-sided Presses

By N. T. THURSTON, The Acklin Stamping Co., Toledo, Ohio



THE simplest and probably the oldest form of power press is the single-action straight-sided type which, because of its simplicity and general usefulness, is widely employed. This press is made in a greater number of sizes than any other one type. The heights range from 51 inches to around 18 feet, while the weights vary from 1400 pounds to 150 tons. The smaller sizes are of the single-crank type, and are driven directly from the flywheel. The intermediate sizes are also of the single-crank type, but are geared. Such a press is shown in the illustrations. The largest presses have two cranks and are double-geared.

Double-crank presses are used in work requiring considerable pressure, but this is not the only reason for employing the double-crank construction. The need of a large die space is often a more important factor than the power which these presses are able to exert. For example, in forming automobile fenders, hoods, bodies, and pans, a press of great strength is unnecessary, but a space large enough to accommodate the dies for forming these parts is an essential requirement. The space necessary for the die used in forming the engine pan of a popular automobile is 42 by 42 inches. A double-crank single-geared press is used for this work, but the press is required to use only one-fifth of its normal working power.

Construction of the Press Frame

The frame of heavy-duty presses is subjected to considerable strain, and this is compensated for by various constructions. In one design the frame sides are cast comparatively light and hollow, and are held to the bed by long tie-rods that extend to the top of the frame. These rods are threaded at both ends, and are provided with nuts that are screwed up while the rods are red hot at several points along their length. The shrinking of the rods, in cooling, puts the frame under a compressive stress greater than any opposing strain to which the press is subjected while in operation, and so keeps the frame rigid.

The heading illustration shows a press of the tie-rod construction being used in the production of gear covers. The blank is cut and the cover formed in one operation. The press is kept running continuously, and every stroke is effective except those lost while a fresh piece of stock is being put in place. The production on work of this kind is limited mainly by the speed of the press, and in the case illustrated is about 230 pieces per hour.

Classes of Work Done on Single-action Straight-sided Presses

Single-action straight-sided presses can be employed for blanking, piercing, wiring, flanging, lettering, embossing, forming, and drawing operations. Many of the difficult forming and drawing operations usually accomplished on double-action presses can be done on the single-action type if a series of proper reductions is made on the part by the use of dies having the proper radii, and when single-action presses are equipped with rubber or spring pressure attachments, they can perform the same sort of drawing work that is done on toggle or double-action presses. Also, when single-action presses are provided with some kind of air pressure attachments, drawing operations on stock which varies in thickness can be performed more successfully than on toggle presses.

This is true because the air attachment gives a constant and uniform pressure on the blank-holder regardless of the variation in the thickness of the metal being drawn, while a blank-holder actuated by means of toggles always assumes the same position on the downward stroke of the press ram and so variations in the thickness of the stock are not compensated for. The result is a pressure on the stock that is either too light or too heavy. An excellent example of the satisfactory manner in which work can be produced on single-action presses equipped with air pressure attachments is the United States Army steel helmet referred to in "Pneumatic Cushions in Metal-drawing Operations," which appeared in April, 1920, MACHINERY. Parts typical of the work handled by single-action straight-sided presses are gear covers, automobile engine pans, fan blades, muffler cones, and universal joint housings.

Feeding the Stock

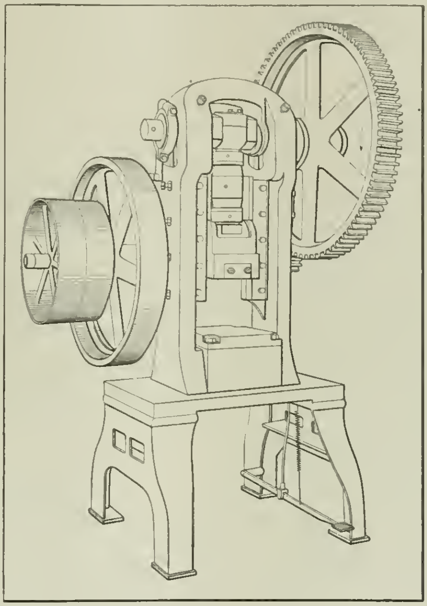
The front-to-back opening in straight-sided presses permits long strips or rolls of stock to be fed through the die. While this method of feeding has advantages, it is not as convenient as the cross-feed possible with inclinable presses. With the latter method the operator can remain seated directly in front of the press, while with the front-to-back feeding method the operator must sit or stand at one side of the press center, as will be seen by again referring to the heading illustration. The ideal job for a single-action straight-sided press is work which can be performed with a die that allows the stamping to fall through the die and bolster and into a pan beneath the machine.

Push-through operations enable the greatest production on this type of press, and a good operator protected by safety devices can keep the press running continuously on such work. On the large presses, which are double-geared and therefore slow-running, there is enough time to remove the work from the die and insert a fresh piece while the press is in motion. This is the procedure with the machine shown in the heading illustration, and it is not as risky as it may seem, because the large presses are equipped with friction clutches which enable the operator to stop the ram at any point along its stroke. Thus if a part is placed crosswise or in any other incorrect position on the die, the press can be stopped before the punch reaches the work.

* * *

PRODUCTION OF LIQUID AIR

The production of liquid air by the Hampson process in the plant installed at the Bureau of Standards is described in Technical News Bulletin No. 55 of the bureau. A four-stage steam-driven compressor delivers air at room temperature and under a pressure of approximately 3000 pounds per square inch; this air then passes through an oil and water trap and a purifying train containing reagents that remove the carbon dioxide and water vapor. The air thus compressed and purified is then delivered to the liquefier, and after it has passed through a coil of copper tubing, it is allowed to expand freely to approximately atmospheric pressure. When this drop in pressure takes place, there is a corresponding drop in the temperature of the air. The expanded air before leaving the liquefier circulates around the copper coil that contains the compressed air, thus cooling it, so that in continuous operation a cycle of progressive cooling is maintained until the temperature ultimately reaches the liquefying point. The liquefier is constructed so that the air that is condensed is delivered into a receiving vessel. The gaseous air exhausted from the liquefier is returned to the intake of the compressor for succeeding cycles because it has been purified, and when used repeatedly will be found to be much less exhausting on the purifying reagents that are employed to remove the carbon dioxide and water vapor.



Single-action Straight-sided Press with Geared Drive

STANDARDIZATION OF SUPPLIES FOR WAR DEPARTMENT

The supply branches of the Army have been directed by the Secretary of War to utilize, in connection with their specifications, the standards that have been or may be adopted by the American Engineering Standards Committee. This is part of the general policy of the War Department to coordinate its whole supply system with the best commercial practice, and to support a national program of engineering and industrial standardization, which represents the difference between being able to get the needed quantities of uniform articles of tested usability, and of being restricted by many varieties, the usable quantities of which are always insufficient. The importance of standardization of war supplies cannot be exaggerated. In times of war the united effort of an entire nation and the combined employment of all its principal industries are necessary. It is possible to harmonize the use of thousands of articles to a common end only by the adoption of a far-reaching and effective program of standardization. Both the business and military interests of the War Department can be greatly assisted by adopting the policy of standardizing supplies.

BIOGRAPHY OF GEORGE WESTINGHOUSE

The life of George Westinghouse is an inspiring record of achievement, and those interested in following the careers of outstanding men in the engineering profession will welcome the new biography of this remarkable man which has been brought out by the American Society of Mechanical Engineers. This book is one of a series of biographies of the great men in mechanical engineering, and is published by Charles Scribner's Sons of New York (price $2.50). It should be an inspiration for those in the engineering field and for business men outside of this field to read the fascinating record written by Henry G. Prout of the part the engineer plays in modern civilization as disclosed in the life of George Westinghouse.

The story is of the rise of a man from a modest early environment to the leadership of many great industrial enterprises, and a position of acknowledged pre-eminence among the engineers of the world. The activities of George Westinghouse were many and varied. He dealt with organization, financial, and executive affairs, commercial affairs and the engineering details of half a dozen companies in two hemispheres. His inventions, particularly that of the air brake, and his development of the use of the alternating current, have had an important influence on civilization. The first chapter of the book contains a brief review of his life, and each of the succeeding chapters is devoted to a distinct phase of his activities.

The book is written in a readable style, and even those outside of the engineering profession will undoubtedly be interested in reading the story of the invention of the air brake and the friction draft gear and their effect in advancing the art of transportation. George Westinghouse's electrical activities, his contributions to the development of signalling and interlocking systems, and his work in extending the use of natural gas, all form part of the interesting narrative. The last chapters of the book treating of his personality and relations to men show that he was as unusual in character and charm as he was in mechanical attainments.

ASSOCIATED TECHNICAL SOCIETIES OF DETROIT

The engineers, architects, chemists, and other technical men of Detroit have realized for some time the need of one central association to represent their combined interests, and as a result an organization has been formed, known as the Associated Technical Societies of Detroit, which includes twelve societies in the fields mentioned. The association will take an active interest in all matters relating to engineering, architectural, and technical subjects, will assist in furnishing definite and accurate information to the public, and will render assistance and advice to city and state officials when required. A temporary council was organized last June, and on December 13 a permanent council met and elected the following officers for 1922: Chairman, P. W. Keating; vice-chairman, A. A. Meyer; and secretary-treasurer, Walter R. Meier.

MACHINE TOOL PRICES

In December MACHINERY a careful analysis was given of various factors in the cost of machine tools for the purpose of showing why a return to 1914 prices, or even an approximation thereto, apparently expected by some purchasing agents, is impracticable under present conditions. One or two cost items which have been considerably reduced are frequently used as a basis for requiring a reduction of the selling price; but the aggregate cost has not been reduced in a like proportion.

Machinists' wages at present are very nearly double the rates in 1914. Skilled foundry workers who were paid $3.50 a day in 1914 in one of the large machine tool centers are now, after a reduction in wages of 20 per cent, paid $7 a day. Although pig iron has been reduced to within 25 or 30 per cent of the 1914 price at the blast furnace, it still costs about 50 per cent more than in 1914 in the machine tool centers, owing to increased freight rates. Bituminous coal has been reduced in price, but when a carload of coal costing $70 at the mine becomes worth $178 delivered on the siding in Cincinnati, the manufacturer finds that it costs him about 100 per cent more than in 1914. Crating lumber, of which large quantities are used by machine tool builders, cost $17.50 a thousand feet in 1915, and now costs $30, which is probably the bottom price for some years, as lumber already has been materially reduced from the peak price and the supply is decreasing.

The general result of complaints about high prices affects public opinion in the machinery industry unfavorably and often works an injustice to manufacturers, when the facts mentioned are not taken into account. Those who expect to buy machine tools as cheaply as before the war and are deferring necessary purchases until prices approach the pre-war level will wait a long time before buying new machinery, and in the meantime will lose the saving represented by the use of new and efficient machine shop equipment.

* * *

A NEW MACHINE TOOL MARKET

The increasing use of machinery and mechanical appliances everywhere, upon the farms as well as in industrial centers, is opening up an entirely new field for men who have the training, a small capital, and the inclination to go into the repair shop business. The old blacksmith shop is gradually passing out of existence, but its place is being taken by small modern repair shops, equipped with good machine tools, and there will soon be work for such shops all over the country.

These shops are required to keep in repair automobiles, tractors, agricultural machinery and other mechanical devices in general use. To function efficiently they should be equipped with at least lathes, drilling machines, shapers and cylinder grinding machines; and as these repair shops grow in size and importance, some of them will add other tools.

The machine tools required for this class of shop differ from those needed in a manufacturing plant. Production is of secondary importance, but the machines must be comparatively inexpensive, easily adapted to a wide variety of work and of quite large range, even though not powerful. Here is a field that has not yet been fully covered by machine tool builders—a market which will gradually expand.

NOW IS THE TIME FOR REPAIRS

Many manufacturers see that now is the best time for thoroughly overhauling their shop equipment and eliminating obsolete and worn out tools and equipment. Old machines are being sold either for junk or to the second-hand dealers, and although some manufacturers may not yet be financially able to replace them, it is evident that new equipment must soon be installed to keep pace with competition. The amount of old machinery that has been scrapped indicates that buying will be active when business revives, because there are many empty spaces in factories left for the installation of new machine tools of higher productive capacity.

In addition to the elimination of old machinery in many plants, the entire equipment is being overhauled and "remade." This is especially true of the machine tool building plants; but judging by the orders for repair parts received by machine tool builders, this overhauling is being carried on in many other shops throughout the country. The forward-looking manufacturer knows that the depression is nearing its end and shows his wisdom by using the present time to re-condition his equipment. Not only will his money go further now than when normalcy returns, but deliveries are prompt, the labor costs less and the productive work of the factory is not interfered with.

Manufacturers who defer this work until good business is actually upon them will lose time, money and opportunity.

* * *

EVER-INCREASING FIELD FOR MACHINE TOOLS

The universal use of machinery in the industries at the present time apparently does not leave much opportunity for designing improved machinery to replace hand labor—at least not in the metal-working field. Yet six machines were installed recently in a large plant in one of our greatest industrial cities that, although operated by but two men, replaced seventeen skilled mechanics. The cost of the entire machine equipment was $3600, and it is not difficult to calculate how long it will take to pay for these machines simply by the saving in the wages of fifteen skilled men. The machines are fed by magazine attachments and turn out a more uniform product than has been possible by hand.

There is a lesson to be learned from the result of this installation. The machines in this case cost $600 each, but if they had cost $1000 or $2000 it still would have been economical to buy them to replace such a large number of skilled men drawing high wages. In other words, they were not worth buying only because they were low priced; but because of their productive capacity.

At the present time, when so many men are out of employment, it may seem heartless to replace skilled labor by machinery, but the reduced selling price of the product in question, which is fixed by competition and yielded no profit by the old method, would have made it necessary for several of the plants to close down had not a cheaper production method been devised. Ultimately, no one would have gained by continuing the hand labor at a loss.

The results of this installation show that great opportunities still wait for saving in production costs by the use of improved machinery, and that we are still far from the limit of productive capacity.

The Machine Tool Market in Asia

By C. F. MEYER, Landis Machine Co., Waynesboro, Pa.

The author of this article has recently completed a trip around the world for the purpose of studying the machine tool markets in India, Java, China, Japan, and Australia. He brings back with him much valuable information, some of which is made available to American manufacturers in this article. The definite information given by Mr. Meyer should prove of great value to manufacturers who are interested in developing their export trade in the Far Eastern countries.

THE market for American machine tools in Asia has had a phenomenal growth since prewar days. Prior to 1914 the majority of the Far Eastern countries were satisfied with their antiquated methods of manufacturing, but things have changed now. The mysterious forces connected with the war have aroused the Far East from her slumbers. The Orient, during 1913, absorbed approximately $200,000 worth of American machine tools. The sales increased yearly until 1919, when the high peak was reached. During that year the sales amounted to nearly $9,000,000. The preliminary returns for 1921 indicate that the exports of American machine tools to the Orient will reach $6,000,000.

This is certainly a very creditable showing, considering the current exchange rates and the price reductions that have been made during the last six or eight months. The Chinese and Japanese rates of exchange have been normal for practically the best part of the year. The present rates in the Dutch East Indies and British India are still unfavorable, but not to the extent that they were in 1919, when the peak was reached. An analysis will show that the value of the sales for 1921 is thirty times the value for 1913. Considering the recent price reductions and the improvement in the exchange, it is safe to assume that the total volume of sales to the Far Eastern countries for 1921 is not much, if any, below the volume for 1919.

Probable Future Demand

The Orient is awake industrially. Japan has for a long time appreciated up-to-date machine tools, but there is still room for improvement. It is said that India learned to use machine tools during the war when she took up her share of the manufacture of munitions. China needs equipment badly, but at present is short of funds. Java may be considered a limited market, but there are good prospects for doing business with the government railways and shipyards and with the sugar mills and mines for certain classes of machine tools.

Labor is also undergoing a change. The workman is demanding a greater return for his labor. To meet this the manufacturer must have greater production. Naturally he turns to production machinery to solve his problem. The demand of the Oriental workman for a higher standard of living has already had its effect on the machine tool business.

In India the industrial development has been much more rapid than in the other Oriental countries. Prior to the World War, India was regarded as a repair shop for reconditioning ships and repairing rolling stock. Her unlimited supplies of raw materials were shipped to England and converted into finished products. Now things have changed. The policy today is to establish industries throughout the land. In the vicinity of Calcutta, jute mills line both banks of the Hugli, the principal delta mouth of the Ganges River. These mills are equipped to spin the raw material, weave the burlap, and manufacture gunny sacks. Practically all the burlap and gunny sacks used in the entire world come from this district. These jute mills have up-to-date machine shops for plant maintenance, and several are equipped to manufacture their own spinning machines and looms.

At Tatanaga, close to the coal and iron mines, stands the Tata Iron & Steel Works. This plant covers a very large area and compares favorably with the best steel mills in the Pittsburg district. It has both Bessemer and open-hearth furnaces and a rolling mill equipped to roll rails and structural steel. It was founded by J. N. Tata, a Parsee, but is now managed by American and British engineers.

Other industries are springing up on every hand. It is impossible to foretell the outcome, but it is safe to say that India with her unlimited supply of natural resources is destined to become one of the greatest manufacturing countries of the world. India's one handicap is her railroads, which have not kept pace with her industrial development. Her greatest need today is rolling stock and motive power to transport the raw materials and coal from the mines to the industrial centers.

How to Secure Far Eastern Trade

The American manufacturer seeking Far Eastern trade should first make a careful study of the various markets. He should proceed with caution. He should not act hastily, as did a certain wall paper house which sent its representative into the Far East for business. Had it taken the trouble to investigate, it could have easily learned that wall paper, due to climatic conditions, will not stick to the walls in British India, Burma, the Straits Settlements, the Dutch East Indies, and some parts of China. The representative encircled the globe and had a wonderful time, but he secured no business.

Practically all the American machinery sold in the Far East is sold through machinery dealers. This is the best and only way to handle the proposition. The largest and most desirable machinery dealers in the Orient have offices in New York City where the preliminary arrangements can be made. These include American, British, Dutch, Chinese, and Japanese houses. The manufacturer should get in touch with the New York offices of several of the machinery dealers in each country where there is a market for his product. He should obtain particulars re-

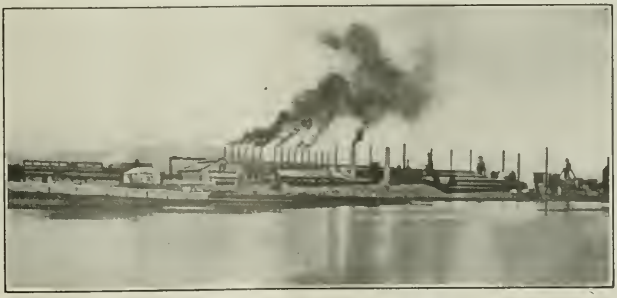

Fig. 1. The Tata Iron & Steel Works at Tatanaga, India

garding their organizations and at the same time find out whether or not they are in a position to handle his line without conflicting with a competitive line. The manufacturer is then ready to weigh the merits of the several dealers and make his choice for each country.

As soon as the connections have been made, the manufacturer should see that each dealer is supplied with descriptive literature, price lists, and advertising matter. No attempt should be made to print these in the native language, as English is read by almost everyone holding an official position. In fact, it is preferred by the majority of the Orientals whose languages are void of technical terms. The shipment of printed matter should be followed by a shipment of machines and accessories for stock.

The Manufacturer's Representative

The next move is to send a representative, preferably an engineer, into the new territory to get the agents started on the right track. Great care should be exercised in picking the right man. He should have a pleasing personality and should understand the art of making friends. Above all he should know his line. Do not consider a man who will boast of his own country and belittle the country he is visiting. This will react against all American manufacturers and consequently will injure America's foreign trade.

Travel in the Far East is expensive, and much of the traveler's time is unproductive. A year's trip with an itinerary including British India, Burma, the Straits Settlements, the Dutch East Indies, China, and Japan will make it necessary for the traveler to spend from three to four months on the seas. He can handle two or three lines, either through the same or different agents, almost as easily as he can look after one. Thus several manufacturers can, by pooling the expense, secure their share of the Far Eastern business at a comparatively low cost.

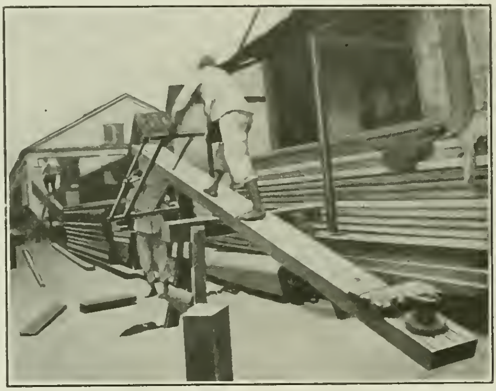

Fig. 2. Chinese Woodcutters sawing Lumber at the Government Arsenal near Shanghai, China

Methods of Selling

The traveler should remain in each country long enough to enable him to call on the most important prospects. He should also take time to instruct the salesmen and arouse in them an enthusiasm for his line. This is very important, as the Oriental salesman will not push the sale of a machine tool he does not know well. He prefers to remain silent rather than run the risk of "losing face."

The majority of the engineers met in British India are British. In the Dutch East Indies the engineers are Dutch. The Dutchman is a born linguist and generally speaks four or five languages. The Chinese and Japanese engineers usually understand some English even though they are unable to speak it. Besides, the traveler is always accompanied by either a foreign or native salesman who is ready at all times to act as his interpreter.

In planning a business trip to the Orient, it is very necessary to know that all the railways, the telegraphs and the telephones in British India, the Dutch East Indies, Japan, and some of the railways of China are under government control. All the government plants in these countries do their buying during the months of December, January, February, and March. Each year they make application to their respective governments for sufficient funds to take care of the coming year's requirements. The appropriations, if granted, are available early in December and must be spent before the last day of March. These shops, together with the government dockyards and arsenals, make up a large portion of the industries of the Orient, and serious consideration must be given to their business methods.

The most extraordinary phase of the government buying system is the requirement that no order can be placed with an agent unless the goods are in the country or en route. The law requires that delivery must be made and all invoices paid on or before the last day of March; otherwise, delivery is refused and the money returned to the government.

The wide-awake dealer keeps in touch with the engineers of the government plants with the view of getting a line on their requirements. He then orders a sufficient stock far enough ahead of time to insure delivery during the buying season.

The Itinerary for a Far Eastern Business Trip

To go back to the traveler and his itinerary, the ideal arrangement would be for him to arrive at his destination a little before the buying begins and remain until the season closes. This fits in very nicely with the cool weather, but unfortunately the buying seasons are the same in a number of countries.

The monsoon or rainy period in India begins about the first week in July and continues until the end of September. During this time the heat is almost unbearable. The best plan is to proceed to the Orient via England and Suez and spend the months of November, December, January, and February in India. Allowing a month to travel from Calcutta to Batavia, the traveler will be in Java by the first of April. April and May are very hot and rainy months in Java. This, however, cannot be avoided. A side trip of several months to Australia and New Zealand will give the traveler a taste of cool weather, the seasons in the southern hemisphere being just opposite to our own. He can then work north by way of the Philippine Islands to either China or Japan, arriving there just prior to the opening of the buying season.

The American engineer is well received in all quarters of the Orient. The visitor is always welcome, especially if he is traveling in an out-of-the-way district where news of the outside world is scarce. He is frequently entertained in a most hospitable manner at the home of the engineer on whom he is calling. During one of my visits to a large steel works in British India I was invited to spend a day and a night with a high official of the company. On another occasion, when I was calling on one of the railway shops in the same country, I was met at the railway station by the chief engineer who had come up from the shops some three miles distant on a push-car. It was a new and strange experience for me to go spinning along the rails on a contraption similar to a hand car, which was pushed along by two half-naked Hindus, each running on top of the rails.

Types of Machine Tools Used in the Orient

The average Oriental workman is lazy and naturally opposed to work. Furthermore, he is afraid of a machine tool and looks upon some of the more complicated types as objects possessed of evil spirits. This is particularly true of the Hindu workmen and has a very important bearing on the types of machine tools used in British India. The Hindu operator always runs his machine at the slowest speed possible. He seems to fear that it will fly to pieces and cause him bodily injury if he speeds it up.

On one occasion, when I was being shown through a large railway shop in British India, my attention was directed to a Landis threading machine. At a glance I noted that the Hindu operator was threading ½-inch bolts at the speed intended for 1¾-inch and 2-inch sizes. I spoke to the engineer who accompanied me regarding this. He was on the job in a second; he grabbed the Hindu by the back of the neck and poked his nose against the high-speed pulley of the cone, remarking at the same time in Hindustanie that for the hundredth time he wanted it understood that the machine must be speeded up. The poor Hindu took this gentle hint and stepped the belt up to the proper speed. My sympathy was with him until, some fifteen minutes later when I passed the same machine on my way out, I observed that he had put the belt back on the slow-speed pulley. I had no desire to see murder committed, so I made no mention of the fact to my friend the engineer.

It would be absurd for American manufacturers to ship multiple-spindle machines into British India, because neither the Hindu nor the Mohammedan will operate more than one spindle of a multiple-spindle machine. This applies to drills, tappers, and threading machines. In British India a machine of this type would require an operator for each spindle; this is a bad condition from the production standpoint. The operators either converse or fight and the output of each suffers. If but one operator is assigned to a multiple-spindle machine, he will work one spindle only and let the remainder run idle. I saw evidence of this in many of the shops which I visited, particularly among operators of multiple-spindle drilling and tapping machines.

Fig. 3. The Author and the Chief Engineer of the B & N Railway enroute to the Shops of the B & N Railway near Calcutta, India

The Effect of Religious Beliefs in India

Two very important items which should be given consideration are the recommendations for belting and cutting lubricant. The cow is sacred to the Hindu and consequently he is opposed to the use of leather belting for driving machinery. On the other hand, the pig is sacred to the Mohammedan and he will not use a cutting lubricant having animal lard oil for a base.

During the war, when the engineering firms in British India introduced automatic and semi-automatic machines for the manufacture of munitions, they found themselves face to face with a peculiar condition. They picked their best native mechanics for these machines. These operators had hardly started when they quit work in a body. They claimed that machinery capable of doing the work that these machines would do must be possessed of evil spirits and flatly refused to operate them. The engineers in charge were then forced to go out and round up natives of the coolie class, who were too ignorant to bother about evil spirits, and train them for this work. These men soon learned that the movement of certain levers was necessary to perform the several operations in the proper sequence. They became expert operators, but without any knowledge of real action of the machinery.

The Prospective Market in China

The Chinese market seems to prefer cheap machinery. This may be attributed to several causes, but one of the most important is that Chinese labor is opposed to labor-saving machinery. They cannot see that they will be benefited by increased earnings and that the introduction of labor-saving machinery into their country will stimulate manufacturing and create work enough for them all. They take the stand that labor-saving machinery requires fewer men and would therefore cause large numbers of their class to be thrown out of employment.

Another obstacle to the introduction of up-to-date machinery into China is the cheapness of labor. I was told that the average mechanic receives in the neighborhood of $12.50 a month and that common labor is paid as low as $3 a month. The apprentice works for a period of three years with no pay except his daily ration of rice. A certain American company attempted to introduce a line of tractors into China by lending them to the farmers in different districts. A demonstrator was sent with each machine. The results obtained by the demonstrators showed the operating cost of the tractor to be approximately $25 a month. This figure seemed low enough to the firm's representative to insure a good business, but the farmers both surprised and disappointed him by claiming they could hire eight farm hands to do the work for the same amount of money.

Still another obstacle to the use of machine tools by the Chinese is the time-honored custom of using their hands. They apparently prefer to stick to the antiquated practice of making everything by hand. During a visit to a large engineering firm in the city of Tientsin, I was invited by the manager to inspect the works. I found the machine shop well equipped with first-class machinery of American and British make. On entering the pattern shop, I was impressed with the absence of woodworking machinery. I made a careful inspection and could find nothing that resembled a machine, not even a wood turning lathe. In answer to my inquiry regarding this, I was told by the manager that he had made several attempts to install suitable machinery, but that his Chinese patternmakers preferred to make the patterns by hand. I was shown patterns of an eight-ton flywheel and a one-cylinder gas engine frame, together with some of the most intricate patterns I have ever seen, all fashioned by hand. It was difficult for me to believe that the cylindrical portions of these patterns had not been turned in a lathe.

In the foundry I found the workmen pouring a 3500-pound casting. There was no tackle for handling the huge ladle. Aside from the head molder, I counted twenty-four coolies assisting in carrying the molten metal from the cupola to the mold. I was told that the head molder would receive the equivalent of $45 for the job and that he would pay his coolie assistants at the rate of 25 cents per day.

I was told that there are only a few sawmills in the whole of China. This means that practically all the lumber used in the country is cut by hand. If one wishes to build a home or a factory, it is necessary to have the rough logs hauled to the site and woodcutters engaged to come and saw them up into studding, joists, rafters, flooring, etc. These men are experts who will do the work just as well as it can be done at the sawmill; and their wages compare favorably with the prices charged by the sawmill.

Until recently, a great deal of the manufacturing in China was done in the homes of the workmen. Even today there are still several hundred machine shops in the city of Shanghai occupying either the front or rear rooms of dwelling houses. These shops, as a rule, operate on a very small scale. The equipment consists of a lathe, a drilling machine and, in a very few instances, a shaper. These machines are principally of Chinese make and are very crude. In one of these shops which I visited, I found them using the lathe to saw off stock. The saw was mounted on the live spindle of the machine and the piece of stock was gripped in the cross-slide. In another place, they were using a lathe to mill a slot in a piece of steel.

Creating a Demand for Machine Tools in China

Before we can look upon China as a good market for machine tools it will be necessary to create a demand. This can be accomplished by educating the masses to use machinery. A well-known oil company created a demand for kerosene in China in a most satisfactory manner. The company knew that the Chinese are very fond of artificial light, but to get them to discard their antiquated lamps which would not burn kerosene was the problem to be solved. A large quantity of tin lamps painted blue (the favorite color of the Chinese) were made. The lamps were filled with kerosene and handed out to the Chinese population in certain districts. These lamps were far superior to the Chinese lamps. John Chinaman was very much pleased with his new possession, and when the oil which was furnished with the lamp was burned up, he immediately purchased more.

The market for up-to-date machine tools might be created in several ways. The first thing to do is to make the Chinese acquainted with the machine and then prove to them that it will turn out a superior quality of work at a lower cost than the cheap and crude equipment with which they are familiar. This can be accomplished by placing machines in the engineering colleges and trade schools in China, and educating the coming engineers and mechanics. This does not mean that the machines should be presented to these institutions. The plan adopted by a large number of American manufacturers is to make their prices fit the pocketbooks of the colleges and schools. Some have even gone so far as to sell their products to these institutions at half price. They hope by this means to induce a portion of the graduates of the engineering and trade institutions to affiliate themselves with the industries of China and replace the present crude equipment with up-to-date machinery.

Educating the Chinese Student in America to Use our Machine Tools

The demand for American machine tools can be helped along in still another way. Each year the Chinese Government picks by competitive examination one hundred Chinese boys and sends them to this country to be educated in our engineering colleges and universities. These students return to China after graduation and are given important positions with the railways and other branches of the government service. They become more or less familiar with American machine tools during their stay here, but the manufacturer can help his particular machine along either by arranging lectures before the foreign student bodies in the engineering colleges, or by extending invitations to these students to visit and inspect his plant.

I am told that it is impossible for a Chinese graduate of an American engineering college to obtain practical training in our factories, except without pay. This is due to our immigration laws and also to the ruling of the labor unions. The result is that the young Chinese engineers are going to England and France for their practical training. Thus they unconsciously develop a leaning toward British and French machine tools. I do not wish to convey that China is totally ignorant of high-class machine tools. On the contrary, there are some fine plants in China, and credit is due the machinery agents who are responsible for what has been done.

Japan is much further advanced than the rest of the Oriental countries and is a well developed market for all classes of machine tools. The Japanese, however, have begun the manufacture of machine tools, and have thus created additional competition not only in their own country, but throughout the whole of the Far East.

INDUSTRIAL CONDITIONS IN FRANCE

By MACHINERY'S Special Correspondent

Paris, January 12

Business conditions in the machine tool field showed a decided improvement during the month of December, many new orders having been placed. Inquiries are becoming more and more frequent, and often lead to the placing of orders. The feeling exists that this is not a temporary improvement, but that the condition will continue and that the year 1922 will witness the end of the great business depression which has swept over the metal-working industries. So far the plants in the vicinity of Lyons have benefited the most by the improved conditions. The machine tool activities are in general the result of furthering the development of the water power resources, increased manufacture of locomotives and railroad cars, and overhauling of railway equipment.

Improvements in Associated Industries

Boiler manufacturing and similar establishments are profiting from the renewed activity in the chemical industry, which has created a demand for tanks and large metal containers. The manufacture of boilers, however, is at a complete standstill. Rolling mills and foundries continue to receive orders, and there is quite a good deal of activity in these fields. Copper and brass foundries have also experienced a decided improvement.

In the automobile field the manufacture of the higher priced touring cars and small commercial cars continues to be active. One automobile plant is running the same as in normal times. There is no great demand for large motor trucks, however, and as a consequence one of the principal truck manufacturers had to close down on January 1. The bolt-manufacturing and wire-drawing fields continue quiet.

Present Prices of Machine Tools

American-built machine tools are still in little demand in France on account of the exchange rates. The prices of a number of machine tools built by French manufacturers are:

Lathes—Gap bed type, 15-inch swing, 40 inches between centers, with all accessories, 6200 francs (about $500, present exchange); another lathe of the same type and swing as the foregoing, but with a distance of 60 inches between centers, 6500 francs (about $530); engine lathe, 14-inch swing, 36 inches between centers and weight about 2000 pounds, 8000 francs (about $650).

Crank Shapers—Maximum stroke of ram 16 inches, horizontal traverse of table 22 inches, dimensions of table 18¾ by 12 inches, and weight about 2650 pounds, 9350 francs (about $760); maximum stroke of ram 24 inches, dimensions of table 25 by 16 inches, and weight about 4700 pounds, 13,600 francs (about $1100).

Planers—Width between housings 24 inches, stroke 5 feet and weight 6600 pounds, 17,150 francs (about $1400); another machine of the same width between housings and the same stroke, weighing 5500 pounds, 13,500 francs ($1100).

Drilling Machines—Sensitive, capacity for drilling holes up to ⅝ inch in diameter, spindle diameter ¾ inch, vertical movement of spindle 8 inches, and weight 500 pounds, 1500 francs (about $120); upright drilling machine with stationary head, normal drilling capacity of 1½ inches when provided with gear-box, and 1¼ inches without gear-box, diameter of spindle 1½ inches, No. 3 Morse taper socket, and weight about 1100 pounds, with gear-box 3600 francs (about $290), without gear-box, 3150 francs (about $255); radial drilling machine, normal drilling capacity 1¾ inches, diameter of spindle 1½ inches, and weight 4000 pounds, 10,000 francs (about $810).

Milling Machine—Single-pulley drive, longitudinal traverse of table 20 inches, transverse movement 6 inches, vertical movement 14 inches, the longitudinal traverse only being automatic, weight 2000 pounds, 9450 francs ($765).

Arc-welding of Cast Iron

Use and Application of Methods for the Welding of Cast Iron by the Electric Arc

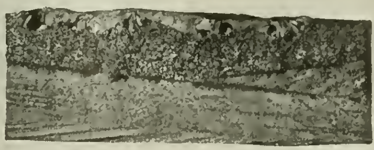

Fig. 1. Structure of Cast Iron welded by the Carbon Arc Method

By A. R. ALLARD
Welding Supervisor
Westinghouse Electric and Manufacturing Company
East Pittsburg, Pa.

THOSE familiar with the merits and limitations of the electric arc welding process for making welds in cast iron recognize the need of a better understanding of the application of the art. It is necessary to understand thoroughly certain fundamental facts concerning the metal and the relation that its ingredients bear to the actual welding process, if satisfactory results are to be obtained. These and other important facts are discussed in the following.

Carbon Arc-welding Process

Carbon arc-welding is probably the oldest and easiest, in point of manipulation, of the arc methods of welding cast iron. It consists of drawing an electric arc between a carbon pencil and the cast-iron part, causing the metal of the casting and the filler rod to become molten at the point of heat application. Cast iron melts at 2300 degrees F. and volatilizes at 3300 degrees F., and becomes fluid under the heat of the arc. This characteristic limits the use of the method to such work as may be welded in a horizontal plane and to metal of sufficient thickness to prevent the intense heat of the arc from melting through. To facilitate the welding operation by this method, a backing of refractory material is often built around the work.

Many metals have a characteristic known as the critical welding heat at which point the metal suddenly changes from the plastic to the fluid state and above which the further application of heat for extended periods causes burning of the metal. Pure iron is more easily welded by the arc than any other metal, and the method becomes more difficult of accomplishment with increasing percentages of carbon until about 2.25 per cent carbon content is reached, which produces cast iron. Cast iron, when held at a red heat for long periods, deteriorates considerably, and if held at high temperatures will disintegrate and become worthless. When the carbon arc method is used, the metal is quickly brought to the molten state at the surface, and the carbon of the metal becomes dissolved in the iron. When the heat of the arc is removed, the cold sections of the casting quickly dissipate the heat from the molten section, thus producing chilled cast iron, the structural formation of which has the appearance shown in Fig. 1. The action is analogous to that which occurs when pouring molten metal into a steel chill. Care must be taken in manipulating the carbon pencil, for if the carbon comes in contact with the surface of the casting it will usually produce a hard spot.

The Steel Metallic Arc Method

Another electric arc method which is quite intensively used for certain applications of cast-iron welding is the metallic arc method. By this process an arc is drawn between the cast iron and a metal electrode of suitable composition, causing the electrode wire to melt and be deposited in the pocket melted in the cast iron by the heat of the arc. Owing to the doubtful nature of the union of the metals obtained by this process it is customary to insert steel studs in the work in order that the filler material may unite with them and aid in anchoring the deposited metal to the cast iron. When this method of welding is used for repairing fractures in containers for steam, liquids, or gases, the seams or edges of the weld may be calked to obtain tight joints. When welding cast iron by this method, using steel wire electrodes, the fusion of the two metals is dependent upon the state in which the carbon exists. It is known that the closer the carbon in the cast iron approaches the graphitic state, the less dependable will be the union of metals, and that the closer it approaches iron carbide the stronger will be the weld. This condition is due to the fact that as carbon approaches the graphitic state there is less continuity of the iron matrix and less cohesion between the iron crystals, due to the laminated structure of graphitic iron.

In addition to this characteristic of the process, there is also the likelihood of producing a layer of residue of slag between the two metals at the line of fusion,. which will prevent a good union. This condition becomes more serious as the carbon approaches the graphitic state. The layer of residue forms as the steel matrix of the cast

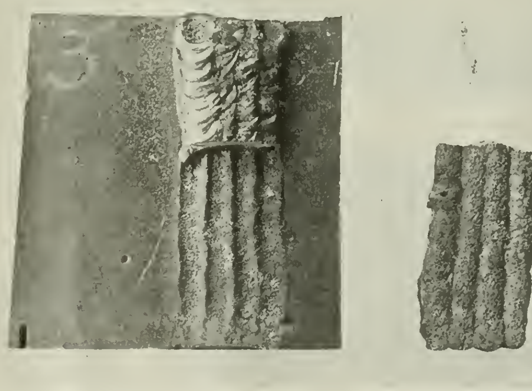

Fig. 2. Appearance of a Cast-iron Weld made by the Metallic Arc Method, showing the Slag Layer at the Line of Fusion

iron becomes molten, and in a molten state is attracted to and unites with the layer of metal already formed and partly solidified. As this movement of metal occurs, due to molecular attraction, most of the graphite in the laminated structure is left without its supporting matrix and settles to the bottom of the depression left by the movement of the metal. This deposit of graphite is a good conductor of electricity, and so concentrates the action of the electric arc, which results in partly oxidizing it and packing it into a layer with the dirt and oxide. The appearance of this accumulated layer of slag is shown in Fig. 2.

The quality of the union can be foretold by the application of the electric arc to a small area of the casting or by a visual examination of a fracture of the casting. This may be seen in Fig. 3, which shows two views of a wedge-shaped casting. The wedge shape enables metal in various physical states to be presented, so that the effect of the application of the carbon arc may be observed. It will be seen that the casting has a fine grain structure at the apex and that the development of the graphitic structure increases with the thickness of the section. The flat deposits in the lower part of the illustration were made with the carbon arc. In cases where the deposited metal spreads over the parent metal to the line of fusion making a smooth appearance, as it does at the left of these deposits, instead of receding at the line of fusion as it does more and more as the graphitic structure increases toward the right, then good fusion can be expected. The string of deposited metal on the upper part of the casting was made by the metallic arc, and in this case also the degree of fusibility and penetration decreases with the graphitic structure.

Factors in Welding Cast Iron

Upon examination of a weld made by the steel metallic arc process, even though good amalgamation of the metals has resulted, numerous small gas pockets are discovered, particularly in the layer adjacent to the casting. These pockets are formed by the gas produced in applying heat to the layer of residue previously mentioned, and by the volatilization of the molten carbon and silicon. There is also a tendency for cast iron to absorb moisture from the air when heated, which upon being gasified may also produce pockets at the joining surfaces.

With this method of welding there exists between the layers of deposited metal and the cast-iron parent metal, a hard carbide area, which cannot be cut except by grinding. This area usually consists of a layer of chilled cast iron adjacent to the layer of slag, and located on the cast-iron side of the weld. On the opposite side of the layer of slag and adjacent to it there is formed a layer of chilled high-carbon steel, produced by the alloying of the carbon in the cast iron with the added steel of the wire electrode or filler rod. This layer of high-carbon steel is of varying thickness, depending on the character of the cast iron and the depth of penetration. It will readily be seen that the deeper the cast iron is liquefied by the application of the arc, the greater will be the amount of molten high-carbon steel to unite with the deposited metal.

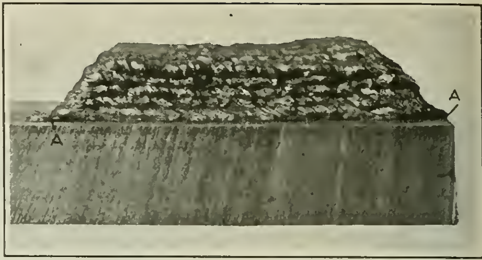

Fig. 4. Steel Filler Material deposited on Cast Iron, showing the Separation of the Deposit from the Original Metal

Difficulty in securing satisfactory welds with the metallic arc is sometimes due to the separation and fracturing of the metals, caused by the shrinkage of the molten metal upon solidification. This trouble is not always due to the difference in coefficient of expansion of the deposited and parent metals, although quite generally attributed to this cause. Contraction and expansion cause more trouble and failure in the welding of cast iron than all other causes combined. Every physical and chemical change in metal is accompanied by internal stresses, and when these exceed the strength of the metal it is not difficult to understand the failures produced by these stresses in a metal that is as rigid and brittle as cast iron. When using a steel filler material in welding cast iron with a metallic arc, the difference in contraction between the two metals usually causes trouble. The strength of the added steel is greater than that of the cast iron, which results in the steel pulling away from the cast iron when contracting, in the manner indicated at *A*, Fig. 4. In some cases, if good fusion has been secured, the cast iron itself will become fractured. The separation usually occurs at the layer of slag, or at the point of contact of the two metals, since this is the line of creepage, and is due to poor fusion. Even though good fusion of the metals has been obtained, separation may occur in the vicinity of this layer of slag and on the cast-iron side of the weld.

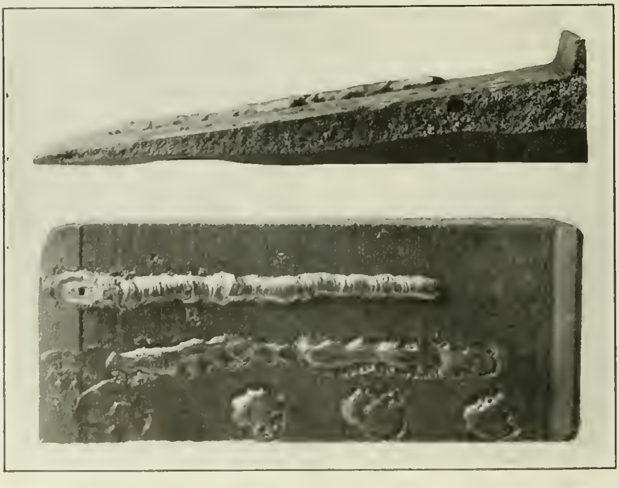

Fig. 3. Effect of a Graphitic Carbon Structure on the Fusibility and Penetration of Metal deposited by the Metallic and Carbon Arcs

The steel metallic arc process of electric welding is the only method adaptable to certain classes of work. Examples of this method are frequently found in castings which permit the use of only a limited amount of heat in performing the weld, and also in jobs which require the operation to be performed by overhead manipulation of the arc. The latter is extremely difficult of accomplishment with any other welding process.

Making a Weld with a Metallic Electric Arc

After cleaning the casting by chipping or sand-blasting the entire surface to which metal will be fused, a square groove is chipped along the line of breakage. The size of this groove depends upon the thickness of the casting, but is usually from 1/4 to 1/2 inch square. The groove is then filled with metal until it is flush with the face of the casting, and a stud is next located in the casting as close to the crack as practicable. The location of the first stud is determined by the thickness and shape of the casting. The amount of studding necessary depends on the volume of added metal required to give sufficient strength. The studs, should be long enough to extend through the first layer of deposited metal, so that good fusion may be obtained between them and the second layer, and they should be set a distance from the edge of the fracture equal to at least twice their diameter.

In welding, the first stud should be surrounded with a sufficient number of rows of deposit to extend to the center of the crack, as shown at *A* in Fig. 5. This procedure will aid in locating the spacing of the remaining studs, which are then set in rows as required to complete the job. Grooves should be placed between the rows of studs, if more than one row is used, and also at the outside edge of the weld area. The preparation as to grooving and studding, as well as the method of depositing the metal, is diagrammatically shown in Fig. 5. All grooves are filled flush with the face of the casting before depositing the first layer around the studs, in the manner followed with the first stud. The outside rows of the pads of adjacent studs are not united at this time except where they merge at their point of tangency. The second layer is deposited around all studs in such a manner as to build up the pads into a cone shape, which will leave a vee to be filled when uniting the pads. As many additional layers as required are then added, in the manner indicated in the illustration. In uniting the pads, those at the line of the break are left until last, in order to permit the greater part of the shrinkage to occur before this union is completed. When more than one layer of deposited metal has been welded around a stud, it is best to follow the circular contour of the pads when filling in between them.

The operation of welding cast iron by the steel metallic arc method should proceed very slowly, each addition of metal being small so that there will be a gradual absorption of the heat by the work. The practice of drilling holes at the end of the fracture is optional, and should not often be required because the casting should never be allowed to get warm enough to expand and extend the break. The use of small wire, low current and straight-line welding, without weaving or oscillating the electrode, will assist in keeping the work cool and in minimizing the stresses which in some measure are bound to occur.

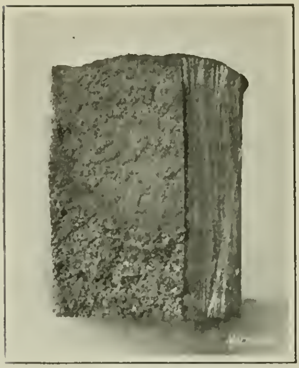

Fig. 6. Part of Cast-iron Section showing Characteristics of the Weld and the Original Metal

One of the errors frequently made in the application of steel metallic arc welding is the practice of building up heavy layers of metal adjacent to the cast iron. When good fusion is obtained, the section of a deposited metal can be safely limited to one-half that of the cast-iron section.

The metal added in the square groove at the break offers a projection against which the adjacent sides of the fractured casting are drawn by the shrinkage of the subsequently added material, thereby overcoming one of the greatest troubles encountered in the welding of cast iron. The other grooves furnish additional strength and insurance against leakage of gases and fluids when welding cast-iron cylinders and containers. The method of "veeing out" the casting at the break was adopted from the practice followed in acetylene gas welding, and may be followed in cases where the carbon is found to be in the state which will permit good fusion between the casting and the added metal. The heavy sections of graphitic cast iron, as usually encountered, should not be veed, as the original surface of the casting offers a better quality of metal upon which to weld than that exposed by cutting below the surface. A less suitable condition is encountered as the cut is made deeper, because the farther from the surface the greater the amount of graphite in the cast iron.

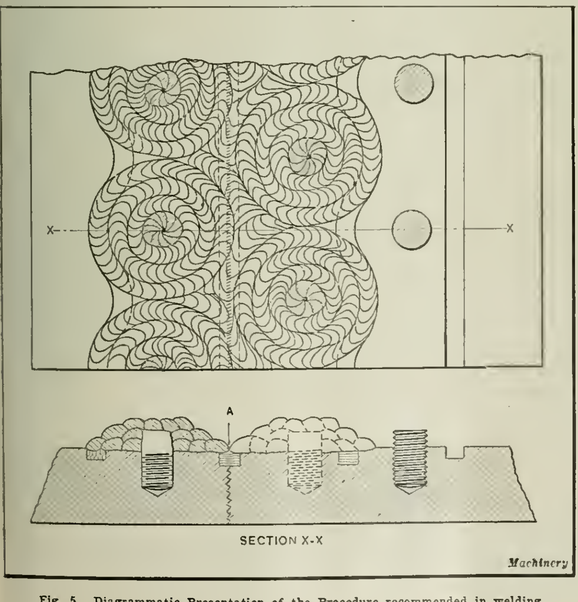

Fig. 5. Diagrammatic Presentation of the Procedure recommended in welding Cast Iron with an Electric Arc

Another disadvantage of the beveling method of preparation is the shrinkage of the filler material, which occurs no matter how carefully the work is done. This shrinkage draws the bevels of the vee against the boss formed by the filled-in metal, with the result that the pressure exerted tends to lift the added metal from the casting. This, in fact, actually occurs in many cases.

By following the practice here recommended, which is the one most widely understood, the effect of shrinkage strains will be kept at a minimum by affording means of equalizing, balancing, and taking advantage of those stresses which cannot be entirely eliminated.

Metallic Arc Process Using Cast-iron Electrode

It is the usual procedure in welding to use filler material which has the same characteristics as the material of the work and which will respond to the same treatment. It is obviously necessary that the amount of expansion and contraction of the parent and added materials be the same, and that good fusion of metals be secured. It is a logical procedure, then, to use filler material having a similar analysis to that of the part being welded, with a suitable allowance in the physical condition of the filler material to compensate for losses of its constituents caused by the effects of the arc. Electrode material for welding cast iron by the use of an electric arc should therefore consist of a cast iron high in carbon and silicon and containing small percentages of manganese, silicon, sulphur, and phosphorus. Cast-iron electrodes of various compositions have been successfully used in conjunction with preheating the casting. The standard filler rods made for acetylene gas welding usually give very good results when protected by a coating of lime.

Fig. 6 illustrates a cast-iron section preheated to 1500 degrees F. and built up by the metallic arc process of welding, using a cast-iron electrode. The section was cut with a hacksaw to show that it can be easily machined, and was then broken to show the characteristics of the weld and the original metal. Note the dense, fine-grained structure of the added metal and the graphitic structure of the original casting. The added material is stronger than the original casting and is easily machined.

Preheating

Preheating is considered necessary in connection with arc-welding of cast iron if the best results are to be secured. Preheating relieves residual strains and compensates for expansion and contraction; it eliminates gas pockets and holes by holding the metal in a plastic or fluid state long enough after deposit to enable the gas to escape and the foreign matter to be released and floated to the surface; it aids in securing good cohesion of metals and reduces to a minimum the formation of the layer of slag; and it prevents chilling of the deposited metal and assists in the desirable slow cooling process.

In connection with preheating to relieve residual strains caused by expansion and contraction, it should be pointed out that breakage caused by these stresses does not always occur at the point where the greatest amount of stress is applied, but at a point where the strength of the section is less than that required to withstand the same stress if applied at that point. If the casting is of simple construction it is usually only necessary to preheat it at the points of stress application. The problem becomes greater as the intricacy of the casting increases, until it becomes necessary to preheat the casting all over in order to compensate for the liberation of the residual stresses. In addition to preheating, it is often necessary to reheat the casting following the operation. Reheating relieves strains caused by welding and anneals hardened sections of the deposited metal. In some cases very good results will be realized by thus annealing the weld in addition to preheating the cast iron before depositing the metal. One advantage of preheating is that the welding operation may proceed rapidly, while if the welding is done by depositing molten metal on cold castings the operation is exceptionally slow and tedious, since it is only practicable to add the metal a little at a time in order to confine the heat and shrinkage to a minimum.

Conclusion

A few years ago results obtained by the use of electric arc methods of welding cast iron were questioned. The progress made within the last few years has been such, however, that at present excellent results are obtained on the better grade of castings and a fair job is possible on castings of almost any kind. As a better understanding of the condition under which cast iron can be welded by any process is reached, the practice will become more general and will rapidly advance. The development of arc-welding cast iron will probably depend largely upon the developments in the use of certain methods of procedure here defined, in the applications of preheating, and in the development of an electrode for use in welding cold castings which will deposit a metal having a minimum coefficient of expansion.

The American Society for Testing Materials and the United States Forest Service have been designated by the American Engineering Standards Committee as joint sponsors for developing standard methods of testing wood. This action resulted from a canvass of the principal national bodies interested.

SCIENTIFIC PRINCIPLES OF COST REDUCTION

By J. H. LINDSAY, Master Mechanic, Armor Plate Machine Shop, U. S. Naval Ordnance Plant, South Charleston, West Virginia

It is obvious that any material gains in effective cost reduction must result from a systematic application of the records of past experience rather than from mere assumptions. It is an unfortunate fact that a great many executives are carried away by the glibness with which young and inexperienced students are able to recite academically stated principles and the ease with which they construct upon and around these principles a system that has the outward appearance of being the real thing.

The scientific principles of industrial organization are within easy reach of the man who has come up through the shop, and are the most valuable of any stock in trade that he can have. They are fundamental to economic production. An understanding of the factors and principles of industrial organization is a force that can be utilized by anyone, regardless of how humble his position may be.

A great many shop supervisors resent the interference and dictation of what they call "office men and book learning." This resentment is reciprocated. The two forces become radically opposed to each other, and cooperation and coordination is prevented. Whether shop executives like it or not, recorded data relative to all phases of production has come to be a potent factor in bringing about efficiency. Loose guesswork methods are no longer adequate. Executives who wish to hold their own and to advance must grasp those fundamentals that enable them to compare and determine the value of different methods and developments.

Recently a prominent executive stated that he had greater respect for the man who had worked himself up to a position of responsibility than he had for the technically educated man holding a similar position. The reason for this is obvious. This executive and others like him have come to learn that the man with a broad practical experience, supplemented and strengthened by an understanding of fundamental principles as they apply to practical work, can strip a theory of all its superfluities and make the practical part of it work.

What we need in order to put our industrial plants on a sound economic basis is to give more time to conscientious study of fundamental conditions. Every idea and suggestion relating to cost reduction should be given consideration. If those who control and direct the organizations that make use of American-made machine tools, of which we are justly proud, are wise in economics as well as in shop practice, we need have no fear of foreign competition.

The foregoing paragraphs have been written with a view to emphasizing the necessity of a thorough grasp of the fundamental principles upon which all system should be based. A ready-made method or system that is locally effective is the result of a close study of local conditions and needs, and the application of recorded data and original thinking to them. Such a system may or may not fit other conditions wholly or in part. If it fits other conditions, it may only bring about a result that is comparable with results obtained elsewhere, whereas leadership implies excelling results obtained elsewhere by the application of fundamental principles in a more thorough manner than has previously been done.

* * *

A joint investigation of the fatigue of metals under repeated stress has been conducted during the last two years by the National Research Council, the Engineering Foundation, the General Electric Co., and the Engineering Experiment Station of the University of Illinois. The results of this investigation have just been published in bulletin No. 124 of the Engineering Experiment Station of the University of Illinois, Urbana, Ill., copies of which may be obtained from the director of the Engineering Experiment Station.

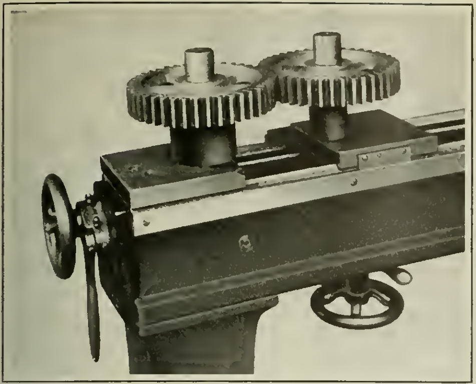

Fig. 1. Fixture for testing the Concentricity of Spur Gears

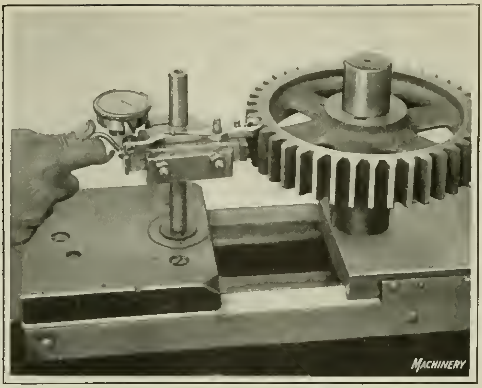

Fig. 2. Method of determining Uniformity of Tooth Spacing

Inspection of Spur Gears

By D. VAUGHN WATERS, Mechanical Engineer, Gould & Eberhardt, Newark, N. J.

CERTAIN qualities are required in spur gears, as well as in other types of gearing, for satisfactory service; these are uniform rotary motion, long life, and reasonably silent operation. In order to obtain these qualities, the following conditions must be met as closely as possible in manufacturing: The tooth curves should coincide with the basic involute for each gear; the pitch circle should be concentric with the axis of the blank; and the teeth should be of uniform thickness. Cutters are now made with a knowledge of basic principles and an accuracy of manufacture that enable a gear tooth contour to be selected and a cutter made which will produce this contour with a high degree of precision. Testing fixtures have also been developed to measure the accuracy of the involute curves on gear teeth. These fixtures have measuring elements which describe theoretically correct involute curves, and any deviation of the gear tooth therefrom can be instantly detected and measured.

In shops with an output of gears sufficient to justify their systematic inspection, certain standards should be established to define just how far a gear may depart from the fundamental requirements given in the foregoing: This article presents a short description of the practice of Gould & Eberhardt, Newark, N. J., in inspecting spur gears, with particular reference to the uniformity of tooth spacing and concentricity of the pitch circle relative to the axis of the gear.

The gears manufactured by this firm are component parts of the machine tools built by the concern, and are held to close limits of error. The inspection operations that do not relate to the spacing or concentricity of gear teeth are not within the scope of this article and therefore will not be dealt with.

Testing for Concentricity

The first operation is the testing of the blanks for concentricity, this, of course, being done before the teeth are cut. Each blank is rotated on a true arbor mounted in the centers of a testing machine. The anvil of a dial gage is brought to bear against the periphery, and any eccentricity can readily be seen. The cut gears are put on the studs of the gear-testing machine shown in Fig. 1, either in pairs or with a master gear, and when rolled carefully by hand, a slight eccentricity of the pitch circles is easily detected. This machine consists of a base somewhat resembling a lathe bed, a bracket near one end holding a vertical stud which can be changed for different sized holes in gears, and a movable slide with another stud mounted on it. There is also a scale and vernier for use in adjusting the studs to the correct center distance of the gears being tested. A screw and a nut inside the bed enable the movable slide to be adjusted, this mechanism being actuated by the handwheel seen at one end of the machine.

Testing the Uniformity of Tooth Spacing

The uniformity of tooth spacing is inspected by means of the fixture shown in Figs. 2 and 3. This consists substantially of a base, a slide, and a dial gage secured to the slide. On one end of the slide is fastened a fixed finger *A* which can be adjusted to different pitches, and at one side of this fixed finger is a movable finger *B* terminating in a lever, the end of which bears against the anvil of the dial gage. The ratio of the length of the lever end to that of the finger is such that each division on the dial of the gage indicates 0.0005 inch in tooth thickness.

This fixture is mounted on the gear-testing machine mentioned in connection with the rolling test. A gear to be tested is mounted on one of the vertical studs and the fixture secured in such a position relative to the gear that the fixed finger *A* enters a tooth space. The slide is next advanced by means of the attached handle, causing the movable finger *B* to enter the space on the opposite side of the tooth from the fixed finger. The dial reading is then taken, the gear rolled around, and the next tooth tested. This cycle is repeated until each tooth has been inspected and the error determined. It will be noted that this process does not check the circular pitch dimension of a gear, but insures uniform spacing around the blank. Fig. 2 shows the gear in place, being tested for uniformity of tooth spacing.

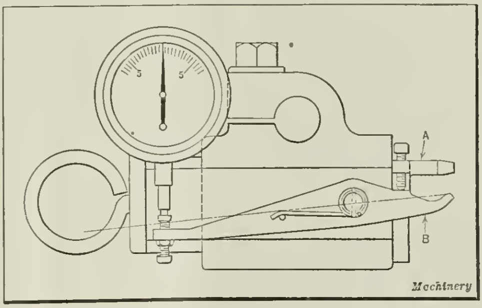

Fig. 3. Diagrammatic Representation of Fixture employed in Fig. 2

Ascertaining the Concentricity of the Pitch Circle

The inspection which closely checks the concentricity of the pitch circle with the axis of the blank is accomplished with the fixture used for the spacing test. For this operation, however, the fixed finger is replaced by a simple stop for the movable finger. The gear to be tested is mounted on a stud on the testing machine, as shown in Fig. 4, and held from rotating by means of a plunger entering a tooth space. This plunger is mounted on a bracket which can be adjusted to accommodate different sizes of gears. The testing fixture is then clamped on the machine so that when the slide is moved by hand, using the small handle referred to in the description of the previous operation, the movable finger will enter a space and bear on one side of the tooth about 180 degrees from the fixed plunger. The reading of the dial gage is then taken, the gear indexed one tooth, and the operation repeated. After all the teeth have been tested, if they have been cut eccentrically relative to the axis of the gear, the dial readings will increase and diminish uniformly from a mean value.

When an arbor is mounted in a lathe and it is desired to test its truth, this may be accomplished by bringing the anvil of a dial gage against the periphery of the arbor. The reading thus obtained is equal to twice the eccentricity, or the diameter of the circle described by the eccentric center rotating about the true center. With the gear-testing method just described, the result is the same as if a dial gage were brought to bear against the work-arbor upon which the gear was cut, thus providing a check upon the care exercised by the machine operator in setting up the work. Attention is called to the fact that if T equals the diameter of the circular path described by the eccentric center, the difference in the reading will be $2T$.

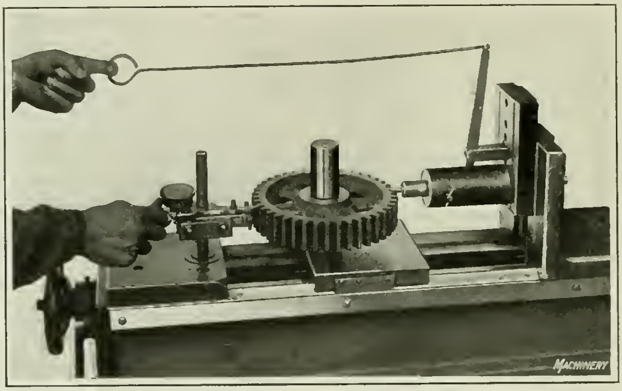

Fig. 4. Arrangement used for checking the Concentricity of the Pitch Circle

If the point of contact of the movable finger and the tooth flank does not lie on a line intersecting the axis of the gear and the fulcrum of the finger, the dial gage will indicate a difference in tooth position slightly in excess of that actually obtained. This discrepancy is so slight and the total difference in dial reading such a small amount, never exceeding 0.003 or 0.004 inch, that the testing fixture may be located in position as nearly as can be judged with the eye, and the possible error resulting from a slightly incorrect setting safely disregarded. When the high point on the gear comes opposite the testing fixture, the tooth is nearer the fixture by an amount equal to T than when the high point is opposite the plunger. This movement, taking place at the mid-position of the finger, will not affect the maximum and minimum dial readings, and may therefore be ignored. Denoting the difference in the dial readings from maximum to minimum as D, the value of T, or the variation a dial gage would show if it were possible to apply it to the pitch circle of the gear, would be $D \div 2$.

* * *

A study of the melting losses in aluminum metallurgical practice and the comparative efficiency of various types of furnaces has been completed by the Pittsburg Experiment Station of the United States Bureau of Mines, and the complete results will soon be available in bulletin form.

PRODUCTION OF MACHINE TOOLS IN THE UNITED STATES

The table on the opposite page, which has been compiled from information furnished by the Bureau of Census, shows in detail the production of machine tools in the United States for 1919. In that year, there were 496 establishments engaged in the manufacture of machine tools and accessories. Of this number, 403 plants were directly engaged in the production of machine tools, and 93 manufactured accessories. The total value of the product manufactured was $222,504,654, of which $212,224,708 worth was produced directly by the machine tool industry.

For a great many years Ohio has led all other states in the production of machine tools. In 1919 that state had 112 manufacturers, producing $65,521,575 worth of machines. Massachusetts came next with 56 plants, producing $23,885,863 worth of machine tools, while Rhode Island, with 18 plants, manufactured machine tools to the value of $23,080,978.

The table gives the total number of machine tool plants in the United States as a whole, and also the totals for the leading states engaged in this industry, together with the value of the machines produced in each. The table is further subdivided to show which states manufacture certain machine tools, giving not only the number of plants in the various states, but also the number of machines manufactured and the total value in each state of the different types produced. While some of the states lead in manufacturing one product or another, it will be noted that Ohio has the greatest number of machine tool plants, and also produces more individual machine tools than any other single state.

In another table compiled by the Bureau of Census, but not published here, it is shown that during 1919 the United States produced a total of $36,347,616 worth of metal-working machinery other than machine tools. Of this total Ohio produced only $4,180,531, while New York led with $9,250,240 worth of metal-working machinery. Illinois came second with $7,904,031 worth, and Connecticut ranked third, with $5,701,238.

PAMPHLET ON DEPRECIATION

The fabricated production department of the Chamber of Commerce of the United States has published a pamphlet entitled "Depreciation—its Treatment in Production," which should be of considerable interest in view of the fact that depreciation is one of the most important problems in costs and general accounting. The material presented is based on extensive experience, and has been prepared in cooperation with many leading authorities in the accounting field, industrial engineers, manufacturers, etc. The topics treated are as follows: The need of charging depreciation into everyday cost; the relation of insurance and depreciation; adjusting depreciation to production; the controlling effect of obsolescence; advantage of standard rates of depreciation; and how the property ledger operates. The publication of pamphlets of this kind is part of the educational plan of the department, and copies will be supplied to those interested upon request.

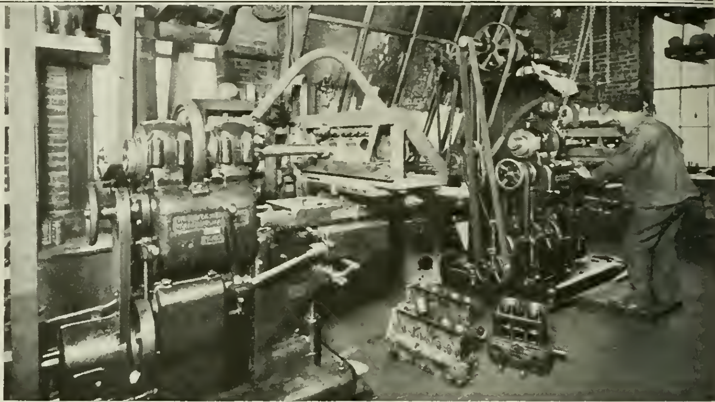
Machinery

Machining Pistons in the Repair Shop

Second of Three Articles Describing Methods and Equipment Commonly Used in Automobile Repair Shop Practice



THE methods used in the Frostholm Bros. shop in Syracuse, N. Y., for machining pistons require only standard machine tools in connection with some special fixtures. This company manufactures cast-iron pistons in standard sizes and in sizes from 0.001 to 0.062 inch oversize. However, the use of aluminum alloy pistons with a split skirt having from 0.001 to 0.002 inch clearance in the cylinder bore is recommended for some motors. These lightweight alloy pistons can be fitted with less clearance than cast-iron pistons, and special features of design provide for expansion, so that the fit is not affected by cold or warmth.

Turning a Recess on the Insidé of a Rough Casting

For the cast-iron pistons a complete line of patterns is carried in stock, and the rough castings are first machined by turning a recess on the inside of the skirt to form a seat for plugs used in locating the piston during the subsequent lathe operations. The set-up of the Hendey lathe in which this operation is performed is illustrated in Fig. 1. The work is chucked in a four-jaw chuck and the recess is turned by a high-speed bit held in an Armstrong tool-holder.

Boring Wrist-pin Hole and Turning Piston-ring Grooves

Fig. 2 shows two lathes, arranged back to back so that the pistons may first be drilled and bored for the wrist-pin in the American lathe shown in the foreground, and then passed to the Worcester lathe at the rear, in which the ring-grooving and turning operations are performed. For wrist-pin boring operations, a fixture of similar design to that shown in Fig. 2 is used in various repair shops. The fixture is keyed to the faceplate of the lathe, and on its main casting are two projecting lugs, one of which has provision for attaching a finished plug of the size required to fit in the turned recess of the piston. A central line is scribed on the piston and a similar line on the locating plug, so that when these two lines are brought into coincidence the work is centrally located. The lug at the closed end of the piston carries a square-head screw for securely locating the work against the plug while the hole is being drilled and bored. An Armstrong boring-bar with a high-speed bit is the tool used in the boring operation.

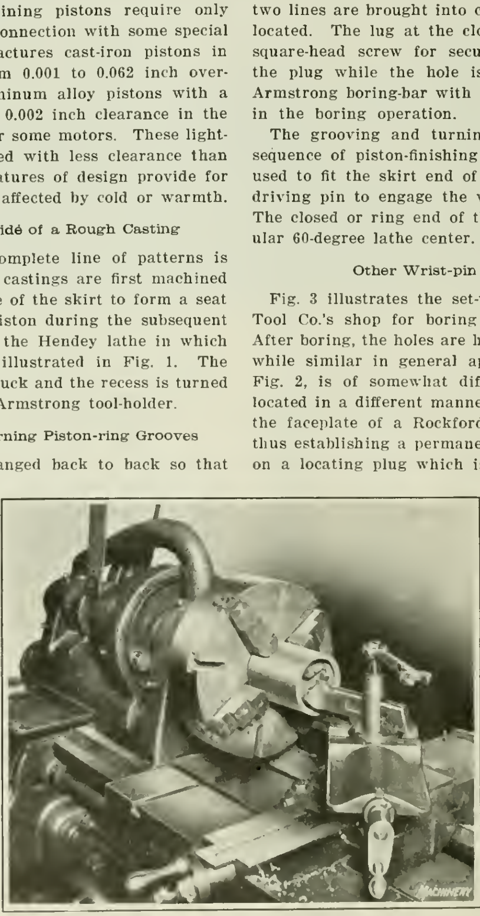


Fig. 1. Turning an Internal Recess on a Rough Piston

The grooving and turning operation is the next in the sequence of piston-finishing operations. A special center is used to fit the skirt end of the piston which also carries a driving pin to engage the wrist-pin lugs within the piston. The closed or ring end of the piston is supported by a regular 60-degree lathe center.

Other Wrist-pin Hole Boring Fixtures

Fig. 3 illustrates the set-up used at the Nixon Broach & Tool Co.'s shop for boring the wrist-pin holes in pistons. After boring, the holes are hand-reamed to size. The fixture, while similar in general appearance to that illustrated in Fig. 2, is of somewhat different design, and the work is located in a different manner. An angle-plate is attached to the faceplate of a Rockford tool-room lathe by dowel-pins, thus establishing a permanent location. The skirt end seats on a locating plug which is fitted in the fixture to accommodate different sizes of pistons. An arbor *A*, one side of which is milled flat, extends through a sleeve *B* in the angle-plate and is prevented from turning during the boring operation by a slab attached to the inside of the sleeve by two machine screws. The arbor extends through and into the piston and at its extreme end carries a V-block which operates against a coil spring interposed between its back surface and a shoulder on the arbor. The V-block seats on the wrist-pin bosses and holds the piston firmly while it is clamped from the closed end by a screw in strap *C* carried at the extremities of two tie-

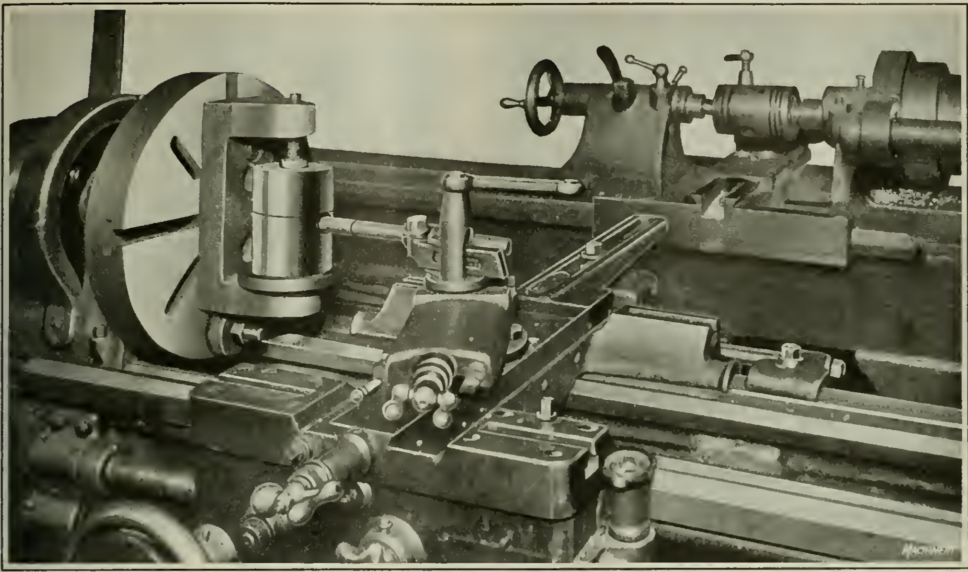

Fig. 2. Two Lathes, One equipped for boring the Wrist-pin Hole in Pistons and the Other for turning the Piston-ring Grooves

rods attached on each side of the angle-plate. This fixture, with proper locating plugs for the skirt end of the pistons, constitutes a self-centering device for any size piston.

The practice followed in the Saucke Bros. repair shop for finishing wrist-pin holes is not materially different from that in the two preceding cases. In Fig. 4 is shown a Davis lathe, to the faceplate of which a V-block fixture is attached. The piston is located in this V-block and adjusted by screws at the ends as required for centering it. A strap and two tie-rods are employed to secure the work in the V-block. The piston holes are first drilled, then finish-bored with a high-speed bit boring-bar, and finally finished by hand-reaming. The pistons furnished on repair work by this concern are manufactured from soft gray iron, the castings being made from their own patterns and afterward seasoned and heat-treated by bringing to a cherry red in a charcoal fire and allowing to cool with the charcoal embers.

Facing the Wrist-pin Bosses on a Drilling Machine

Inasmuch as the refitting of cylinders with over-size pistons sometimes involves the complete machining of the piston from the rough casting, it may be well to follow through some of the other operations in the Frostholm Bros. shop where this practice is followed. In Fig. 5 the operation of facing the bosses which surround the wrist-pin hole on the inside of the piston is illustrated. This work is done on a Barnes drilling machine, equipped with a sub-press type of V-block fixture. The posts of the base of this fixture carry a cast-iron clamp, which may be raised and lowered to suit different diameters of pistons, and clamped by knurled nuts. The clamp contains a finished central hole in which the shank of the piloted cutter-bar is guided. The cutter is a double-facing tool and is fed in alternate directions as required to face each boss. The bar extends beyond the cutter and acts as a pilot at the lower end to assure parallelism between the faces.

Finishing the Outside Diameter

The outside diameter of the pistons is first finished by rough-turning. They are then heat-treated, after which they are machined to within 0.010 inch of size. The skirt of a piston is usually ground straight, and at the head, where

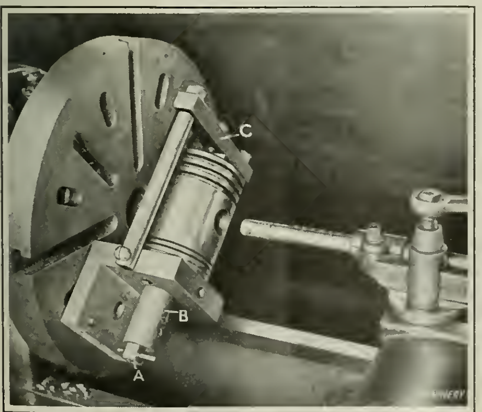

Fig. 3. Fixture for holding Pistons while finishing Wrist-pin Hole

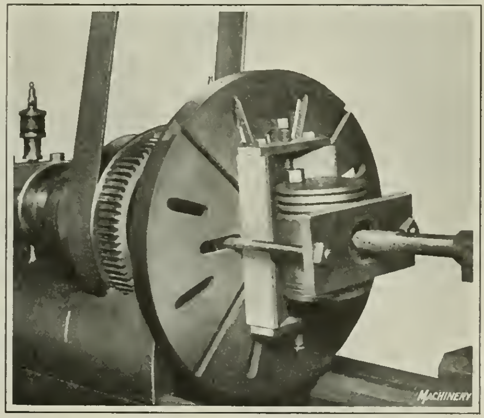

Fig. 4. Method of holding a Piston while boring the Wrist-pin Hole

Fig. 5. Drilling Machine and Fixture used for holding Pistons while facing the Wrist-pin Bosses

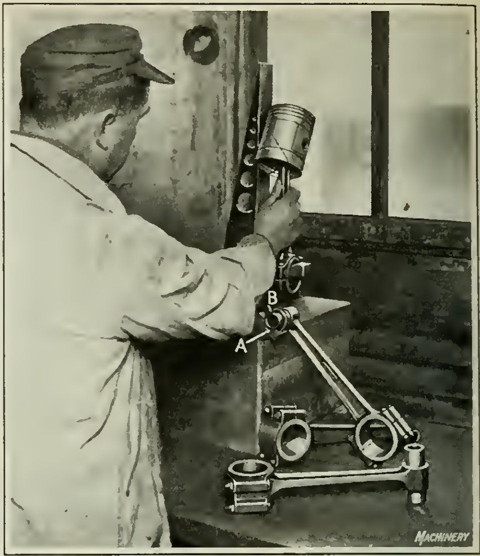

Fig. 6. Testing the Alignment of the Assembled Piston and Connecting-rod

the ring grooves are, it is necessary to grind to smaller diameters, reducing the size in steps toward the top of the piston. As there is more metal in the top, it is natural that it will expand more. The grinding is done on a No. 2 Brown & Sharpe cylindrical grinding machine, on the driving head of which a special taper center is used to engage the skirt end and drive the work, as shown in Fig. 7. For this operation a 12-inch diameter, 1¼-inch face aloxite wheel, made by the Carborundum Co., 24-36 grit, N grade, is used.

The practice followed by the Nixon Tool & Broach Co. in machining pistons is first to turn them to within 1/32 inch of the required finished diameter and then heat-treat them to remove the strains. After heat-treatment, they are finished by grinding on any standard cylindrical grinder, the rough-grinding operation removing stock to within 0.003 inch of the finished size. For both the finishing and roughing a 36-J Norton grinding wheel is used.

Testing Pistons and Connecting-rods

After the pistons have been finished and before they are reassembled in the motor, they are fitted with the proper size wrist-pins and assembled on the connecting-rod preparatory to testing for alignment. For this work Frostholm Bros. use a Dyer piston aligning gage in the manner indicated in Fig. 6. This illustration also indicates how the connecting-rod is tested before the piston is assembled. There are a number of connecting-rods shown on the bench with the piston-pins in place, and one of the piston-pins carries a parallel A, in one side of which a V-groove is cut in which the wrist-pin is seated by a coil spring *B* looped over it. This simple device is slipped on the end of the pin, and the connecting-rod placed on the fixture, as illustrated, in the same manner as when the piston is assembled.

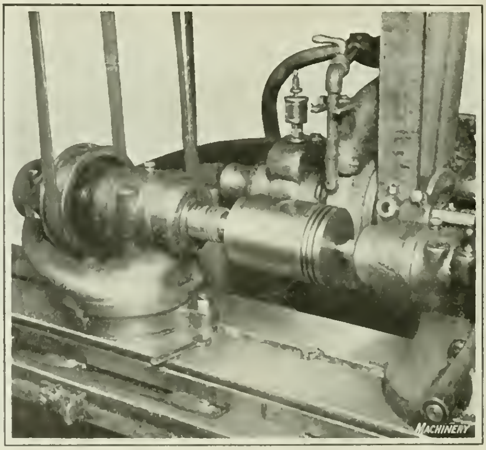

Fig. 7. Finishing the Outside of a Piston on a Cylindrical Grinder

If the test of parallelism and twist of the crankpin and wrist-pin holes is satisfactory, the surface of the piston is tested relative to the crankpin in the manner shown. By tipping the piston and moving the connecting-rod so that the surface to be tested passes by the vertical gage surface, and watching for the appearance of light as the two surfaces are brought into contact, the amount of deviation from perpendicularity with the crankpin hole is readily detected. For straightening the connecting-rod to overcome any inaccuracy that may exist, either a vise with special jaws or an arbor press may be employed, according to the equipment available in the repair shop.

* * *

STATISTICS ON MACHINE BUILDING FOR 1921

The Census Bureau has begun to collect statistics for the year 1921 covering machinery of various classes, including machine tools and metal-working machinery. The 1921 statistics will be made very complete, provided the Department of Commerce obtains the necessary cooperation from the various manufacturers in this field. The success and value of the statistical information will depend largely upon the rapidity and accuracy with which manufacturers make the reports asked for by the Department. Blanks will be sent out to all the manufacturers in the field to be filled in and returned to the Bureau of Census. The information thus obtained, when collected and tabulated, will be of value to everyone in the entire machine-building field, and for that reason the data necessary to compile these statistics should be freely given.

The French Machine Tool Market

By W. P. MITCHELL

Paris, January 10

RECONSTRUCTION of industry since the armistice has demanded all the new equipment that economic conditions would permit; but it has been the French policy to discourage purchases from abroad, assuring buyers that the French machine tool industry would be capable of furnishing equipment equal to that imported either from the United States or Germany, the two chief sources for both metal-working and woodworking machinery in France.

It was for this reason that after the armistice extensive transformations were made in many war industries with a view to supplying both the home and the export market with machine tools of French manufacture. Since that time these transformed war plants have produced—in some cases merely attempted to produce—in addition to metal-working and woodworking machinery of all classes, a great variety of mechanical accessories to modern life and industry, from sewing machines and typewriters to molding machines for foundries, and grain- and coal-loading equipment for docks and warehouses. Today there is a list of at least two hundred French manufacturers, making some types of machine tools, advertising their product in the technical and daily press, each competing with a product hitherto imported.

Since the armistice there has also been a great increase in the imports of machine tools. The market of France has proved itself susceptible of a development hitherto not believed possible. Yet many French manufacturers would have added still further to their machine tool equipment had they not been prevented from making any but the most urgent purchases by the present high cost, because many manufacturers realize the necessity of modernizing their plants. American machine tools, to be paid for by what the Frenchman calls a "three-dollar dollar," suffered more than the substitute home product when the latter was available, but even the home product price, as compared with the price before the war, was based upon at least a "two-dollar dollar," and often more. There remained the possibility of finding what was wanted in Germany. With a natural aversion to pouring gold francs into Germany to take the place of paper marks many French manufacturers would not buy from across the Rhine, but turned to Switzerland, Denmark, and Holland, often even then obtaining a German product.

French Trade with Germany

Germany, for the moment, is the natural source of supply for the varied industries of France. Owing to the low value of the mark as compared with American and English money, obviously that is where France will buy, and the recent Wiesbaden conference has aided this tendency.

During the first six months of 1921 France imported from Germany machinery and tools to the value of nearly 400,000,000 francs, whereas from the present almost inexhaustible resources in iron ore, France sold to Germany in the same period only 100,000,000 francs worth of iron ore, pig iron, and semi-finished iron and steel products. On the face of it, Germany profited, on this one item alone, to the extent of 300,000,000 francs.

French Trade with the United States

A comparison is made in the following between the imports into France from the United States during the first six months of 1920 and the first six months of 1921; and also between the exports from France to the United States for the same period. The values are given in francs.

IMPORTS INTO FRANCE FROM THE UNITED STATES

	1920 Francs	1921 Francs
Machinery of all kinds	351,835,000	259,587,000
Tools and hardware	84,650,000	22,869,000

EXPORTS TO THE UNITED STATES FROM FRANCE

	1920 Francs	1921 Francs
Machinery of all kinds	1,750,000	4,154,000
Tools and manufactures of metal	3,277,000	27,200,000

These figures should be carefully studied. Exports from the United States to France decreased more than 150,000,000 francs, while French exports to the United States increased in a remarkable ratio. France exported in 1921 more tools and manufactures of metal to the United States than she imported. The low figures for the exports of machinery to the United States indicate that France is not equipped to produce machinery to compete in price with American products. That this is true is evident from the fact that France still continues to import many classes of machinery from the United States, paying 50 per cent or more over the price of the French product. The main cause for the falling off of American imports is undoubtedly German competition.

French Machine Tool Requirements

There is a greater appreciation of up-to-date and efficient machine tools than ever before. The French customs figures indicate the change between yesterday and today. The importation of machine tools in 1913 amounted to 48,000,000 francs, or 23,735 metric tons. Of this, 12,512 tons came from Germany.

In 1919 the imports of machine tools into France rose to 226,000,000 francs, or 33,504 metric tons. In 1920 the imports were 384,000,000 francs, or 56,940 tons. During the first eight months of 1921, the latest for which complete figures are available, a falling off due to the general economic conditions is noted, yet the imports were 49 per cent above the imports in 1913, the comparison being on the basis of tonnage. While there has been a drop in the imports, it is not believed that this is caused by the absorption point of the French market having been reached. It is partly due to the French manufacturers' supplying the domestic market.

There are no statistics available to show the quantity or value of French machine tools actually produced, but the export figures give some indication of the status of the industry in 1913 and its later growth. In 1913 the exports of French machine tools amounted to 4600 tons; in 1919 to 3600 tons; in 1920 to 8700 tons; and in the first eight months of 1921 to 5250 tons (or the equivalent of about 7900 tons for the entire year).

With high tariffs intended definitely to protect this new industry and the low value of the franc as compared with the dollar, it is easily seen why American machine tools are not readily sold in France. The French manufacturers, in spite of the high cost of raw materials and wages, transportation, and fuel, have taken advantage of the situation, and are not likely to give up their competitive position in the future. France, with the reannexation of the mineral resources of Lorraine, and the acquisition of the admirably built German steel plants there, must develop home industries for utilizing all of this to the best advantage. This means to sell, not raw materials or unfinished iron and steel, but the highly finished product. This is the keynote of the French policy in the metal-working field. In the machine tool industry, the results may already be noted.

Assembling Watch Pinion Bearings

Methods and Equipment Employed by the Waltham Watch Co., Waltham, Mass.

THE bearings for the pinion staffs of a watch consist either of nickel composition bushings and jewels for the cheaper grade of watches or of jewels entirely for the better grade. The bearings are staked into the pillar plate to support the lower pivoted end of the staff, while the upper bearings are assembled into the top plates. Before the assembling process is performed, it is important to so grade the staffs and the jewels in which the pivots have their bearing that the least possible amount of play is produced, and yet so that the pinions can run freely.

Some interesting methods are employed for this assembling process in the plant of the Waltham Watch Co., Waltham, Mass. First, a special dial gage, shown in Fig. 2, is used to measure the diameter of the staff at the point where the bushing or jewel is to fit. The gage has a stop for locating this point, and a staff carrying a wheel *A* is placed between the jaws of the gage and against the stop for determining the measurement. In connection with the inspection work, a blank form is used, which is ruled into squares, there being one square for each of the two bearings of every staff that is to be assembled. There are ten vertical rows of squares to accommodate lots of ten watches which go through the assembling process at once.

The selective assembling methods used are as follows: The plates, wheels, and other parts are delivered to the assembling bench in trays such as shown at *B*, each of the compartments being numbered. As soon as the diameter of a pivot has been determined, it is entered in a square of the blank form referred to, this square being in the vertical column corresponding to the compartment of the tray from which it was taken and opposite the name of the staff. Thus, if the upper pivot of a balance staff were gaged, and if this pivot wheel were taken from the first compartment in the tray, the entry would be made in the square at the upper right-hand corner. After all the pivots have been thus gaged, recorded, and placed back in the tray, the work is delivered to another bench where the jewels are selected for each pivot bearing. The special forms, with the entries made at the previous bench, accompany the tray, and when the proper jewels have been selected they also are placed in small compartments of the tray and passed on to be assembled.

The jewels are contained in small glass vials, as shown in the illustration, each of which is properly labeled to designate the staff for which the jewels are to be used and the size of the hole. All the jewels which are to be used for a particular set of bearings are graded by steps of 0.0005 centimeter (about 0.0002 inch) and by following the notations previously made on the form, the proper vial from which to select the jewel can be determined. After the jewel has been taken from the vial, it is gaged by a graduated needle gage *C* for diameter of hole, after which it is placed on the particular square which will indicate a running allowance between the hole of the jewel and the gaged pivot of the staff of 0.001 centimeter. The unit of measurement used at the Waltham Watch Co.'s factory is the centimeter. Fig. 2 shows a number of these jewels properly located in the squares of the blank form referred to.

Fig. 1. Presses on which Watch Jewels and Bushings are staked in the Plates

In addition to the determination of the running qualities between the pivot and the jewel hole, the degree of fit between the outside diameter and the hole in the plate in which the jewel is assembled is also inspected. The jewels, or bushings, as the case may be, must fit into the hole and still be free to move up or down. This establishes only one limit, that is, the upper limit, but if the jewels are too loose this will be discovered when they are being staked into the plates. Some of the jewels are set into the plate by being screwed in, while others are staked by the use of small bench presses, as shown in Fig. 1.

Staking Jewels and Bushings

The jewels in the lower plate are staked first, an air-operated press such as shown at *A* being employed. The punch must, of course, be long enough to extend through the bearing holes in the upper plates and reach the lower plate. The holder for locating the watch plate and its assembled parts consists of a flat disk with posts by means of which the watch assembly is positioned. After the watch has been thus located, a ring is screwed down to hold it securely in place. One of these holders is shown on the bench at the right of the press with the ring removed, and another on the table of the press at *B*, in readiness to have the bearings staked. The vertical posts of the main disk of this holder are of such height that they form the locating surfaces against which the jewels are pressed while being staked into position. Au air pressure of fifteen pounds is used in this operation.

For the upper plates a foot-operated press *E* is used. This press is equipped with a sapphire punch so as not to abrade the jewel when pressure is exerted during the staking operation. It is necessary to predetermine the distance between the face of the sapphire punch and the jewel, and this is done by locating the assembly on a disk by means of posts, as in the staking of the lower jewels, and then safeguarding against crushing the jewel by the use of a special stop for the punch which is independently set for each bearing. This adjustment is secured by pressing down the knob shown at

Fig. 2. Equipment used for inspecting Watch Staff Pivots and Jewels

the top of the press, against the tension of a coil spring until the sapphire punch seats firmly on the vertical post of the locating disk, in which position it is secured by swinging the yoke *C* into position for locking the punch at the predetermined height. When the foot-treadle is depressed, pressure is transmitted through a toggle lever which bears against a stop-pin *D*, and raises the table to keep the amount of pressure within the crushing strength of the jewel. A graduated dial *F* is used to set the stop-pin accurately. The connecting-rod which joins the toggle lever to the foot-treadle is shown extending through the bench at the rear of the press.

SETTING UP LARGE WORK FOR PLANING

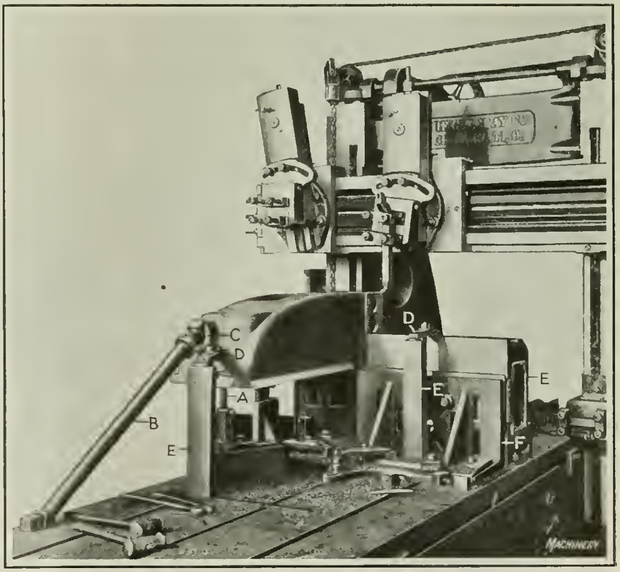
There are few types of machine tools that are required to handle as wide a range of work as planers. The methods of setting up these different classes of work naturally vary according to the size and type of the pieces to be planed. In setting up large castings, a considerable amount of ingenuity is often required to provide a sufficiently rigid support for the work in order to prevent it from springing.

Cast iron and other metals may sometimes be sprung out of shape through the application of relatively small loads. Such a deflection of the work produced by the pressure of the cutting tools on a planer may assume the form of either a temporary strain or a permanent set, but in either case the dimensions of the planed piece are almost sure to be seriously affected in cases where a high degree of accuracy is required; and to avoid trouble from this cause, it is necessary to take the greatest care to see that all overhanging parts of the work are well supported to prevent deflection. The accompanying illustration shows a good example of a set-up in which adequate provision is made for the support of the work. Here the body of a gear-cutting machine is shown set up on a G. A. Gray planer in the Brown & Sharpe plant. When the casting is delivered to the machine, the bearings have been planed for the cutter-head slide and for the work-holding spindle-head slide, in addition to some other surfaces, so that these may be used as locating points.

As set up on the planer the column that supports the work-spindle head of the finished gear-cutting machine overhangs in a manner that would be likely to cause serious deflection, if especial care were not taken to support the casting at this point. For this purpose there is a jack-screw *A* which may be adjusted under the casting to carry the weight of the overhanging part and any additional load imposed by the pressure of the tool. The work is further supported by an inclined jack *B*, at the lower end of which there is a wedge-shaped block that bears against a plug set in one of the table clamping bolt holes, while at the upper end there is a screw-operated V-block that enters hole *C* in the work. This inclined jack serves the double purpose of supporting both the vertical load and the horizontal thrust of the planer tool. The casting is held down on the planer table by two bolts and straps *D* arranged in such a way that one end of each of these straps bears on the work, while the opposite end is carried on a vertical strut made of a piece of 2- by 4-inch timber *E*. The bearing for the cutter-spindle head is bolted against angle-plate *F*, which is secured to the table by straps.

* * *

According to Census figures, 246,139 tractors were in use on farms in the United States at the end of 1919, and the farm equipment production and sales statistics of the Department of Agriculture show that 162,988 tractors were sold in 1920, so that a total of about 400,000 tractors are now in use in the United States. There are still 2,000,000 farms which represent prospects for the sale of tractors.



Method of setting up Large Castings for planing

Cutting Costs with Riveting Hammers

By FRED R. DANIELS

SEVERAL examples of cold-heading and rivet-setting operations performed on high-speed riveting hammers made by the High Speed Hammer Co., Inc., Rochester, N. Y., are illustrated in this article. One of the reasons that a high-speed riveting hammer is a valuable cost-reducing factor in metal-working plants is that the machine is easy to operate and regulate, so that boys and women are able to turn out as satisfactory a product as the more skilled machinist. The riveting hammer referred to consists of three main units—a pedestal, an attached hammer-head, and an adjustable anvil support. The hammer head carries a friction drive on one side and a pulley that revolves the spindle of the machine on the other, both being mounted on the crankshaft that actuates the hammer movement of the heading tool. The shock of the blows delivered is absorbed by the use of a hickory helve and large rubber bumpers.

The principle of hand riveting is incorporated in this machine in that the cold metal is caused to flow under repeated blows. The force required in delivering these blows for different classes of work is under the control of the operator through the friction clutch and foot-treadle by means of which the machine is operated.

The applications of the riveting hammer mentioned in the following are only examples of the wide field in which this type of hammer is in common use. For the delicate work required in typewriter construction and in the manufacture of camera parts and electrical apparatus, the high-speed hammer is regularly used. When parts are riveted with a hinge joint and freedom of movement is the prime requisite, the possibility of controlling the force of the blows permits rivets to be set without closing the hinge and causing the leaves to bind.

When rivets are pressed into place before riveting, two operators may be employed for the assembling and the riveting operations, one to press or hammer in the rivets and the other to do the riveting. Often the rivets are not a press fit, but may be assembled by hand in the parts to be riveted, and the work thus assembled passed to the riveter. In this case a boy can do the assembling work and keep the riveting machine in constant operation.

Riveting Rear Axle Drive Shaft Caps

The work being done in the set-up shown in Fig. 1 is the cold-riveting of forged steel hub caps to high-carbon steel rear axle drive shafts, 1 1/4 inches in diameter. The nature of the work performed in this operation is indicated at *A* in Fig. 3, from which it will be seen that the shaft extends 3/16 inch beyond the end of the cap, this metal being cold-riveted into the countersunk hole in the cap. This is an example of heavy cold-riveting, the work being done in the plant of the Reo Motor Car Co., Lansing, Mich. For work of this kind it will be readily understood that the peen must be properly shaped to fit the curvature of the cap so that as the tool revolves the rapid elastic blows will set the end of the shaft down even with the curvature of the cap. The work is seated on a special fixture and chucked from within

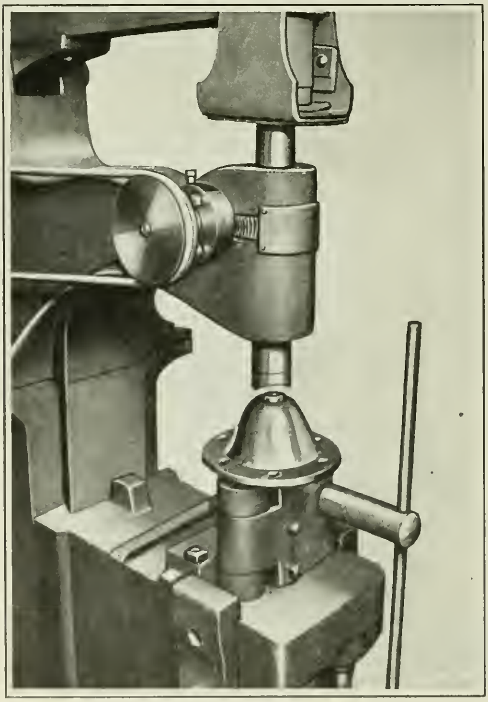


Fig. 1. Set-up for riveting Rear Axle Drive Shafts over Hub Caps

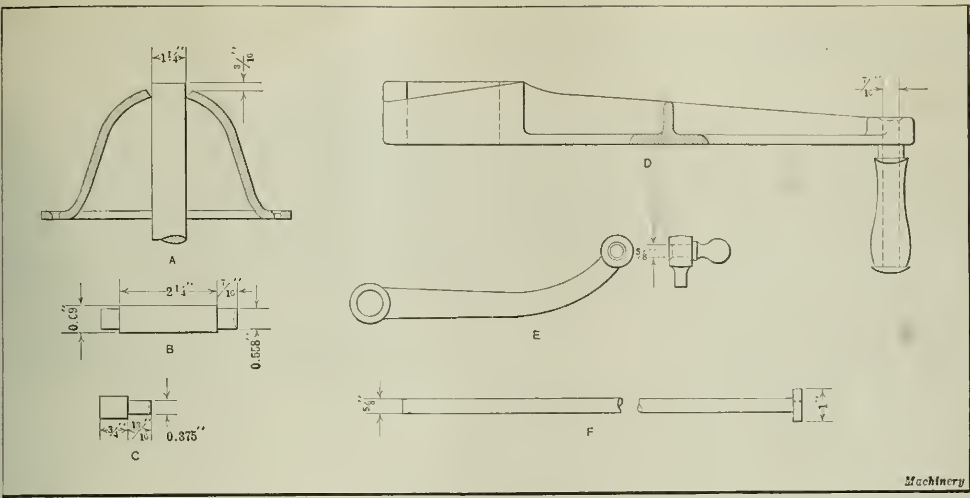

Fig. 3. (A) Shaft and Hub Cap before riveting; (B) Pin used in Differential Gear-case; (C) Wire Wheel Hub Flange Pin; (D) Automobile Crank-handle; (E) Pitman Arm; (F) Drill Rod with Cold-rolled Steel Head

by simply turning the lever-handle a part revolution. The work was formerly done by hand, by which method neither uniformity of product nor speed were realized. Using the sledge hammer the production time was four minutes per shaft; with the machine and set-up illustrated, the time is one minute per shaft.

Operations on Differential Gear-cases

Another manufacturing operation in the automotive industry is illustrated in Fig. 2; this is the riveting of eight heat-treated steel studs in automobile differential gear-cases. This also is a heavy riveting job. The work, which is performed in the New Process Gear Corporation's plant, Syracuse, N. Y., consists first of loosely assembling the side plates, pinions, and studs. These studs are 0.558 inch in diameter on the end to be riveted, as shown at *B*, Fig. 3. With the gears and studs loosely assembled in the plates, the work is placed on a fixture and a locking pin inserted through the central hole to align the gears while the first stud is riveted. After the first stud is set, the locking pin is withdrawn and the differential gear-case turned around to rivet a second stud located diametrically opposite the first stud. The operation continues from side to side in pairs until eight rivets have been headed over on the upper side of the case; then the work is reversed and the sequence repeated on the opposite side. During the riveting operation the gears are constantly manipulated by the riveter to detect any tendency for them to bind. The production for one man is from eight to ten completely assembled gear-cases per hour or an average of 144 headed studs.

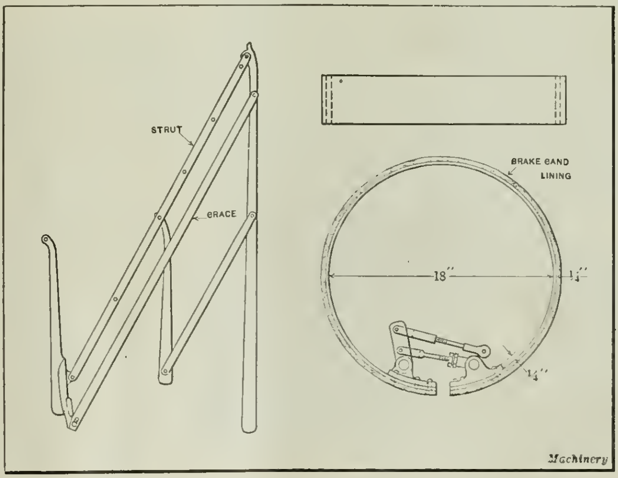

Fig. 4. (Left) Side Frame for an Automobile Top; (Right) Friction Brake-band

Application to Wire Wheel Manufacture

Many of these hammers are in use in the manufacture of automobile wire wheels in which their most common application is for riveting the six steel pins in the hub flanges. In one shop this job is handled by two men, one driving the pins into the flanges, and the other setting the rivets. In this way a satisfactory production rate can be obtained.

In another shop, the work is performed by one workman, the operation consisting of cold-heading six steel pins such as shown at *C*, Fig. 3. It will be seen that the end to be riveted is 3/8 inch in diameter. A fixture plate may be used to hold the rivets in the hub flange in the correct position for riveting after they have been pressed into the holes. The pins are set flush with the face of the flange which, of course, requires a straight-end peen. The production with one man working alone, is 75 hubs per hour, not including the assembling of pins, or 450 pins headed in one hour.

Riveting Crank-handles and Levers

At *D*, Fig. 3, is shown an engine starting crank on which the riveting operation is the setting over of the pin that passes through the wood handle. These steel pins are 7/16 inch in diameter, and some time is consumed in assembling them in the handles. The riveting operation is slowed up, because of the fact that more attention must be given to holding the overhanging end of the crank up at right angles to the face of the peen. The production is 75 cranks an hour.

The riveting of a nickel steel ball-end into a forged steel pitman arm for an automobile steering gear requires the use of a large size hammer. The hammer used for this purpose in one plant is equipped with a special anvil in which the ball-end fits while the head is being set. A diagrammatic view of the assembly of a ball-end and pitman arm of the type referred to is shown at *E*. The diameter of the shank to be riveted is 5/8 inch and it is pressed into the arm on an arbor press, leaving about 1/8 inch projecting to form the rivet head. The head is rounded to 3/4 inch diameter, using an oval-head peen, at the rate of 440 per hour.

The setting of a cold-rolled steel head 1 inch in diameter on the end of a 5/16-inch drill rod is a good example of machine riveting. This unit, which is shown at *F*, forms a driver used in the construction of nailing machines for box manufacture. It will be noticed that the drill rods are comparatively long and slender, and they must be firmly clamped on end during the riveting operation. The type of vise used for this purpose encloses the rod and is split longitudinally, being readily tightened on the rod by a hand-lever.

Riveting Brake-brands

The brake-band shown at the right in Fig. 4 is made of steel 1/4 inch thick, and is 18 inches in diameter. It is covered with a brake lining which is assembled to it by copper rivets, this being a hand operation. The brackets that hold the lever-and-link device have a foot 1/4 inch thick through which the brackets are riveted to the steel band. The illustration shows the position of these brackets after assembling. Steel rivets 1/4 inch in diameter are used, sixteen of these being required to assemble both brackets. The production is 304 headed rivets or 19 brake-bands per hour.

Power Riveting in Chain Manufacture

Riveting the ends of pins on which the steel links of silent chains are assembled is regularly performed on the high-speed riveting hammer. The pins used in the particular size of chain illustrated in Fig. 5 are 9/32 inch in diameter, and the width of the chain is 4 inches. The riveted head is set over a washer and the operation must, of course, be so performed that freedom of movement is obtained between the links and spacers of the chain. The average production on this kind of riveting is 600 pins per hour.

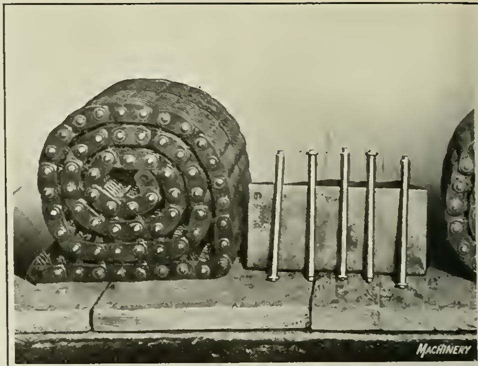

Fig. 5. Coil of Link Chain and Pins on which the Steel Links are assembled

Automobile Top Frame Riveting

The braces, posts, struts, etc., which go into the side frame of automobile tops are assembled by riveting, and practically all this work is done on power-driven machines. One example of work of this type is shown in Fig. 6 which illustrates the operation of riveting malleable iron forged clips to a frame post. This post goes into the frame of a Chevrolet automobile top, the work being performed in the American Forging & Socket Co.'s plant at Pontiac, Mich. The post is made of sheet steel with beaded joint, and is prevented from collapsing during the riveting operation by inserting a mandrel by which one end of the work is held, while the post rests on the specially formed anvil. Two flat-head rivets, 7/32 inch in diameter by 7/16 inch long are used to assemble these clips, the rivets being inserted in place by a boy or woman who then hands them to the riveter to be set down. In operations of this kind when it is necessary to handle the work in this way, a production of 2000 pieces in a nine-hour day is considered very satisfactory.

At the left in Fig. 4 is shown the assembly of the side frame for an automobile top. The operation to which attention is here directed is setting the seven long rivets in the strut and the short one in the lower end of the brace. Rivets of different lengths are headed without changing the dies. This is accomplished by the use of two anvils which are operated to bring them into alignment with the peen by a foot-treadle. Two of these side-frame assemblies constitute a set, and the production is 250 sets per nine-hour day, or a total of 4000 rivets daily. This operation shows the possibilities of riveting work of an irregular or peculiar shape by the use of special mechanical devices and fixtures for holding the work.

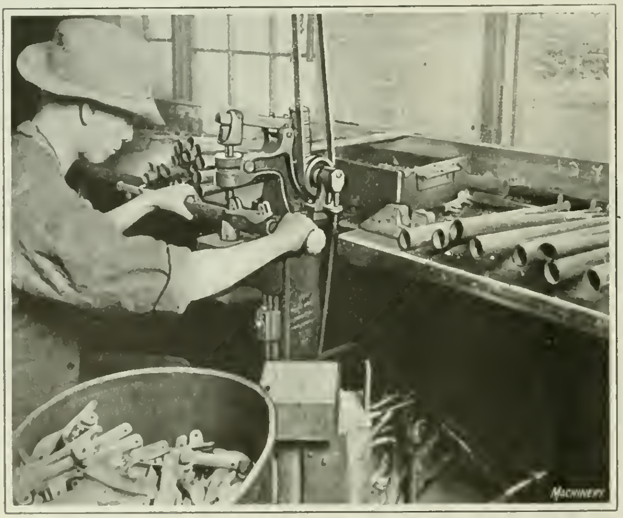

Fig. 6. Using Power Riveting Machines in the Manufacture of Automobile Top Frames

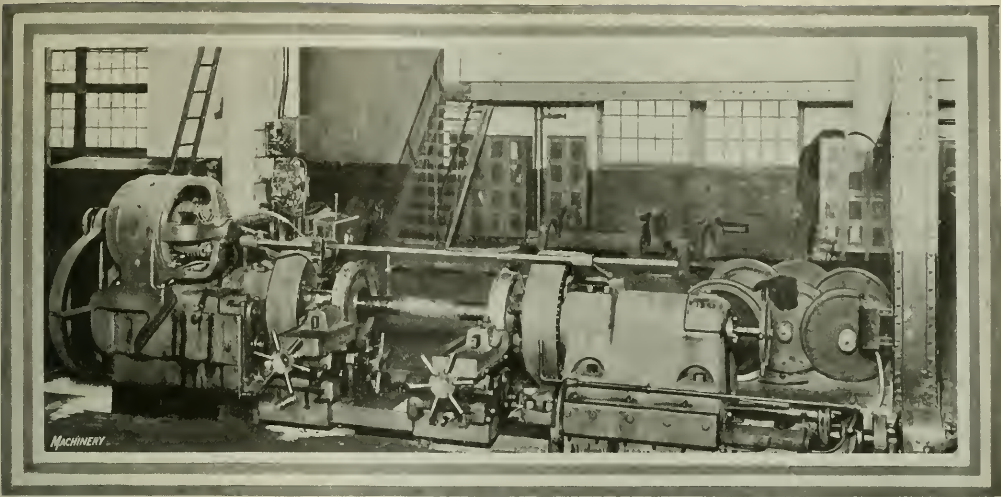
Power Riveting on Agricultural Implements

The riveting hammer is a common machine in the agricultural machinery plant. It is used in the making of malleable iron chains, shoe runners, mowing machine pitmans, and various other parts. In the plant of Henry & Allen, Auburn, N. Y., malleable iron ends are riveted to mowing machine pitman arms using eight 1/4-inch rivets, four in each side. The heads are set at the rate of 400 per hour, 50 pitmans being completed every sixty minutes.

* * *

The use of treated wood block floors in factories, machine shops, foundries, and mills of various kinds, showed an increase in 1920 of over 80 per cent as compared with the 1919 figures, according to the Service Bureau of the American Wood Preservers' Association, Chicago, Ill. Creosote oil and creosote coal-tar paving oil were used as preservatives.



Electric Drives in Railroad Shops

Selection of Motors—Types of Motors—Application on Different Kinds of Machine Tools

By BERTRAM S. PERO, General Electric Co., Schenectady, N. Y.

INDIVIDUAL electric motor drive becomes practically a necessity in a railroad shop, because of the various machine tools required, and the nature of the work performed. This form of drive allows free use of overhead cranes, unrestricted location of machine tools, low maintenance, and provided the correct electrical equipment is used, high efficiency. As an illustration of the advantages, two views of the same woodworking shop are shown in Figs. 1 and 2. These might be called "before" and "after," respectively. The transformation has really enlarged the shop and increased the possible production of each machine, because the belt slip has been eliminated.

Selection of Motors

In selecting the electrical equipment for any shop, it is well to keep in mind a few general principles. A system using alternating-current motors on all constant-speed machines, with direct current for the remainder is probably the best. The second choice is direct current, because any machine tool can be successfully driven by this type of motor. If alternating current only is available, individual drive is still most desirable, even though there is no satisfactory commercial adjustable-speed alternating current motor, and gears must be used to obtain different spindle speeds.

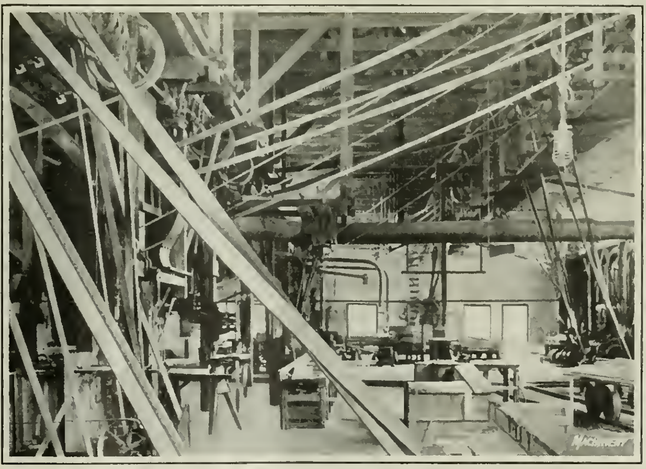


Fig. 1. View of Woodworking Shop before Installation of Motor Drives

Many machine tool manufacturers provide for speed changes through gears built as an integral part of the machine. This scheme allows a constant-speed motor to be used in many applications, but to obtain the speed increments possible with a direct-current, adjustable-speed motor would require an absurd gear combination. Very often, a simple gear change is used with an adjustable speed direct-current motor to obtain a wide speed range.

The squirrel-cage and wound-rotor alternating-current motors are the two forms generally used. The squirrel-cage motor is practically a constant-speed machine, and should be used for driving machine tools producing a constant load. The wound-rotor motor is capable of exerting greater starting torque with less current than the squirrel-cage type. The so-called "high torque" squirrel-cage motor is similar in appearance to the standard constant-speed machine, the only difference being in the rotor resistance.

Common Types of Direct-current Motors

The three types of direct-current motors generally used are the shunt, compound, and series. The series motor is not employed as extensively as in the

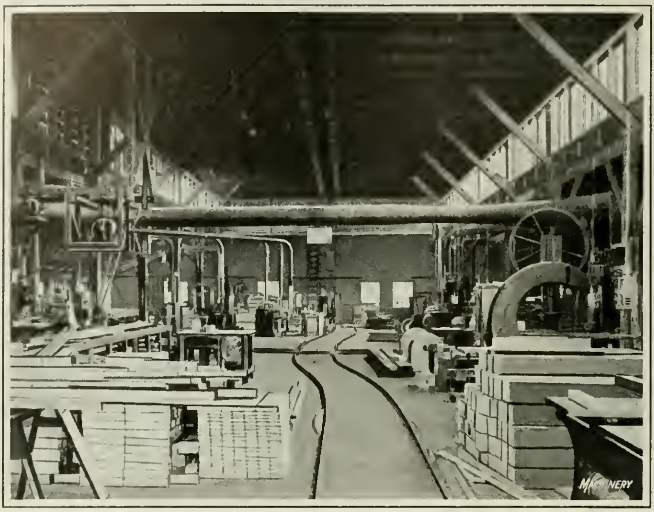

Fig. 2. Shop illustrated in Fig. 1 after Electric Drives were installed

decreased. The horsepower output of an adjustable-speed motor is constant in that the rating at high and low speeds is the same.

Compound-wound Motors

Compound-wound motors, which have a part of the field energized by the armature current, slow down under overloads, and speed up with light loads, due to the varying field strength. This produces a motor with a higher slip than the shunt machine, which is an advantage for certain drives. The average compound-wound motor has fields of which 80 per cent is shunt, and 20 per cent series. This means that with full load there is full field, while with 25 per cent overload, the series portion becomes 0.20 × 1.25, or 25 per cent. This added to the 80 per cent part, which is constant, makes a total of 105 per cent, causing a speed reduction.

High-torque Alternating-current Motor and Wound-rotor Type

The high-torque alternating-current motor is comparable to the compound-wound direct-current machine. This motor to all appearances is like the constant-speed squirrel-cage type, but the rotor is designed to have a greater resistance, producing greater slip at full load and higher torque at starting. When resistance is introduced in the rotor, there will be heat generated proportional to this resistance, and in the larger motors this heat becomes quite a factor; therefore, it is a good plan to use the wound-rotor type, connecting a permanent resistor outside the rotor, so as to obtain an equivalent slip, with the minimum heat inside the motor.

The wound-rotor or slip-ring type of motor is used for variable-speed service as required by cranes, bending rolls, etc. It is brought up to speed by connecting the motor to the source of power and gradually short-circuiting the external resistor connected in the rotor circuit, through collector rings mounted on the rotor shaft. This type of motor is well adapted to starting heavy loads, because the torque per ampere throughout the starting period is greater than that of a squirrel-cage machine. This is because the resistance in the rotor circuit can be adjusted to produce the best torque conditions for each speed during acceleration, whereas the resistance in the squirrel-cage machine is fixed

past. Because the compound-wound motor does not attain as high light-load speeds, it is preferable for general use. The shunt-wound direct-current motor is essentially a constant-speed machine, the slip or reduction in speed from no load to full load being about 5 per cent for the average motor. This factor is inherent in any motor, whether of the alternating- or direct-current type. The speed of any direct-current motor is governed by the rate at which the armature conductors pass through the flux set up by the field magnets. This rate is a product of armature conductors per unit time and flux, and is constant, under definite conditions, in any particular motor. Therefore, in a motor where the field strength is constant, the speed will be constant, and the current will increase rapidly if the load tends to lower this speed.

When the field strength is varied, as for the shunt-wound adjustable-speed motor, a speed variation is obtained, because to maintain the particular "product" or "rate" with a varying field strength, will require a change in the number of armature conductors passing through the flux, per unit time. It is obvious that the armature speed must change to accomplish this. The squirrel-cage induction motor is comparable to the shunt-wound, constant-speed, direct-current motor.

Variable-speed and Adjustable-speed Motors

Variable speed must not be confused with adjustable speed. So-called "variable" speed is obtained (usually with a constant-speed motor) by introducing resistance in the armature circuit. The reduced speeds obtained by this method will vary with each change of load. This is not an economical scheme, because a certain part of the power taken from the line is wasted in heat generated in the resistor. This loss is dependent on the speed reduction, being equal to the output of the motor, when the speed is reduced to one-half. Besides the energy loss in the resistor, the motor output is reduced. The adjustable-speed motor uses a resistor in the shunt field circuit, and while there is a loss in this resistor, it is negligible, because the total energy input to the field is only about 3 to 4 per cent of the input to the motor; furthermore, since the field current is reduced at the higher speeds, this loss is

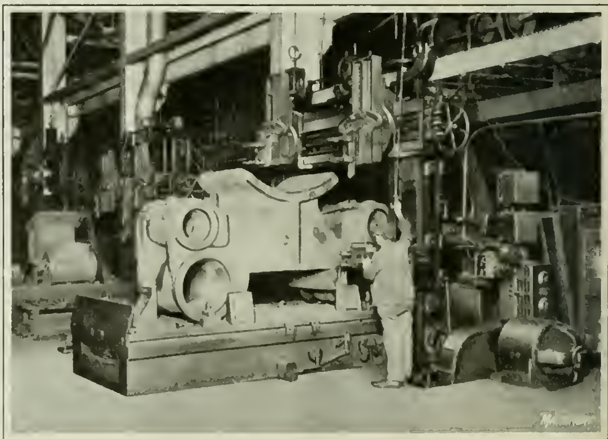

Fig. 3. Planer driven by 25-horsepower Adjustable-speed Reversing Planer Motor

and is comparable to the wound-rotor type of motor at one speed only.

Series Motors

In the series motor, all the field is produced by armature current. It is obvious that with a very light load there is practically no field, and the armature will run at a very high speed to maintain the "product" or "rate" referred to above. Also, with a 25 per cent overload, the field will have a strength of 125 per cent instead of 105 per cent as for the compound machine, and a lower speed will result. Commercial series motors do not produce the same speeds or torques on overload that a theoretical motor would, because the iron used in the fields becomes saturated after a certain flux is produced, and any current in excess of that which will saturate the fields has practically no effect on the field strength. Because of this condition, it has been found more desirable to use a motor with 50 per cent shunt and 50 per cent series on many of the machines heretofore driven by a series motor. The "50–50" motor will produce nearly the same torque per ampere, and has the advantage of a lower no-load speed. Approximately 150 per cent full load speed is obtained on light load.

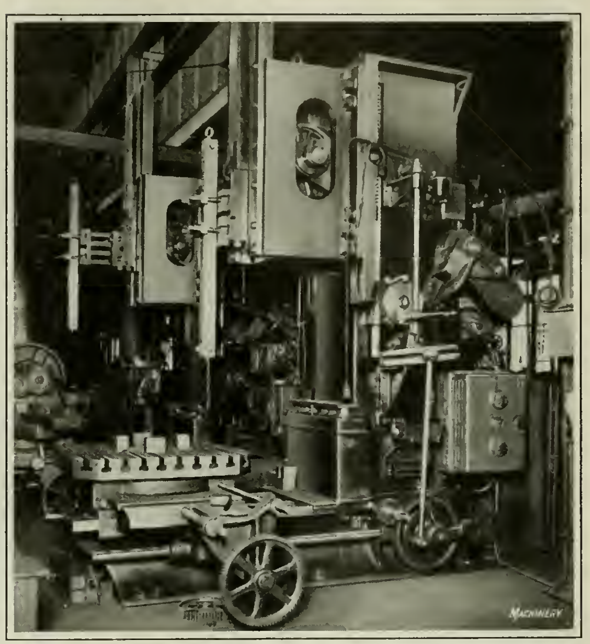

Fig. 4. Slotter driven by 15-horsepower Adjustable-speed Reversing Planer Motor

Motors for Different Types of Machine Tools

In general, machine tools, can be classed in two groups. The first group includes those machines that are used for the purpose of removing metal by cutting tools or abrasives, such as lathes, boring mills, grinders, etc. Practically all machines of this group produce a continuous load, requiring a constant torque for any given condition of speed and cut. These machines should be driven by shunt-wound direct-current, or squirrel-cage induction motors. Because of its freedom from sliding contacts, the squirrel-cage induction motor is desirable for driving woodworking machines; if direct-current motors are used for service of this kind, the fire hazard is increased.

The second group of machine tools includes those machines used for forming or shearing metal, such as punches, bending rolls, etc. Generally, compound-wound motors should be used for driving this class of machines. There are exceptions to this, however, as for example, rotary beveling shears and punch presses used on rapid cycle work, where the load is practically constant for a certain operation, and in such cases a shunt-wound motor can be applied.

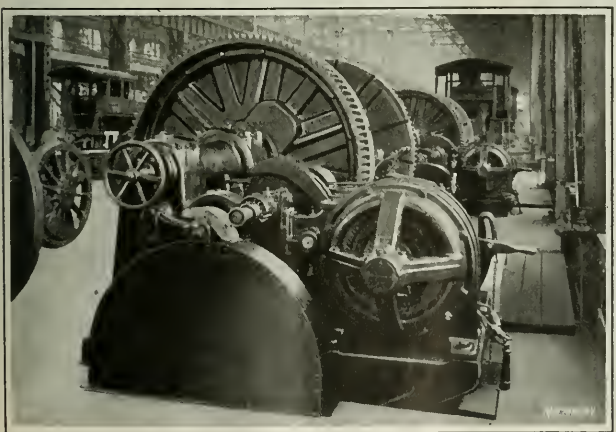

Fig. 5. Wheel Lathe driven by 75-horsepower Wound-rotor Alternating-current Motor

Type of Motor for Machines Having Flywheels

In general, all machines having flywheels which deliver energy during the working period, or machines requiring high torque intermittently, or for "break away" conditions, should be driven by a compound-wound motor. The reason for this application to flywheel machines is to allow the use of a smaller motor, and therefore greater efficiency. We have shown that the compound-wound motor has a greater slip or speed reduction, from no load to full load than the shunt-wound motor, and since the energy delivered by a flywheel is dependent on the speed reduction, a motor with a tendency to slow down with load, will allow a greater reduction in flywheel speed, without injurious overload currents on the driving motor, and enable the flywheel to furnish more energy for the work. After the work stroke is completed and before the next stroke, the motor accelerates the flywheel, thereby restoring the energy consumed. When a motor is correctly applied, it will be delivering a non-injurious overload at the moment the work is completed. This overload decreases as the flywheel attains speed, and then the motor furnishes only the power required for windage and friction load, until the next cycle.

The loads on presses and similar machinery usually last only a very short time, and even though the power required might be high for this time, a comparatively small motor, with several seconds to replace the energy in the flywheel, would take care of the load. Obviously, when the time between strokes decreases, there will be less time to restore the energy to the flywheel and the motor must be of greater capacity, up to the point where the work strokes are so rapid that the flywheel is of very little use, the motor delivering all the energy.

When a load demands high torque for "break away," such as for large lathe carriages, cross-rails, etc., the compound-wound or series motor should be used, because, since the torque developed by a motor is a function of the field strength and armature current, and it has been shown that the field strength of a compound or series motor increases beyond 100 per cent for overload currents, the torque per ampere input is greater in these motors than in a shunt-wound machine. Series motors should never be belted because, should the belt break and remove the load, the motor would attain dangerous speeds.

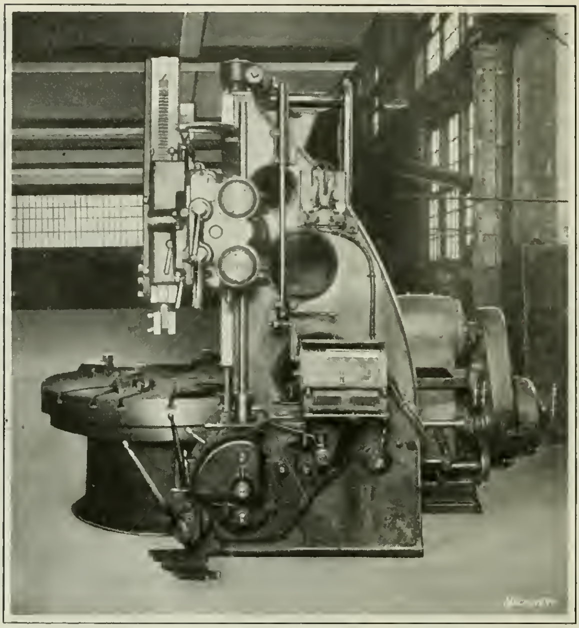

Fig. 6. Boring Mill driven by a 15-horsepower Adjustable-speed Motor

The Type of Control

In selecting the control for any application, it is good practice to arrange to have all control, such as starting, stopping, reversing, and speed changes from one handle or station. This is especially important on machine tools where the operator should watch his work while starting, such as with lathes, boring mills, etc. The controlling station should be convenient to the operator, when he is in the most advantageous position to watch his work.

Open type control should never be used when there is any chance of chips or other foreign matter coming in contact with any of the working parts. Automatic control is applicable to machines performing repeated cycles, such as planers, slotters, etc., or for motors driving pumps, air hammers, wheel lathes, milling machines, etc., but for engine lathes, bending rolls, or any machine tool where a set, or predetermined, speed is not applicable, manual control has been found to answer the requirements best. A control that allows the operator to change to the most efficient operating speed without leaving his work will usually permit the greatest production to be attained.

Under-voltage protection should be provided by the control. This means that if the voltage fails, the motor will not start unexpectedly when the power returns. An equipment without this protection might easily cause an accident. Under-voltage release, which means that the motor will restart, should not be confused with under-voltage protection.

Dynamic braking, which is generally used on reversing equipments, and sometimes on non-reversing control, causes a motor to come to rest, because the motor, driven by the stored energy in the rotating parts of the machine, acts as a generator, and changes the stored mechanical energy to electrical energy, which is transformed into heat in the brake resistor.

Examples of Motor Drives for Machine Tools

The direct-current reversing planer drive shown in Fig. 3 employs an adjustable-speed motor with a speed range of 250 to 1000 revolutions per minute. The motor is direct-connected, which thereby eliminates the losses caused by belt slip. By actual test, it has been found that with

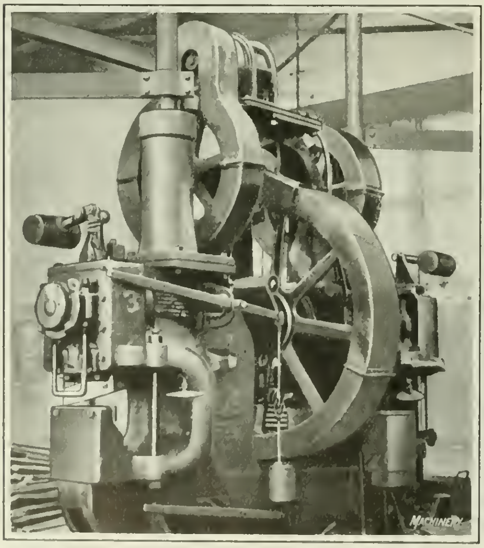

Fig. 7. Punch and Shear driven by a 10-horsepower Alternating-current Motor

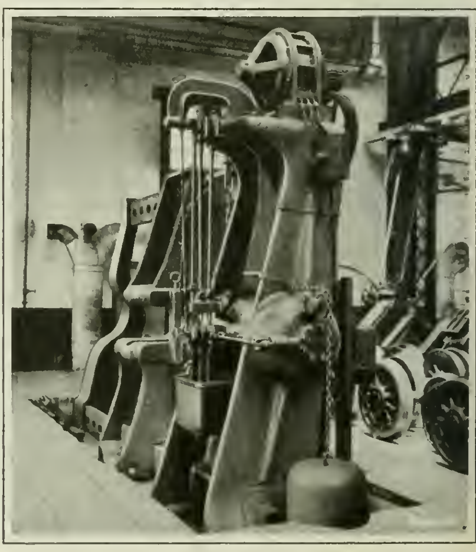

Fig. 8. A 660-ton Wheel Press driven by a 25-horsepower Alternating-current Motor

80 per cent load on a belted planer, the slip reduced the cutting speed 12½ per cent, and with slightly over 100 per cent load, the limit of the pulling power of the belt was reached. The control for the reversing equipment starts, stops, and reverses the motor in the shortest practicable time, and allows independent adjustment of either the cutting or return speeds. The cutting speed range is from 250 to 500 revolutions per minute, and the return speed, 500 to 1000. The same equipment is applicable to rack and screw driven slotters. The slotter shown in Fig. 4 is driven by a 15-horsepower reversing planer motor having a speed range of 250 to 1000 revolutions per minute.

The electrical equipment on the wheel lathes shown in Fig. 5 provides automatic acceleration and manual slow-down when hard spots are encountered. With the direct-current equipment, an adjustable-speed motor is used. It is possible to set the speed at some value within the range, and the control will cause the motor to accelerate to this predetermined speed each time. By means of a portable push-button, the operator can slow down the motor to at least 50 per cent speed, when the tool approaches the hard spot. After this is past, releasing the button allows the motor to accelerate to the set speed. When the stop-button is depressed the motor is brought to a quick stop by dynamic braking. A switch is mounted on the panel for emergency reversing.

Fig. 6 shows a motor-driven boring mill equipped with a drum controller and a 15-horsepower motor, having a speed range of from 550 to 1650 revolutions per minute. Boring mills of the larger sizes are generally provided with magnetic control. The punch and shear shown in Fig. 7, and the wheel press shown in Fig. 8, are driven by continuous-running, alternating-current motors, while the straightening rolls, Fig. 9, are driven by a wound-rotor motor with drum type control. The guide grinder illustrated in Fig. 10 is driven by a 10-horsepower induction motor. The methods of mounting these motors and the general arrangement of the transmission of power from motor to machine, are clearly illustrated. With the installation of new equipment in railroad shops, more electric drives may be expected.

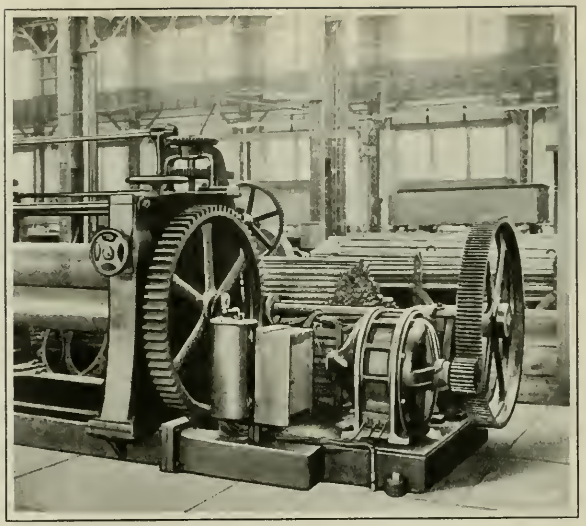

Fig. 9. Streightening Rolls driven by a Wound-rotor Motor having Drum Type Control

ESTIMATED DEMAND FOR AUTOMOBILES

Since 1916, the increases in the annual output of automobiles have largely been accounted for by the increased output of Ford cars and of other relatively inexpensive makes. The total number of higher priced cars built annually since 1916 has not materially exceeded the number built in that year. Up to the present time the actual replacement of automobiles is estimated never to have exceeded 500,000 cars in a year, but it is believed that shortly the replacement market will mount to at least 1,500,000 cars per year. It is interesting to note that the present productive capacity of the automobile industry is more than 1,000,000 cars per year greater than would be required to replace the number of cars annually worn out or destroyed. In a pamphlet issued by Leonard P. Ayres, vice-president of the Cleveland Trust Co., Cleveland, Ohio, the statement is made that unless the exports of cars increase very much, the present productive capacity of the automobile industry is sufficient to double the number of cars in use within the next five or six years. It appears extremely doubtful if the foreign or domestic markets can be sufficiently expanded to take care of this capacity, and if they can, it seems probable that some motive power other than gasoline will have to be developed. Furthermore, it seems probable that very considerable price adjustments will have to be made within the next few years, as manufacturers must compete for purchasers whose buying power is comparatively limited.

* * *

HARDENING HIGH-SPEED CUTTERS

The best method for hardening high-speed form cutters is to use a muffle gas or oil furnace for heating the cutter. The cutter should first be preheated to a temperature of from 1600 to 1700 degrees F., and then placed in a muffle furnace and heated to a temperature of 2200 degrees F. As soon as the cutting edges have attained the latter temperature, the cutter should be removed from the furnace immediately and quenched.

The German Machine-building Industries

From MACHINERY'S Special Correspondent

Berlin, January 7

CONDITIONS in the industrial life of Germany at the beginning of 1922 are encouraging. Many firms give lower figures of idleness and larger numbers of orders on hand than ever before in the history of the various industries. Yet manufacturers and industrial leaders look into the future with deep concern, because they fear that, due to the increased costs of many raw materials which must be imported and the continual falling in value of the mark, the prices of all industrial products will soon be so high as to prevent German competition in the markets of the world and even sales at home.

Low Percentage of Unemployment in the Metal-working Industries

The small number of unemployed is directly due to the present favorable selling conditions. Within the workmen's organizations connected with the metal-working industries, the unemployment is only 1.31 per cent, this figure being the same as in March, 1907. Even in 1917 and 1918, when war materials were being turned out, the unemployment figure was 0.7 per cent. The maximum percentage of unemployment in the past has been 22.4, which was the figure in August, 1914, just after the outbreak of the war.

In a report for the week of November 6 to 13, covering 27,762 establishments and 2,052,900 workmen, 27,398 plants having 2,032,325 employes were working full time; 208 plants with 15,600 employes were working part time; and only 156 plants having 4975 employes were completely shut down. Whole industrial districts are working full time, and in the district of Essen only three plants having 855 workmen are operating on a reduced time basis. In the district of Cologne, three establishments with a total of 157 employes are shut down. In Berlin, one of the greatest industrial centers of Germany, there are 3213 plants with 251,775 employes. Of these, according to official reports, only 61 plants with 20,600 employes are running at reduced time. The figures given in the foregoing refer only to organized employes in the metal-working industries.

Orders Ahead for Machine Tool Builders

The statements concerning unemployment are reflected in the reports of industrial leaders relative to orders on hand. The management of J. E. Reinecker Aktien Gesellschaft of Chemnitz, recently announced that business is extremely brisk, there being more orders booked than ever before in the history of the works. All contracts for machines and tools are at fixed prices. "Sliding" prices could not be obtained, and consequently the prices of machines to be shipped abroad have been greatly increased in order to avoid risk of losses. This concern has declared a 20 per cent dividend to stockholders. These conditions may be considered typical of those existing in many machine tool plants.

Business Prospects in Allied Industries

In order to give an idea of the prosperous business conditions in industries closely allied to that of machine tool building, it may be mentioned that many brass works are so busy that only orders calling for delivery after the next four or five months are accepted. The price of brass sheets has been increased to 80 marks per kilogram (about 40 cents per pound, present exchange).

In the automobile field orders on hand will enable operation at full capacity during the next five months. Demands steadily increase, and come not only from home dealers but also from abroad. The various plants ask terms of delivery in from two to six months. The great increase in prices, especially of the important raw materials and of semi-finished products required in the manufacture of automobiles, is, however, a factor of great uncertainty which may considerably influence the future of this industry. For this reason, the leading firms, in order to avoid dangerous risks do not accept orders at fixed prices, and the buyer must therefore reckon with price advances during the weeks and months prior to delivery that were scarcely imagined at the time of placing the order.

The metal-stamping industries also report that the orders on hand are sufficient to keep most plants fully occupied during the coming months. However, the high prices of sheet metal will probably cause many shutdowns in this field in the near future. These high prices are principally due to the fact that Germany imports as much as 80 per cent of its iron ore.

In the world's commerce Germany now shares only 5 per cent, as compared with 20 per cent in 1913. Its exports in iron and steel products dropped from 6.5 million tons in 1913 to 1.7 million tons in 1920. These figures speak for themselves.

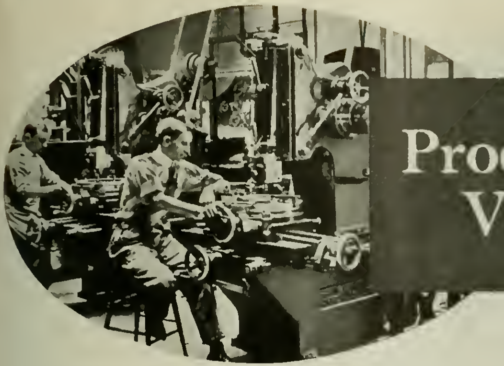
No Great Technical Progress During the Year

There has been little progress in methods and equipment in the machine-building industry during 1921, as the industry did not need to increase its production by building new and modern plants or by introducing improved working processes in order to compete with foreign manufacturers. The depreciation in the value of the mark has made wages in Germany, already low before the war, still lower in comparison with other countries. Thus German manufacturers can produce at much lower costs than foreign competitors. This fact secured for the machine tool industry a monopoly in the home markets, and gave sufficient protection against competitors abroad. German manufacturers, although able to under-bid foreign producers, still make good profits.

News Notes of the German Machine Tool Industry

The Zimmermannwerke Aktien Gesellschaft, of Chemnitz have paid a dividend of 12 per cent for the year, and have sold the greater part of their stock which had been on hand for a long time. This company has increased its productive capacity considerably and spent large sums in organizing its selling force. It has founded the Industrie-Lloyd, a selling organization which a number of other firms have also joined. Max Hasse Aktien Gesellschaft, of Berlin, manufacturers of turret lathes, have paid a 10 per cent dividend and have orders on hand to keep the establishment busy for four months. Wotanwerke Aktien Gesellschaft, of Chemnitz, have paid a dividend of 40 per cent; the Werkzeugmaschinenfabrik Union, of Chemnitz, 25 per cent; Sondermann & Stier Aktien Gesellschaft, of Chemnitz, 15 per cent; Schiess Aktien Gesellschaft of Düsseldorf, 16 per cent; and Bernhard & Alfred Escher, Ltd., of Chemnitz, 20 per cent. Many machine tool builders have greatly increased their capital, and several large stock companies have been formed.

Statistics are not yet available showing the total exports of machine tools from Germany during 1921, but it is expected that the figures will be quite large. France, especially, has bought a great deal of German machine tools, and considerable shipments have also been made to Holland, Spain, Switzerland, Italy, and the Scandinavian countries.



Production Work on Vertical Shapers

Operations Advantageously Performed on Shapers of the Vertical Type

By EDWARD K. HAMMOND

VERTICAL shapers built by the Pratt & Whitney Co., of Hartford, Conn., would scarcely be classed as machines that find wide application for the performance of manufacturing operations. However, there are numerous examples of detail work required in producing small and medium sized metal parts, for which a vertical shaper will give more satisfactory results than other machines. Such a case is shown in Fig. 3, where it will be seen that a slot *A* has been milled in work of the form shown. It is required to square the ends of the slot where they have been left curved by the milling cutter. To secure this result, the vertical shaper is equipped with a vise having its jaws in a vertical position, an end-bar *B* being placed under the work to support the downward thrust of the tool. Held in this manner, it is an easy matter for the shaping tool to square up one end of the slot, after which the work is traversed to bring the opposite end under the tool.

Shaping a Hexagonal Hole

When it is required to perform such an operation as shaping a square, hexagonal, or other shaped hole in a quantity of duplicate parts, the usual method is to handle the work on a broaching machine, provided the quantity of pieces is great enough to justify the making of a special broach. But if only a moderate number of parts have to be machined, the cost of a broach would make an excessively high tool charge against each part. For this reason it will be found more advantageous to handle a job of this kind on a vertical shaper.

An example of such a job is shown in Fig. 1. In this case it is required to produce a hexagonal shaped opening *A* in a moderate number of short cylindrical pieces. For this purpose, the work is laid out with carefully scribed lines, showing the exact shape and size of the hole; and the opening is started by drilling a round hole of a diameter slightly less than that of the inscribed circle of the hexagon. The work-holding fixture has a pocket in it to receive the piece to be shaped, and the bottom of this pocket is made with a shoulder to support the work, but open at the center to allow clearance for the tool under the work and to permit the chips to fall through. The piece is held down in the pocket by means of the straps shown in the illustration at *B*.

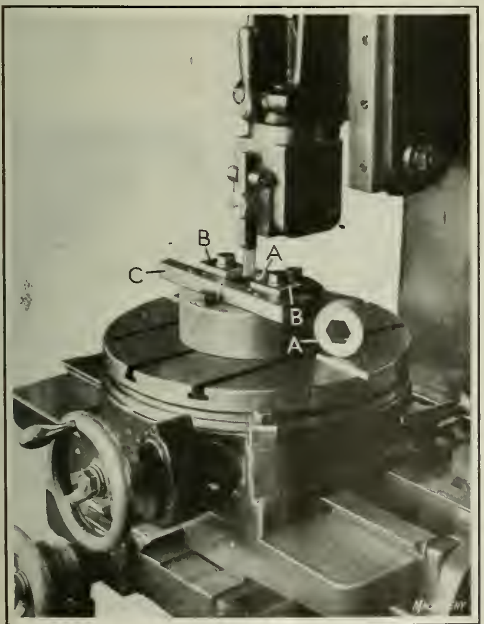


Fig. 1. Vertical Shaper equipped with a Fixture for Use in shaping a Hexagonal Hole

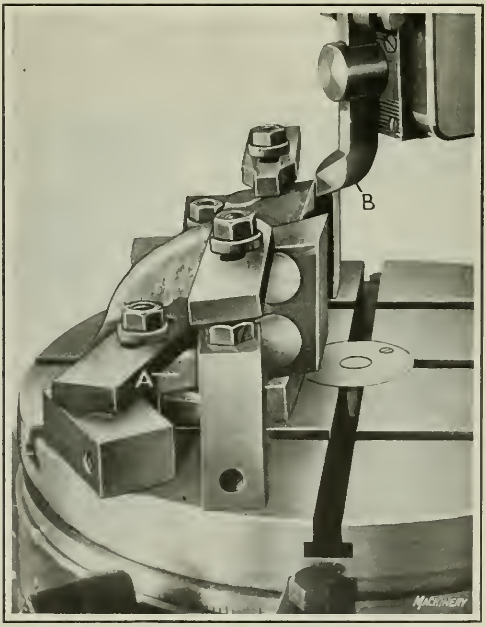

Fig. 2. Planing the Inclined Sides of a Dovetailed Bearing on a Vertical Shaper

In setting up this job, care is taken to align strip *C* accurately with the longitudinal travel of the table, by the use of a dial indicator mounted in the toolpost, and the work is then placed with one side of the hexagon parallel to strip *C*. The shaper tool is made of a width equal to one side of the hexagon, and is started in the round opening, the work being fed up to it until one side of the hexagon has been formed. After one side is finished, the work is indexed through 60 degrees, so that the next side of the hexagon can be formed, and this process is repeated six times to finish the job. The rotary table of the machine is graduated, which facilitates indexing the work.

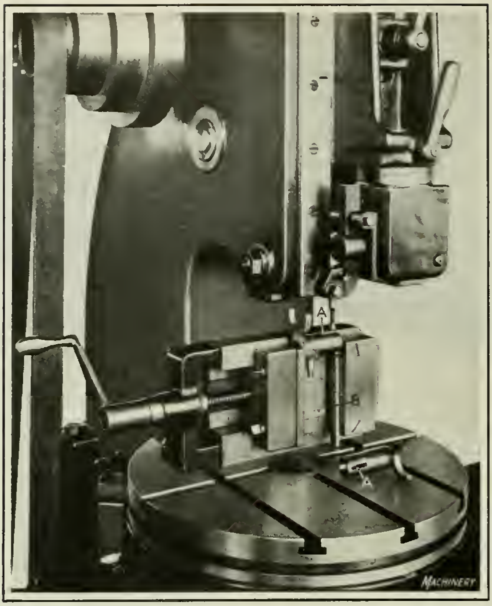

Fig. 3. Use of a Vertical Shaper for squaring up the Ends of a Milled Slot

Shaping a Short Dovetailed Bearing

Another application of the Pratt & Whitney vertical shaper in handling a production job is illustrated in Fig. 2, where it will be seen that the work consists of shaping a short dovetailed bearing. At the time when the casting *A* comes to this machine, the lower face has been finish-planed, and this surface is utilized as a locating point in setting up the work which is strapped down to the shaper table. Held in this way, the bottom of the dovetail is elevated sufficiently so that clearance is provided for the tool and chips under the work. The work consists of taking roughing and finishing cuts. The tools are offset as shown at *B*, so that they may be used in a ram that reciprocates vertically.

Shaping Plane and Cylindrical Surfaces

The universal shaper and milling machine built by the Cochrane-Bly Co., Rochester, N. Y., was primarily designed for use in tool-rooms, but machines of this type are demonstrating their adaptability for production work. A case in point is shown in Fig. 4, which illustrates a machine of this type engaged in shaping the outer surface of the swivel worm bearing for use on the Cochrane-Bly rotary table. As a clear understanding of the form of this piece is important, in order to grasp the possibilities of the combination of a vertical shaping machine and a rotary work-holding table in generating cylindrical surfaces and planes tangent to such surfaces, an illustration showing three views of the swivel worm bearing is presented in Fig. 6. It will be seen that there are two plane surfaces *A* which are tangent to the semi-cylindrical surface *B* at each side. In shaping this piece, the casting is mounted on the rotary table with a bolt extending through the hole *C* to secure the work in the desired position, the location of this bolt corresponding to the axis of rotation of the rotary table.

The method of procedure is to generate one of the plane surfaces by using the straight traverse movement of the table in conjunction with the reciprocating action of the vertical ram. When the tool point reaches the position of tangency of the plane and semi-cylindrical surface, longitudinal traverse of the table is discontinued and the rotary feed of the table is employed. This provides for generating the semi-cylindrical surface, and when the tool point reaches the position where the plane surface becomes tangent to the cylindrical surface at the opposite side of the work, longitudinal traverse movement of the table is substituted for the

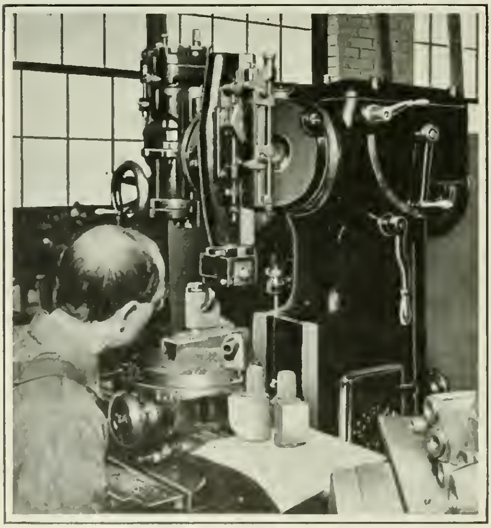

Fig. 4. Utilizing Straight-line and Rotary Feed Movements for shaping an Irregular Piece

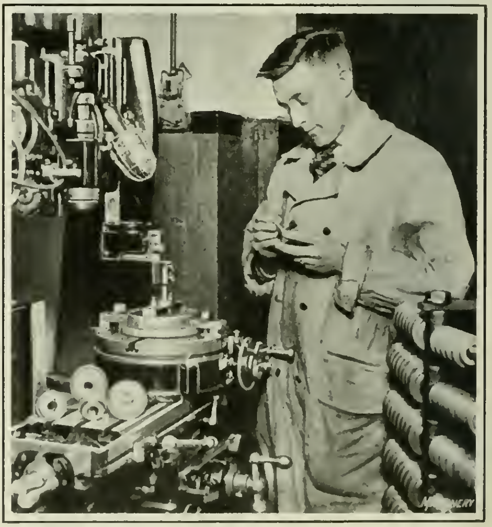

Fig. 5. Cutting Three Equally Spaced Spline Grooves on the Vertical Die Shaper

rotary feed movement, to generate the second flat side of the work. A high degree of accuracy is required on these pieces, it being especially necessary to maintain the cylindrical surface concentric with the bore *C*. With this method of machining, practically all hand work is eliminated, and the entire job is completed at a single setting within limits of ± 0.001 inch.

Shaping Three Keyways in a Tapered Bore

At the Gleason Works, Rochester, N. Y., there were 10,000 chrome-nickel steel gears in each of which it was required to cut three keyways in a bore tapering 2.4 inches per foot. The form of the work and its dimensions are shown in Fig. 7, where it will be noticed that the small end of the tapered hole is only 0.488 inch in diameter. The cutting of these keyways is a difficult job, as they are required to be parallel with the bore and all dimensions must be held within limits of ± 0.001 inch.

After giving this problem careful consideration, the planning department of the Gleason Works decided to put the job on a Cochrane-Bly universal shaper, as shown in Fig. 5. A special holder was provided to clamp the gear blank to the indexing table, and the shaper head was inclined at the proper angle for the taper of the bore, by the micrometer adjustment. With this equipment it was possible to cut the keyways with satisfactory results at the rate of six gears per hour, which corresponds to a cutting time of 3.33 minutes per keyway.

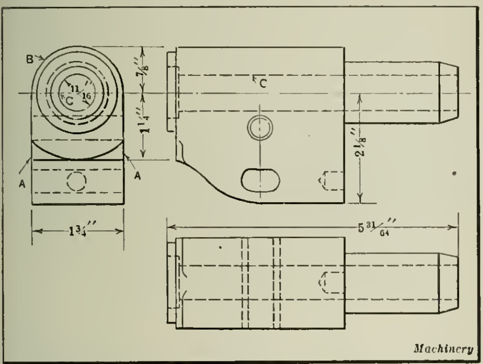

Fig. 6. Design of Piece to be shaped on the Machine shown in Fig. 4

EARLY DISCOVERY OF THE RECALESCENCE POINT IN HEATING STEEL

In a publication issued in 1778 by one of the industrial associations of that time in Sweden, there is an article on the hardening of steel, written by J. F. Angerstein, in which the author mentions that he has observed a means whereby the correct hardening temperature for steel may be accurately determined. He points out that at the right hardening temperature there is a sudden shadow or lack of brightness in the object being heated. This shadow is evidently caused by the temperature reduction which takes place when the steel passes the recalescence point. It was not possible for the early observer to understand the exact reason for the loss of brightness or shadow in the heated steel, but he had learned that this was the point when the right hardening temperature had been reached, and by observing it he was able to harden at a temperature determined by the same principle as is employed in modern means of determining the recalescence point. It has generally been believed that the earliest observer of this phenomenon was the Russian, Chernoff, who about 1860 called attention to this characteristic of steel when heated. The practical value of these observations was finally clearly laid down by Brinell.

ROTATION OF BALLS IN BALL BEARINGS

On page 330 of December MACHINERY, a description is given of a ball-bearing grinding spindle of unusual construction. It is stated that each ball revolves on its own axis approximately once in every 365 revolutions of the bearing. Is it meant that the balls twist like a bullet once in 365 revolutions, with a motion sometimes called "corkscrewing"?

The test of correct rolling is to assume gear teeth on the contacting surfaces. In fact, we must assume all contacting surfaces having relative motion to be gears with an infinite number of teeth. If a device will not roll correctly with gear teeth on the contacting surfaces, it will not roll at all; in other words, sliding and grinding will take place.

A ball bearing, if assumed to have gear teeth on the contacting surfaces, is simply a planetary transmission. As shown in Fig. 1 in the article referred to, each ball would make about 1.3 revolutions about its axis for each revolution of the bearing. This is decidedly different from one revolution for 365 revolutions of the bearing. Actually, at 10,000 revolutions per minute of the bearing, each ball would make approximately 13,000 revolutions on its axis.

Aurora, Ind. L. LANGHAAR
Vice-president, Langhaar Ball Bearing Co.

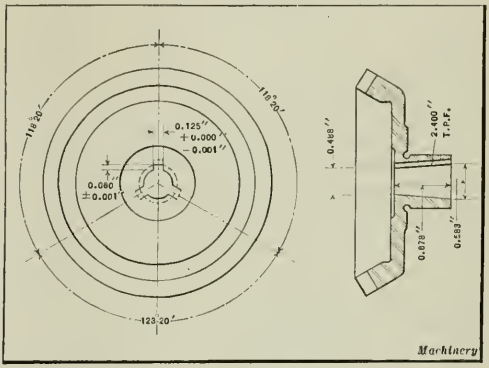

Fig. 7. Design of Work to be shaped on the Machine shown in Fig. 5

Reply by the Ex-Cell-O Tool & Mfg. Co.

We believe that your correspondent does not understand the construction of our ball races. In the second paragraph of the article, beginning with the second sentence, the difference in angle is explained. Perhaps a better way of expressing the true condition would be as follows:

In this design the point of contact of a ball on one race is farther from the axis of rotation than on the other, and this condition causes the balls to revolve about their own axes at right angles to the axis of the device, as well as in the same direction as the device. The number of right-angle revolutions is dependent upon two factors—the diameter of the balls and the difference in the angles of the race.

The ball must necessarily revolve about its own axis in the same direction as the race, and this condition is the same as in a planetary transmission. However, we cannot understand how the figures given in the preceding are arrived at, inasmuch as the number of revolutions of the ball about its own axis in the same direction of rotation as that of the race is dependent upon the size of the balls used and the diameter of the races.

Detroit, Mich. N. A. WOODWORTH
Manager, Ex-Cell-O Tool & Mfg. Co.

* * *

It is reported that the Ford Motor Co. is planning to install the largest steel-melting furnace ever built. The capacity will be 9000 kva., which is said to be three times the size of any previously installed furnace.

Exports of Metal-working Machinery before and after the War

A REVIEW of the foreign markets for American machinery shows that as far back as 1910, the United States exported more machine tools and metal-working machinery than any other country in the world, nearly $6,000,000 worth being exported during the twelve months ended June 30, 1910. These exports have gained steadily since that time up to the present period of depression. The decrease during the last two years is a natural result of the general industrial depression; but in comparison with the pre-war figures, these exports show a decided advance, the demand in all countries of the world for American machinery having increased considerably, particularly in non-European markets. During the twelve months ended June 30, 1921, the United States exported machine tools and metal-working machinery amounting approximately to $34,000,000 as compared with a total of $14,000,000 for a similar period ended June 30, 1914. This gain was not actually as great as the figures would seem to indicate, because the prices of metal-working machinery of all kinds had increased approximately 100 per cent since 1914; yet, there is a definite gain. The exports amounted to $58,000,000 in 1919, and $44,000,000, in 1920. With the return to normal conditions, the exports in this line are likely to be substantially above the pre-war level.

TABLE 1. VALUE OF EXPORTS TO JAPAN, CHINA, INDIA AND DUTCH EAST INDIES FOR 1914 AND 1920

Countries	1914	1920
Japan	$120,166	$4,250,583
China	17,668	932,351
India	17,953	1,374,068
Dutch East Indies	20,216	326,086

Machinery

The Market in Asia

Asia presents the most interesting feature in the expansion of our foreign markets in metal-working machinery, the demand for the American product there having increased steadily since before the war, rising from about $207,000 for the year ended June 30, 1914 to over $7,000,000 for the calendar year 1920, a gain of over 3300 per cent in less than seven years. The rapid industrialization of Asia, particularly of such countries as Japan, China, India, and the Dutch East Indies, has helped materially to increase the Asiatic market for machine tools and metal-working machinery. Of these countries, the greatest gain is found in India, where the market for American machines increased nearly 7600 per cent during the period mentioned. Table 1 gives the value of machine tools and metal-working machinery exported to these countries for the year ended June 30, 1914, as compared with the calendar year 1920.

American Machines in Great Britain

For the fiscal year ended June 30, 1914, Great Britain imported $376,000 worth of machine tools from the United States, or 88 per cent of her total imports in this line. For the calendar year 1920 American exports of machine tools to Great Britain totaled $6,000,000. In 1914 the total value of machine tools and metal-working machinery exported to England was approximately $3,000,000 as compared with more than $10,000,000 in 1920. The extensive use of American machines in Great Britain during the war no doubt did much to establish a permanent market in that country for many types of American tools.

Exports to France and Germany

In France a similar increase has been manifested. During normal times, previous to the war, there was a rise from $307,000 in 1909 to a total of nearly $2,000,000 worth of machine tools and metal-working machinery for the fiscal year ended June 30, 1914. The market, of course, was greatly inflated during the war, rising to a peak of $29,000,000 in 1917, and receding to $7,500,000 for the calendar year 1920. This figure, however, is much larger than the immediate pre-war total of $2,000,000.

The German market presents an entirely different situation. Previous to the war, for the twelve months ended June 30, 1914, Germany imported over $2,000,000 worth of machine tools and metal-working machinery from the United States. At that time the German market for American machines was second only to that of Great Britain. Since the war, however, the market has been very poor, reaching a total of only $144,000 for 1920.

Table 2 gives the value of exports of machine tools and metal-working machinery from the United States for the years 1914 and 1920, together with the value of the exports to the leading European countries and Asia. Attention is called to the fact that the per cent of increase relates to the total value of the exports and not to the increase in tonnage. As the price of machine tools has practically doubled during the last seven years, the number of machines exported has not increased in so large a proportion as their value.

TABLE 2. VALUE OF EXPORTS TO ENGLAND, FRANCE, GERMANY AND ASIA FOR 1914 AND 1920

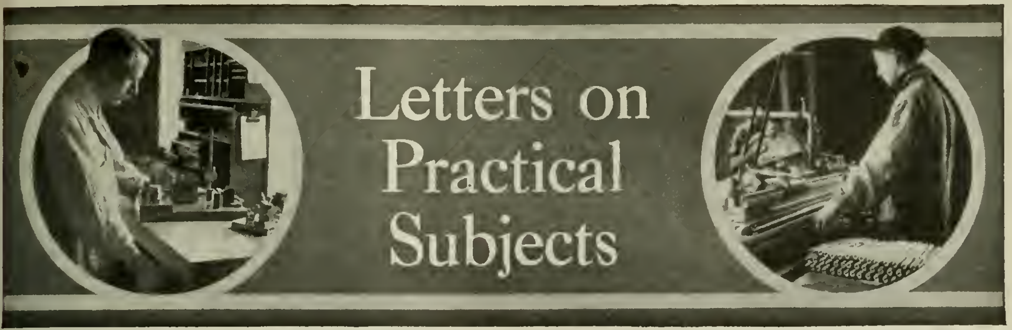
	1914	1920	Per Cent Increase
Total Exports	$14,011,359	$44,312,233	215
Exports to England	2,988,684	10,760,957	260
Exports to France	1,771,525	7,595,733	329
Exports to Germany	2,167,240	144,192	...
Exports to Asia	207,389	7,181,435	3369

Machinery

Comparison of Machines Manufactured and Exported

In 1919 the value of the machine tools and metal-working machinery manufactured in the United States was $212,000,000. Of this amount $58,500,000 worth or 27½ per cent were exported to the various countries of the world, England absorbing $15,000,000 worth, France $15,000,000 worth, and Asia as a whole, $8,500,000 worth of these machines. In comparison with the pre-war figures, however, this percentage shows practically no change. During the twelve months ended June 30, 1914, the manufactures of machine tools and metal-working machinery totaled $48,000,000, the exports amounting to $14,000,000 or 29 per cent of the machines manufactured.

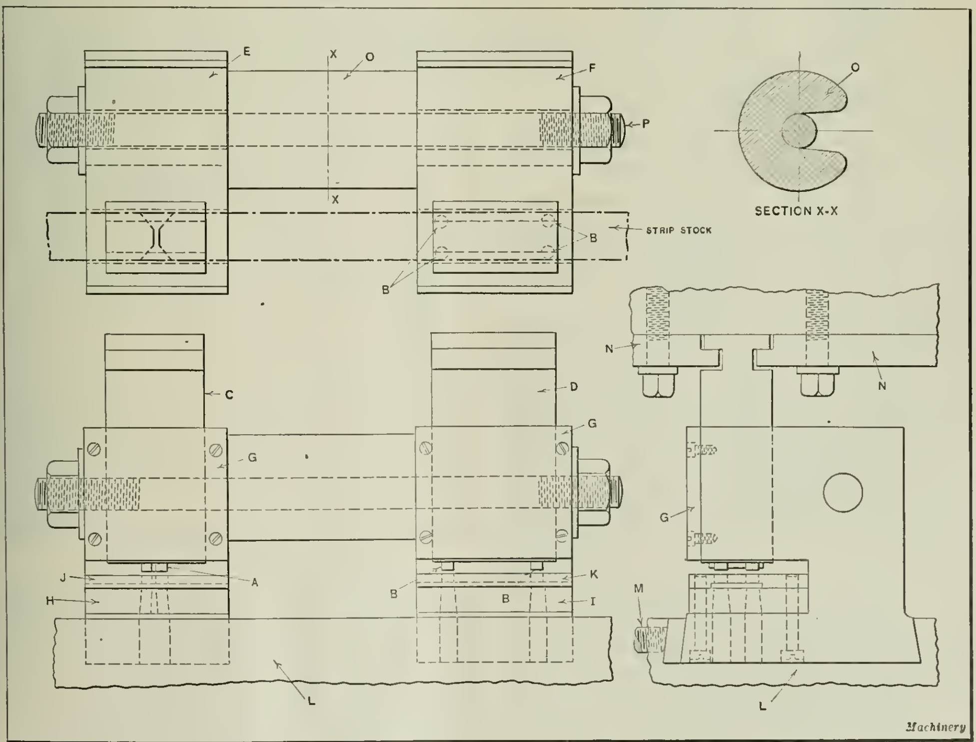
The figures quoted show that, even allowing for the difference in prices in 1914 and 1920, the exports in the latter year were so much greater that it would not be reasonable to expect them to remain at those figures continuously. The exports of 1920 may be greatly reduced, and yet our metal-working machinery exports will exceed the pre-war exports.



DIES OF UNIT CONSTRUCTION FOR GANG PUNCHING

Where adaptable, dies of unit construction, such as the one shown, will be found particularly satisfactory from the point of view of economy. In many cases it is possible to build up a die by combining a number of die units, thereby avoiding the necessity of making a complete die or sections of a die. The units of sub-press dies formed in this way are, of course, separable. Each unit contains punches for one group of holes or perforations. It is therefore an easy matter to arrange the units for the production of parts made by piercing, perforating, and cutting off strip stock. The illustration shows two units set up for the production of perforated straps from the strip stock indicated by dot-and-dash lines. The die unit at the right contains the punches used to pierce a group of four holes in the stock, while the unit at the left is equipped to cut off the stock to the required length. It will be noted that the cutting-off punch *A* is designed to cut the corners of the stock at an angle of about 45 degrees.

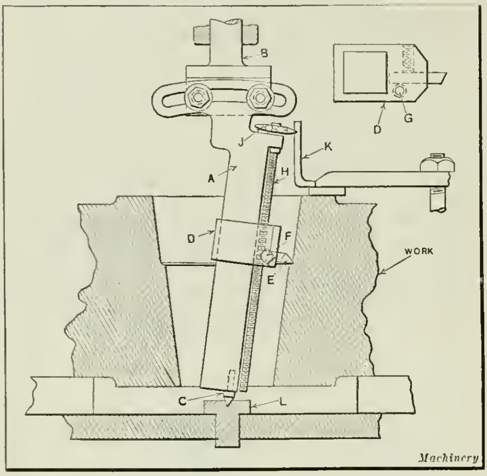
The cutting-off punch *A* and the perforating punches *B* are held in blocks *C* and *D*, respectively, which slide in cast-iron holders *E* and *F*, being held in place by plates *G*. The die members are shown at *H* and *I*, and the stripper plates at *J* and *K*. The material being worked is fed through the slot cut in the stripper plates. The entire assembly, consisting of the punch-holder, holder slide-block, die, and stripper plate, is slid into a die base *L*, in which it is clamped by means of screws *M* while punch-holding slides *C* and *D* are clamped to the ram of the press by strips *N*. Thus it will be seen that the usual up-and-down movement of the press causes the four punches in holder *D* to perforate the stock while the cutting-off punch in holder *C* cuts off the previously punched stock. A pin or block (not shown) at the left of die *H* serves as a stop for determining



Gang Punch of Unit Construction for perforating and cutting off Strip Stock the length to which the stock is to be cut. A spacer *O*, placed between blocks *E* and *F*, locates the dies the proper distance apart. A screw *P* with nuts at each end completes the equipment. Instead of the two units shown in the illustration, as many as six or more may be used with spacers of the proper length placed between them. It is obvious that a great many set-ups can be provided by this arrangement. One of the chief advantages of the unit construction is that work of many lengths having the same general lay-out of holes or openings can be produced by merely changing the spacing blocks *O*. F. SERVER

TAPER BORING ATTACHMENT FOR DRILLING MACHINE

The taper boring tool described in the following can be used on a drilling machine or on a horizontal boring mill. The swiveling action of the tool-carrying bar *A*, which can be clamped rigidly to the taper shank *B*, held in the drilling



Taper Boring Attachment for Drilling Machine

machine spindle, permits a wide range of adjustment, so that the tool can be used for boring cylindrical holes as well as holes having steep tapers. Holes in large castings, such as side frames, etc., and jobs too large to be bored on the lathe, as well as rush jobs for which extra machines must be rigged up can be handled with this tool.

As will be apparent from the illustration, the tool is simple and designed to secure accurate results. The head of the tapered shank *B* is planed off square with the center line of the shank, in order to form a clamping surface for the head of bar *A*. The tool-bar is made from an iron casting of the form shown. It is shaped or planed square and true, and is drilled at the bottom to receive a small center *C*. This center must be exactly in the center of rotation when the tool-carrying bar is set vertical.

A small carriage *D*, which is slotted to hold a square tool bit *E*, is mounted on the squared end of bar *A*. The tool bit is held in position by a set-screw *F*. The carriage is made of cast iron or steel, and must be a close sliding fit on bar *A*. A hole *G* in the carriage, at the rear of the tool, which is shown in the view in the upper right-hand corner of the illustration, is tapped to fit the feed-screw *H*. This feed-screw extends down from the top bearing, and carries at its top end a star-wheel *J*. The star-wheel is operated by setting a finger *K* so as to rotate it one space every revolution of the tool. If a heavy feed is desired, as when using a square-nosed finishing tool, two fingers may be employed instead of one.

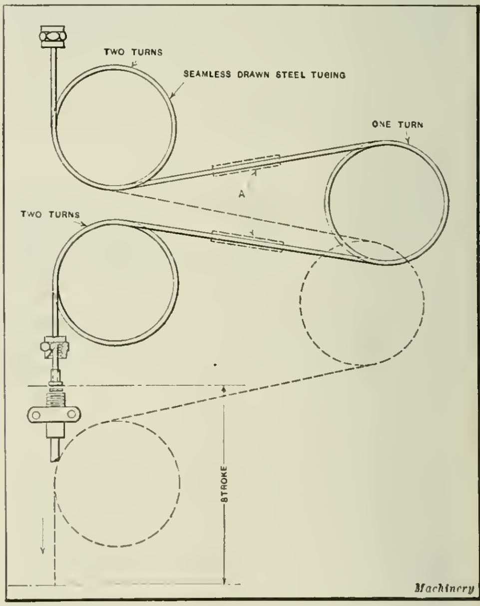
When using this tool, the center *C* rests and rotates in a hardened female center *L*, set into a tight fitting hole in the drilling machine table. The work is centered by clamping a wire finger or pointer to the tool-bar and rotating it around the outside of the job, or over a line scribed on the work. When used on a horizontal boring mill a suitable center hole in a block or clamp can be used in place of center *L*. Care should be taken in making the tool to have the forward edge of the tool slot exactly on the center line, and also to grind the tools accordingly; otherwise the taper will not be true. Most tapers are given on drawings as inches per foot, or in degrees, in which case a bevel protractor is used to set the angle of the tool.

Allentown, Pa. JOE V. ROMIG

SPRING PIPE CONNECTION FOR HYDRAULIC PRESSES

The spring pipe connection here illustrated was designed by the writer for use on a hydraulic press in place of a telescope pipe. The telescope pipe connection was employed to supply the water pressure required to move the table back and forth. The rapid wear on the packing, the tendency for the telescope pipe to buckle under high pressure, and the frequent breaking at the point where it was screwed into the bracket made this type of connection a source of annoyance.

The breaking and buckling was overcome by using a telescope pipe of larger size, but the packing still had to be frequently renewed. With the large pipe it was necessary to use throttle washers in the fittings to reduce the amount of water delivered, so as to decrease the speed of the back-



Spring Pipe Connection for Hydraulic Presses

and-forth movement of the table. Finding that a very small opening in the throttle washers gave the desired result, it occurred to the writer that a small size spring pipe connection of seamless drawn steel tubing might be employed in place of the telescope pipe. Accordingly, some tubing of suitable size was obtained, and experiments were made which resulted in the development of the connection shown.

The seamless drawn steel tubing, coiled and bent to the shape indicated, was found to be capable of withstanding the fluctuating pressures and consequent vibration of the hydraulic press and accumulator pipe-line system, and to be capable of being sprung back and forth from the position shown by the full lines to that indicated by the dotted lines. This arrangement gave little or no trouble.

It will be noted that two turns are made in the coils next to the unions and one in the middle coil. It was found that one coil next to the unions would not withstand the strain of opening and closing, combined with that produced by vibration. An extra turn, however, overcame this difficulty and eliminated breakage at the unions. The complete set of coils in the pipe seemed to float, and did not vibrate as might have been expected. The satisfactory action of the connection is due chiefly to the fact that the coils can move in all directions. This device or a similar one could probably be used to advantage on many types of machines where a flexible pipe connection that will not whip when subject to fluctuating pressures is required. Unions attached to the ends of the coil tube make them readily detachable in case of breakage, so that a renewal can be made quickly, but this is seldom necessary. If it is difficult to obtain seamless steel tubing of sufficient length to make a complete coil, two or three lengths of tubing may be used. The joints should be made as indicated by the dotted lines at *A*.

Lyells, Va. W. R. Ward

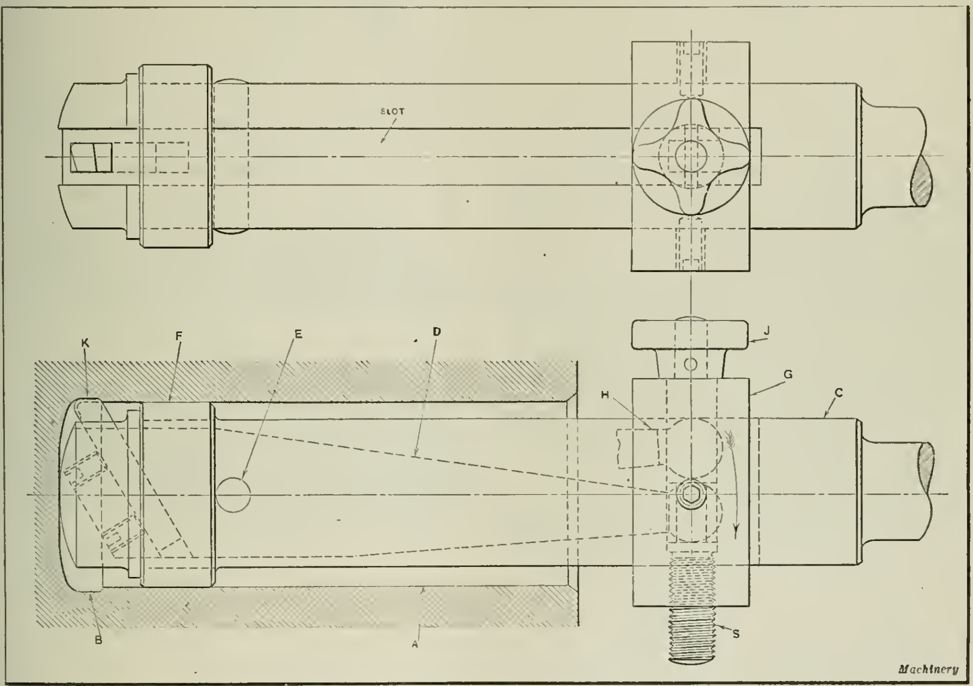
DEEP-HOLE RELIEVING TOOL

The tool shown herewith was designed for cutting a recess *B* in the combustion chamber of an automobile engine cylinder *A*. This recess is made to provide a clearance for the grinding wheel when finish-grinding the bore. As the cylinder block for which this tool was designed had four bores and was 25 inches long, it was found impractical to perform the recessing operations on a lathe or boring machine. It will be noted, however, that only one bore of the cylinder block is shown in the illustration. The depth of the recess *B* is 1/16 inch, and its length is ½ inch.

The tool is provided with a heavy shank *C* which has a taper at one end that fits the drilling machine spindle. A slot is machined at the opposite end of the shank for the tool-arm *D* which is pivoted on pin *E*. The ring *F*, pressed on the shank, is made a running fit in the cylinder bore, and provides a means of guiding the end of the tool. This ring also prevents the split ends of shank *C* from spreading. The ring *G* is pinned to the shank, and carries the feeding mechanism of the tool-arm.

The tool-arm must be adjusted to the position indicated by the dotted lines at *H* before it can be lowered into the cylinder bore. When the tool-carrying end of the shank rests on the head of the combustion chamber, the machine is started. The knob *J*, pinned to screw *S*, is turned at intervals in order to feed the right-hand end of tool-arm *D* in the direction indicated by the arrow. Cutter *K* is thus fed outward a sufficient distance to cut the recess to the required depth. The knob *J*, coming in contact with ring *G*, serves as a stop for determining the depth of the cut. When the recess *B* has been cut to depth, the machine is stopped, after which screw *S* is turned back by means of knob *J* until cutter *K* is drawn back into the shank, thus permitting the tool to be removed and inserted in the bore of the next cylinder. This tool has proved accurate, can be operated rapidly, and eliminates considerable heavy lifting and setting-up work.

Pittsburg, Pa. William Owen



Tool for cutting a Recess in the Combustion Chamber of an Automobile Engine Cylinder

A COUNTERSHAFT TEMPLET

The installation of a heavy overhead countershaft which is in any way complicated requires the personal supervision of a foreman or master millwright. Some machines have several pairs of hangers, or, several countershafts, which must be in close alignment with each other and with the machine in order to function properly.

In some factories the plan has been adopted of laying out beforehand, a temporary wooden templet of any counter-

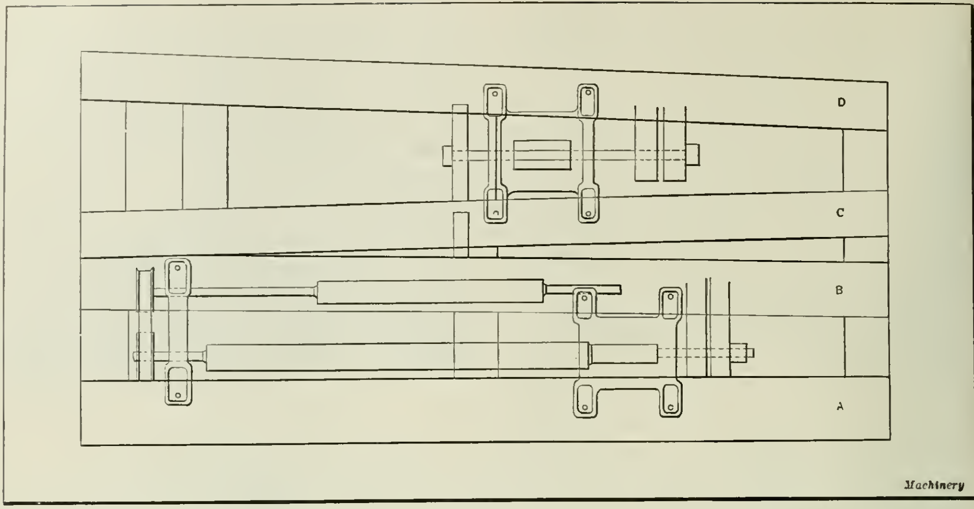


Fig. 1. Ceiling Plan of Countershaft Equipment installed by the Aid of the Templet shown in Fig. 2

shaft which promises to give trouble. It has been found that such a templet enables the workman to put the countershafts in their proper places without the constant supervision of the foreman, and thus enables the latter to attend to work elsewhere in the factory.

In Fig. 1 is shown a ceiling plan view of the overhead countershaft equipment of a grinding machine. The wheel-speed countershaft with its hangers, and the work-drive drum and the table-drive drum with their hangers and countershafts are shown. The positions of the stringers on the ceiling, as obtained from the dimensions given on the erecting print of the machine are indicated at *A*, *B*, *C* and *D*. The master mechanic's templet, Fig. 2, which is made up from the dimensions given on the erecting print is used by the workmen as a guide in placing the stringers in their proper positions on the ceiling.

The templet should be made from ⅞- or 1-inch stock. When in use, it is placed on the ceiling beams, or ceiling-insert plates in a cement constructed building. The straight-edge *E* of the templet is aligned with the main lineshaft and an outline drawn on the beams or ceiling to give the location of the stringers. The templet is next removed and the stringers bolted in place, after which it is clamped in position on the stringers to locate the holes for the hanger bolts. These holes, three of which are shown at *F*, *G* and *H*, are, of course, accurately laid out and drilled, in the templet, according to the dimensions shown in Fig. 2. R. J. S.

* * *

It is stated in a recent Commerce Report that about 62.7 per cent of the world's shipbuilding is being done in British shipyards. Of this amount nearly all is constructed in the United Kingdom; yet there is a serious depression in the shipbuilding industry. Of the 3,500,000 tons of shipping now building, 2,750,000 tons are almost completed. Only about four months full time work is in sight.

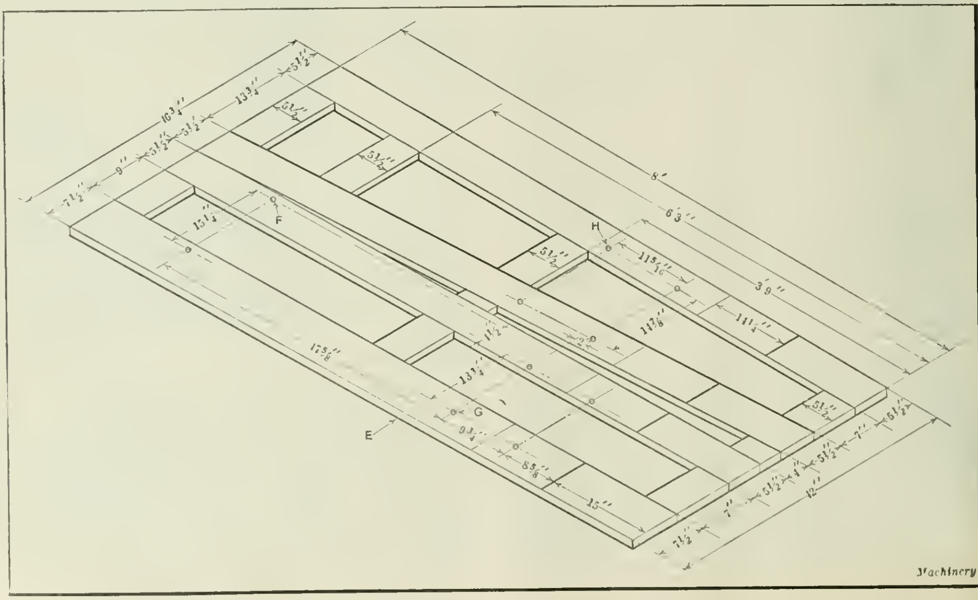

Fig. 2. Details of Templet used in putting up Countershaft shown in Fig. 1

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

DRAWING A DEEP WIDE-FLANGED SHELL

J. E. J.—I want to draw a flanged cup from 1/16-inch sheet steel, 1½ inches deep, 1 inch in diameter, and having a 3½-inch diameter across the flange. What is the best way to make the dies, and how many operations are necessary?

A.—Specific information regarding drawing die work is difficult to furnish, because no matter what procedure is recommended, the practice is dependent on the equipment with which it is intended to do the job. Press work is always more or less of an experimental proposition. In the present case, the problem is a difficult one, because in addition to the deep cup to be drawn there is a very wide flange. It will probably require four operations to produce the shell. As regards the design of the dies, the information contained in the article published on page 964 of June 1920, MACHINERY will prove of value. The stock used is much heavier than mentioned in the present case, but the design of the dies will be helpful in designing similar ones.

DETERMINING DIAMETER OF DISK TANGENT TO THREE OTHER DISKS

G. R. P.—Can someone give me a formula for finding the diameter of disk X in Fig. 1, when the diameters of the other disks and the distances between their respective centers are known?

ANSWERED BY W. W. JOHNSON, CLEVELAND, OHIO

A.—This is the problem of four tangent circles. It is a special case in which the diameters of two of the circles are equal, but it can be solved by the general solution which is as follows: Referring to Fig. 2, let L, M, and N be the centers of the three given circles whose radii are a, b, and c, respectively, and let $MN = x$, $LN = y$ and $LM = z$; then find r. An equation of the second degree can be obtained as follows:

Let $LO = p$, $MO = q$, $NO = s$, and angle $LOM = \theta$, angle $MON = \phi$, and angle $NOL = \alpha$.

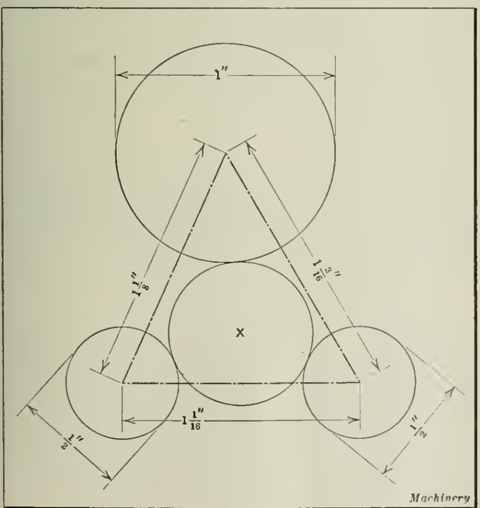

Fig. 1. Diagram illustrating Problem to find Diameter of Disk X

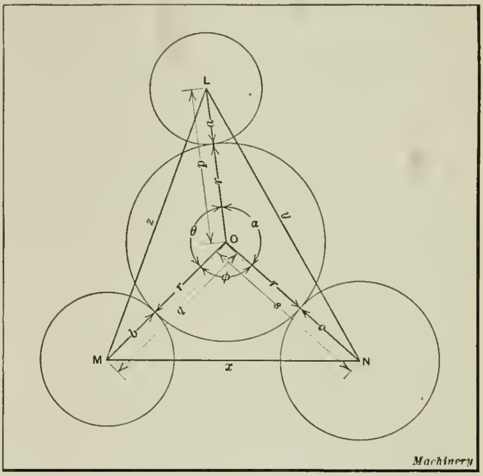

Fig. 2. Diagram used in Solution of Problem presented in Fig. 1

Then

$$\theta + \phi + \alpha = 360 \text{ degrees}$$
$$\theta = 360 \text{ degrees} - (\phi + \alpha)$$
$$\cos\theta = \cos(\phi + \alpha) = \cos\phi\cos\alpha - \sin\phi\sin\alpha$$
$$\cos\theta - \cos\phi\cos\alpha = -\sin\phi\sin\alpha$$

Squaring both sides,

$$\cos^2\theta - 2\cos\theta\cos\phi\cos\alpha + \cos^2\phi\cos^2\alpha$$
$$= \sin^2\phi\sin^2\alpha$$
$$= (1 - \cos^2\phi)(1 - \cos^2\alpha)$$
$$= 1 - \cos^2\phi - \cos^2\alpha + \cos^2\phi\cos^2\alpha$$

Hence,

$$\cos^2\theta + \cos^2\phi + \cos^2\alpha - 2\cos\theta\cos\phi\cos\alpha = 1 \qquad (1)$$

From the cosine formulas in trigonometry:

$$\cos\theta = \frac{p^2 + q^2 - z^2}{2pq} = 1 + \frac{(p-q)^2 - z^2}{2pq}$$
$$\cos\phi = \frac{q^2 + s^2 - x^2}{2qs} = 1 + \frac{(q-s)^2 - x^2}{2qs}$$
$$\cos\alpha = \frac{s^2 + p^2 - y^2}{2sp} = 1 + \frac{(s-p)^2 - y^2}{2sp}$$

Put, in the numerators, $p = r + a$, $q = r + b$, and $s = r + c$, and let A, B, and C represent certain expressions in the results; then,

$$1 + \frac{(p-q)^2 - z^2}{2pq} = 1 + \frac{(a-b)^2 - z^2}{2pq} = 1 + \frac{A}{2pq}$$
$$1 + \frac{(q-s)^2 - x^2}{2qs} = 1 + \frac{(b-c)^2 - x^2}{2qs} = 1 + \frac{B}{2qs}$$
$$1 + \frac{(s-p)^2 - y^2}{2sp} = 1 + \frac{(c-a)^2 - y^2}{2sp} = 1 + \frac{C}{2sp}$$

By substituting these values in Equation (1), performing the operations indicated, clearing of fractions and cancelling, the following equation is obtained:

$$A^2s^2 + B^2p^2 + C^2q^2 - 2ABsp - 2BCpq - 2CAqs - ABC = 0 \qquad (2)$$

Putting $p = r + a$, $q = r + b$, and $s = r + c$, in Equation (2), performing the operations indicated, and combining,

$r^2 [A^2 + B^2 + C^2 - 2AB - 2BC - 2CA] + 2r[A^2c + B^2a + C^2b - AB(a + c) - BC(a + b) - CA(b + c)] + [A^2c^2 + B^2a^2 + C^2b^2 - 2ABca - 2BCab - 2CAbc - ABC] = 0$ (3)

This is a general quadratic equation, from which two values for r are always found; one applies to the circle making internal contact with all three circles, and the other to the circle making external contact with all three circles.

From Fig. 1, a = ½ inch, b = ¼ inch, c = ¼ inch, x = 1 1/16 inches, y = 1 3/16 inches, and z = 1⅛ inches.

For convenience, reduce all values to sixteenths and use only the numerators in carrying out the calculations; this is the same as multiplying the roots of Equation (3) by 16. Then, a = 8 inches, b = 4 inches, c = 4 inches, x = 17 inches, y = 19 inches, and z = 18 inches; and

$$A = (a - b)^2 - z^2 = -308$$
$$B = (b - c)^2 - x^2 = -289$$
$$C = (c - a)^2 - y^2 = -345$$

Inserting these values in Equation (3), and solving, the different coefficients can be found as follows:

Coefficient of $r^2 = A^2 + B^2 + C^2 - 2AB - 2BC - 2CA = -292{,}544$

Coefficient of $2r = A^2c + B^2a + C^2b - AB(a + c) - BC(a + b) - CA(b + c) = -1{,}590{,}960$

Absolute term $= A^2c^2 + B^2a^2 + C^2b^2 - 2ABca - 2BCab - 2CAbc - ABC = +23{,}998{,}500$

This gives the quadratic equation,

$$292{,}544r^2 + 2(1{,}590{,}960)r - 23{,}998{,}500 = 0$$

Dividing by 4, this equation reduces to:

$$73{,}136r^2 + 2(397{,}740)r - 5{,}999{,}625 = 0$$

Solving for r,

$$r = \frac{-397{,}740 \pm \sqrt{397{,}740^2 + (73{,}136 \times 5{,}999{,}625)}}{73{,}136}$$

Using this equation with the plus sign before the radical to find the radius of a circle making external contact with all three circles,

$$r = 5.1262$$

Since the roots of the equation were multiplied by 16, divide the value of r by this number. Thus, r = 0.3204. Therefore, the radius of the disk X in Fig. 1 is 0.3204 inch, and the diameter is twice that or 0.6408 inch.

STRAIGHT PIPE THREADS

C. H. B.—Has any standard been adopted for straight pipe threads, and where are such threads generally used?

A.—The following information conforms to the American Standard pipe threads and to the standard approved by the National Screw Thread Commission:

The straight pipe thread has the American or Briggs tapered pipe thread in regard to pitch and depth of thread. The basic pitch diameter for straight pipe threads equals the pitch diameter at the gaging notch of the tapered plug gage. In the report of the National Screw Thread Commission a table of the pitch diameters for straight pipe threads is given, and other tables relating to different classes of screw threads with recommended allowances, tolerances, etc.

Occasionally it is advisable to use a straight pipe thread of the largest diameter it is possible to cut on a pipe. This thread has also been standardized and is designated in the report mentioned as the "maximum external and minimum internal lock-nut threads." The pitch of this lock-nut thread is the same as the pitch of a standard taper thread of corresponding size. To illustrate the difference between a straight lock-nut thread and the straight pipe thread first referred to, we shall consider the difference between the diameters of the 1-inch normal size. In the case of the straight pipe thread the basic pitch diameter is 1.2386 inch, whereas, in the case of a lock-nut thread, the maximum pitch diameter for an external thread is 1.2603 inch.

The straight external pipe threads are recommended only for special applications, such as long screws and tank nipples. In gaging, the tapered working plug gage for the American or National standard is used, allowing the same tolerance for the notch as for a taper thread.

LENGTH OF QUARTER-TURN BELTS

C. M.—Is there any formula for finding the length of a quarter-turn belt?

ANSWERED BY D. C. PAGE, FITCHBURG MASS.

The standard handbooks do not give formulas making it possible to determine the length of a quarter-turn belt. Several years ago, therefore, the writer developed the formula given below, which has proved satisfactory in practice.

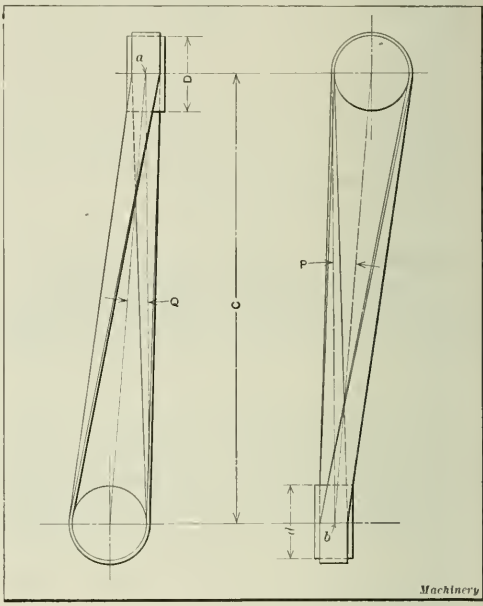

Diagram used in Connection with Formula for finding the Length of Quarter-turn Belts

Referring to the accompanying illustration,

C = distance between centers of pulley shafts;
D = diameter of one pulley;
d = diameter of other pulley;
L = total length of belt;
½ $D \div C$ = cot P;
½ $d \div C$ = cot Q.

The values of C, D, d, and L must, of course, be given in the same unit of measurement; that is, they must all be given in inches or feet. Employing the above symbols, the length of the belt is found by the formula

$$L = 2C + \frac{(D + d)\pi}{2} + 0.01746D\ (90 - P) + 0.01746d\ (90 - Q)$$

In working out this formula it was assumed that the belt leaves pulley D at point a, and pulley d at point b, as indicated in the illustration. Actually, however, the belt does not leave the pulleys at exactly these points. For this reason the formula will give a result which is slightly in excess of the exact length. This error, however, is so slight that it does not affect the operation of the belt provided that distance C is always greater than $4(D + d)$. It is obvious that the amount of error decreases as the distance between the pulleys is increased.

Charting the Conditions of Business

By ERNEST F. DuBRUL, General Manager, National Machine Tool Builders' Association, Cincinnati, Ohio

THE chart shown in the accompanying illustration, if kept for each line of product made by a manufacturer, will assist him to control his production in accordance with the actual demands. The great variations in economic cycles occur because of maladjustments between supply and demand, and the greater the number of firms that control their own business in accordance with the demands of the market, the healthier will all business be. In this chart the lines are made up on the cumulative plan. This means that by simply adding the monthly increments of each item, it is possible to measure upward on any vertical line on the chart to obtain the total amount of that item up to date.

The lowest line, which represents consumers' sales, starts at zero. The line which represents shipments starts at the figure above zero that shows the amount of stock of a given machine in the hands of dealers at the beginning of the year. The line marked "Production Finished" starts with the figure plotted above the line marked "Factory Shipments" showing the amount of manufacturers' finished stock on hand at the beginning of the year. The line marked "Production Started" begins with the figure plotted above the line designated "Production Finished" showing the number of units in process but unfinished at the beginning of the year.

The line marked "Net Orders" is a composite line. It starts with the number of machines on unfilled orders at the beginning of the year, plotted above the starting point for the shipment line. It represents the result obtained by deducting the month's cancellations from the new orders received during the month. The order line is the only line that can cross the production or process line. None of the other lines can cross each other, although some might meet and diverge. The order line is also the only line that can show a dip from a previous high point. This would occur only in months during which cancellations were greater than the new orders received. The amount of dip would therefore be the minus quantity resulting from this condition.

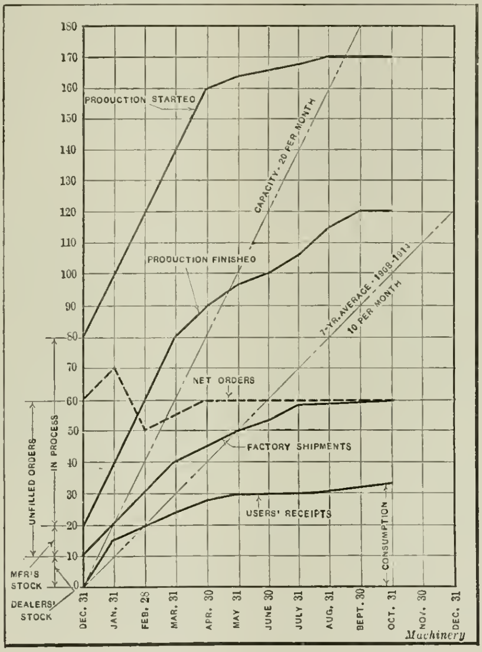

Chart for controlling Production to suit Actual Demands

Two faint dot-and-dash lines are shown running diagonally. The upper one of these represents the accumulated monthly economic capacity of the plant for producing this particular type of article, due account being taken of the quantities of other production which normally accompany the type for which the chart would serve. The second dot-and-dash line represents the monthly average shipments of this particular type, taken over a period covering, say, the pre-war years 1908 to 1914 inclusive, if that would seem to be the highest standard figure that this industry could reasonably expect to count on for some time to come. In this chart these two lines show quite a divergence on their cumulative rise, due to an excess of capacity. The spaces between the various curves on the chart correspond to the balances at the end of the month. The dip in the order curve shows an excess of cancellations during one month.

The chart as drawn shows the situation in the plant of a supposititious manufacturer who has allowed conditions to get out of balance. It will be noted that at the beginning of the year he had ten units of finished product on hand, corresponding to half of one month's capacity. Plotted above this is the amount in process—sixty units, representing three times the capacity, and it may be assumed that the process required three months. His unfilled orders of fifty units were plotted that many points above the dealers' stock. At the beginning of the year these covered not only what he had on hand, but also forty in process. The fact that he had finished product on hand and unfilled orders in addition would indicate that some of these unfilled orders were suspensions.

In the month of January net orders and shipments from the factory showed a rise, but so did the balance in stock in the hands of the dealers. As the shipments went out at only half the production rate, the number of parts finished during the month amounted to as much as would be shipped in two months. The line of actual shipments to the consumer flattened out faster than the line of total shipments, due to the dealers' stock gradually getting larger and larger. With production going straight ahead, the manufacturer's finished stock also grew larger.

For three months the "Production Started" and "Production Finished" lines ran parallel. Supposedly, after February cancellations, and poor sales in March, the manufacturer began to slow down the amount of work completed, although in April he started the usual amount of new work.

The executive using the chart illustrated did not control production with an eye on the actual sales to users, and he greatly over-anticipated sales. The users actually took thirty-three units in ten months, while the manufacturer finished 120 units, counting his own and the dealers' stocks. An over-anticipation of this kind means at the least a period of idleness for the producer. When the whole industry is in the same condition, it indicates such a serious maladjustment between actual supply and demand that loss to someone is inevitable. A chart of this sort is good not only for individual concerns but also for the industry as a whole.

The Metal-working Industries

REPORTS on conditions in the machine tool field vary considerably according to the line of machines built. Some manufacturers say there has been a decided improvement during the last three months, while others find insufficient change to warrant making definite plans as yet, based on increases in their business. But the fact is that there has been, on the average, a marked improvement. There has been more actual buying of machine tools during this period than in any other three consecutive months of 1921. This can be stated with certainty, and is confirmed by machine tool dealers, some of whom have done enough business during the last three months to pay running expenses and overhead, which very few found possible during the early part of the past year.

The small tool business shows a greater degree of activity than the machine tool trade, and while these shops also are all running on very much reduced schedules, it is interesting to note that, compared with pre-war sales, the present business is not abnormally low. One manufacturer of small tools is doing 70 per cent of his pre-war business, and another confidently expects to equal his pre-war sales during the coming year. Even in the machine tool field there are instances where present output is equal to 40 per cent of present capacity, which in many cases is equal to the manufacturers' pre-war business.

General Outlook in the Machine Tool Field

The prospects for 1922, upon which manufacturers generally agree, is that business will improve slowly during the first eight months or so, and the pace will be more accelerated during the last four months of the year. Many manufacturers and dealers expect that 1923 will be a normal year in this field, meaning by normal, a business that will sustain the industry as a whole, although by no means demanding the entire capacity at present available for machine tool building—a capacity expanded to meet the extraordinary demands of the war period, and, therefore, far in excess of peace requirements.

It is not unreasonable to expect, however, that in a few years even this excess capacity will be absorbed; at least, the history of the machine tool industry in this country warrants the belief that it will be. Time and again, during periods of depression, it has been generally held in the industry that capacity greatly exceeded the requirements for many years, but as soon as the business pendulum swung back to prosperity the machine tool plants found themselves working to full capacity and under the necessity of increasing their facilities. Periods of extreme depression and of unusual activity are now recognized as inevitable in the machine tool industry, for the reason that this basic industry is active only when other industries are expanding.

Demand for Cost-reducing Machinery

It is interesting to note that even though very little of the present machine tool equipment is employed, manufacturers are, nevertheless, buying certain types of high-production machinery and discarding the less productive in order to reduce manufacturing costs. With this object in view, orders have recently been placed for some highly automatic machinery, and machine tool manufacturers are concentrating on the development of types that will increase production and reduce labor costs. One of the machines recently completed doubles production without increasing labor costs, while the first cost of this equipment is increased by only 15 per cent. In another case the rapidity of performing a certain operation on automobile parts has been so improved within the last two years, through the efforts of two competing manufacturers, that the output is now three times what was formerly considered extremely good production. It is believed that the next two years will see some remarkable advances in machine tool design, and particularly in the field of automatic and semi-automatic machinery.

The Iron and Steel Industry

The iron and steel industry—the basic industry and the barometer for the entire metal-working field—is definitely looking toward better business during 1922, and is justified in this by steady markets and the slightly improved percentage of operation during the month of January. The United States Steel Corporation is operating at about 45 per cent capacity, and the independent companies, on an average, at nearly this percentage. Pig iron production for December was the largest since last February, and additional furnaces have been blown in. Taking an average of all iron and steel products, the output in 1921 was about one-half that of 1920. The exports of iron and steel products have steadily increased since September.

The Automobile Industry

During 1921, 1,535,000 passenger cars were built, and approximately 145,000 trucks. The export trade fell off heavily, as compared with 1920. In that year 140,000 passenger cars and 30,000 trucks were exported, as against 31,000 passenger cars and 8000 trucks in 1921. The figures show that the output of automobiles and trucks in 1921 was approximately 80 per cent of the output in 1920, the banner year in the automobile industry. The production for 1921 was far in excess of expectations in the automobile trade a year ago, and this great industry may be considered to have made a very rapid and quite remarkable recovery from what was expected to be not only a severe but a rather lingering depression. For 1922 it is estimated that practically the same number of cars will be built as in 1921.

The General Price Situation

The Federal Reserve Bank of New York regularly computes the average price of twelve basic raw materials, and the most recent compilations show that this price has remained close to the 1913 average ever since last July. This not only indicates stability in the prices of raw materials, but also a basic price level upon which to establish prices in all other industries at levels likely to restore confidence and encourage activities in all fields.

In machine tools there have been decided reductions, and the best thing for this industry now would be the establishment of prices based upon present labor and material costs and a strict adherence to these prices. Until definite price levels are generally maintained, manufacturers will have difficulties with buyers, who naturally seek bottom prices when there is no stability.

MACHINERY on many occasions has stated the reasons why there is no possibility of a return to pre-war prices for machine tools. The improvements made in all kinds and types of machines increase their manufacturing costs as well as their efficiency. The skilled labor employed in the manufacture of machine tools is also on a permanently higher wage level than before the war, and selling expenses have materially increased as a result of increased freight rates, passenger fares, hotel expenses, and similar items on which the advances have been very great and the reductions relatively insignificant.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW AMERICAN METAL-WORKING MACHINERY

The New Tool descriptions in MACHINERY are restricted to the special field the journal covers—machine tools and accessories and other machine shop equipment. The editorial policy is to describe the machine or accessory so as to give the technical reader a definite idea of the design, construction, and function of the machine, of the mechanical principles involved, and of its application

Heald Automatic Ring Grinding Machine

CONSIDERABLE interest was manifested at the automobile show held in New York City the early part of January, in an automatic surface grinding machine developed for grinding the sides of such circular parts as piston-rings, ball and roller bearing races, collars, washers, gears, and valve seats, on a quantity production basis. This machine, known as Style No. 25, was exhibited by the Heald Machine Co., 16 New Bond St., Worcester, Mass., and was set up for the grinding of piston-rings which were automatically fed to the wheel. In addition to the applications mentioned, it may also be employed for general work. One of the unusual features of the machine is that the wheel-slide is driven through a simple hydraulic arrangement operated by oil, which enables any speed from zero to maximum to be instantly obtained, and allows the table to be reversed instantly at any point without shock. This hydraulic arrangement may be seen in Fig. 1, attached to the front of the column.

The automatic feeding of the work to the grinding wheel is effected by means of a patented device, it being only necessary to load the magazine and take away the finished product. As will be seen by reference to Figs. 3 and 4, the device consists of a feeding plate having five holes bushed to take rings up to 5 inches in diameter. As the plate indexes, a ring is slid from the magazine to the center of the magnetic chuck, where it is ground by the wheel and then slid from the chuck. The feeding plate is indexed by a lever connected to a crank disk at the back of the machine, which

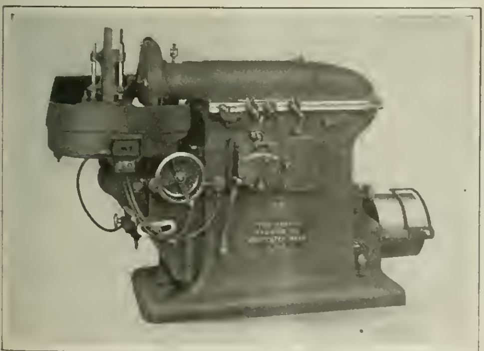

Fig. 1. Automatic Surface Grinding Machine developed by the Heald Machine Co.

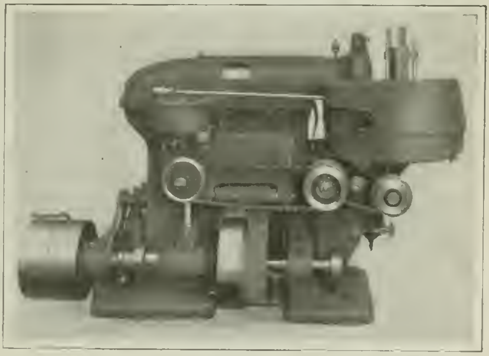

Fig. 2. Rear View of Grinding Machine, showing the Main Driving Shaft

is operated by a simple friction device. This disk is held stationary by a latch while the wheel-slide moves forward to enable the wheel to grind the ring on the chuck, but as the wheel-slide returns, the latch is tripped, allowing the crank disk to revolve and thus index the feeding plate one-fifth of a revolution. A guard placed over the ring being ground prevents any danger of flying parts in case the ring should break.

The wheel-spindle is made of chrome-vanadium steel, and it is mounted in an adjustable bearing at the wheel end. Adjustment of this bearing can be readily effected through an opening in the top of the wheel-slide. The rear end of the spindle is mounted in a self-aligning ball bearing. The main driving shaft is located at the rear of the machine, as illustrated in Fig. 2. It is mounted in roller bearings and has a two-step cone pulley giving two speeds to the grinding wheel, thus enabling the wheel to be run at an efficient surface speed throughout its entire life.

The chuck spindle is mounted in ball bearings and driven through spiral gears, the spindle housing being absolutely tight so that the bearings and gears may always be immersed in oil. When the machine is used for general work without the automatic feeding device, the chuck bracket can be adjusted to permit concave and convex surfaces to be ground. A diamond located on the chuck pan can be readily adjusted to true the wheel so as to obtain the desired thickness of the work. In order to bring the wheel in position for dressing, the left-hand reversing dog, seen on the wheel-slide in Fig. 1, is thrown up to allow the slide to travel toward the back of the machine until the reversing lever engages a safety latch-dog. The latter controls the reciprocations of the slide past the diamond. The dogs on the front of the machine, besides controlling the travel of the wheel-slide, also govern the action of the feeding device.

A disk at the rear of the machine equipped with an electrical contact, furnishes current for the chuck at the time that the work is being ground. However, as the disk revolves the current is automatically shut off for an instant and reversed, thereby demagnetizing the chuck and the work before the latter is removed. By the time the next ring is slid into place over the chuck, the current is automatically switched on again. An automatic vertical feed can be furnished with this machine when it is to be used for general work, but this device is not adaptable to a machine furnished with the ring-feeding device. A water equipment, including a pump, tank, water guard, and connections, can also be furnished when desired.

This machine can be equipped with an 8-, 12- or 16-inch magnetic chuck, but the automatic feeding device for rings can be furnished only with the 8-inch size. Some of the

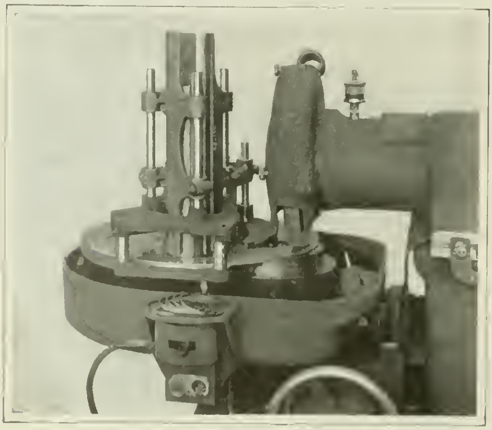

Fig. 3. Close-up View of the Grinding Wheel, Magnetic Chuck, and Automatic Feeding Device

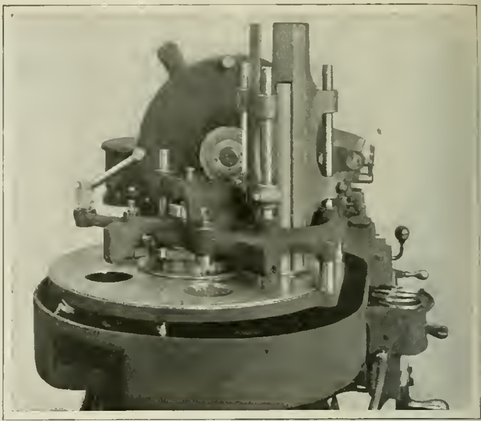

Fig. 4. Another View of the Automatic Feeding Device, looking directly toward the Grinding Wheel

principal dimensions of the machine when equipped with an 8-inch chuck are as follows: Maximum and minimum distances from top of chuck to center of grinding wheel, 12 and 4¾ inches, respectively; vertical adjustment of chuck, 7¼ inches; maximum diameter of work automatically handled, 5 inches; and maximum thickness, 2 inches. When the machine is to be driven directly by a motor, a 10- to 15-horsepower size is recommended, depending on the nature of the work.

ABBOTT BALL BURNISHING BARREL

The principal feature in which the ball burnishing barrel shown in the accompanying illustrations differs from other burnishing barrels manufactured by the same concern is in holding the articles to be burnished stationary on the inside of the barrel body and carrying them through the mixture of balls, soap, and water, whereas in previous designs the work was placed in the barrel loose and allowed to tumble in the mixture. This machine was brought out by the Abbott Ball Co., Elmwood, Hartford, Conn., to enable large work to be burnished without the different pieces coming in contact with one another in such a way as to scratch their surfaces. The periphery of the barrel is eight-sided, each side having a hinged hand-hole cover over an opening into the barrel.

The edges of the openings are beveled to an angle of 45 degrees, and a lid machined to suit these bevels fits into each opening. This lid is held in place by the hinged cover coming in contact with a flat spring on the top of the lid, which also serves as a handle to facilitate the removal of the lid. The hinged covers have packing rings which prevent the mixture from leaking out of the barrel. On the inside face of each removable lid is attached a fixture for holding the work it is desired to burnish. Fig. 2 shows a barrel with a portion broken away to show the manner in which it is equipped for burnishing parts of hacksaw frames.

The machine is designed primarily for the use of manufacturers having large quantities of one or more classes of work to be burnished. Two or three sets of lids may be provided, equipped with fixtures suitable for the different classes of work. Then, in operating the machine, while eight fixtures filled with one class of work are being revolved in the barrel, another set of fixtures can be unloaded and loaded. After the work has been finished, it is removed from the barrel by lifting each hinged cover in succession and raising the corresponding lid and work-holding fixture. Of course, another fixture with unfinished work is put into place in each instance before the next hinged cover is raised, so that the mixture is retained in the barrel.

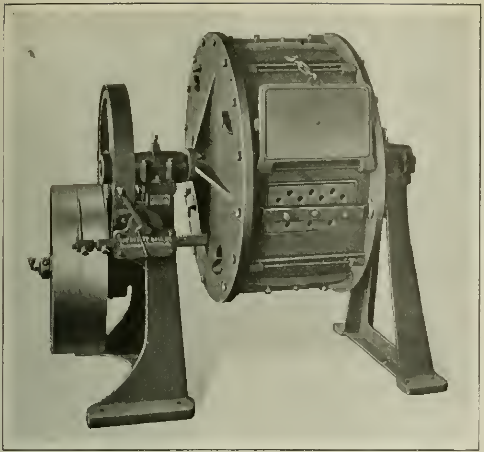

Fig. 1. Ball Burnishing Barrel which is a Recent Development of the Abbott Ball Co.

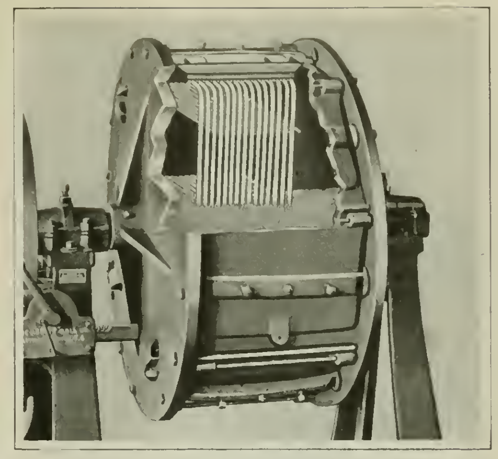

Fig. 2. Close-up View of Barrel broken away to show Manner of holding the Work

With work that is to be plated, it will be found advantageous to have at least three sets of fixtures so that when the work is removed from the barrel ready to be plated, it may be left on the fixtures while being put through the plating operation and then brought back to the burnishing barrel for the final burnishing. Fig. 1 shows the method of holding the hinged cover in a raised position and also shows a lid fitted up with wire screening. This screening is of a mesh that will not allow any of the balls to come out, and is for the purpose of furnishing an easy method of keeping the inside of the barrel and the balls clean. In cleaning the barrel, it is first filled with water, then the strainer cover is put in place, and the barrel revolved. The inside of the barrel and the balls are satisfactorily rinsed in this way.

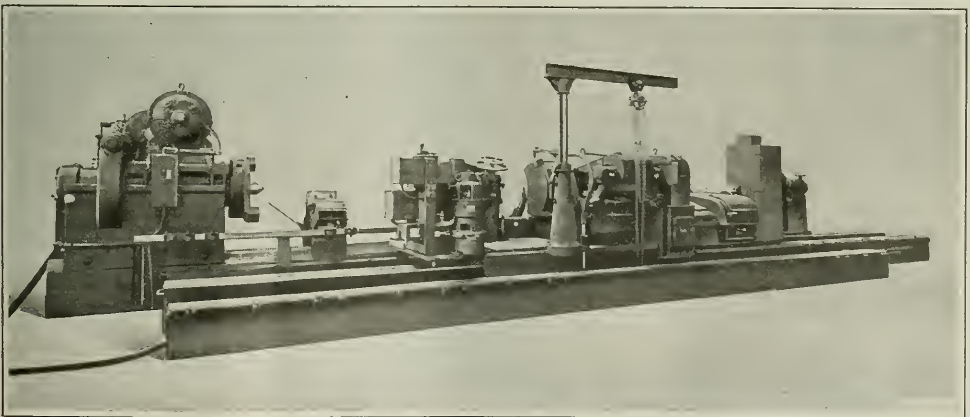
NORTON ROLL-GRINDING MACHINE

Two cylindrical grinding machines of the single-wheel type, designed for dressing steel-mill rolls up to 54 inches in diameter and 28 feet in length, have been recently installed in the shops of the Jones & Laughlin Steel Co. by the Norton Co., Worcester, Mass. These machines are among the heaviest of their class ever built, weighing about 50 tons, and are quite similar in design to other Norton machines built in the past for the same purpose. Each machine is electrically driven and controlled throughout. Four Westinghouse motors are provided, a 40-horsepower unit being mounted on the wheel carriage for revolving the grinding wheel and traversing this carriage, a 20-horsepower motor on the headstock for revolving the work, a 3-horsepower motor on the footstock for traversing this member along the ways of the work-base, and a 3-horsepower motor on the wheel carriage for driving the pump and traversing the grinding wheel at right angles to the work.

The operation of the machine is governed by magnetic controllers, the position of the operator being on the wheel carriage and beside the grinding wheel, where he may look down between the work and grinding wheel faces and observe the grinding process.

The rolls may be rotated either between centers or on specially constructed adjustable bearings. Within the reach of the operator are all the handwheels and levers necessary for starting and stopping the wheel, starting or stopping the roll, reversing the traversing wheel carriage either by hand or by power, moving the wheel carriage for slight adjustments by hand, moving the wheel toward and away from the work either by hand or by power, starting or stopping the traverse of the wheel carriage, changing from the maximum to the minimum speed of the wheel-carriage traverse, and controlling the amount of water or coolant flowing over the wheel and work.

Changes in the speed of the work are accomplished at the headstock by means of a drum controller and change-



Cylindrical Grinding Machine built by the Norton Co. for Rolls up to 54 Inches in Diameter and 28 Feet in Length

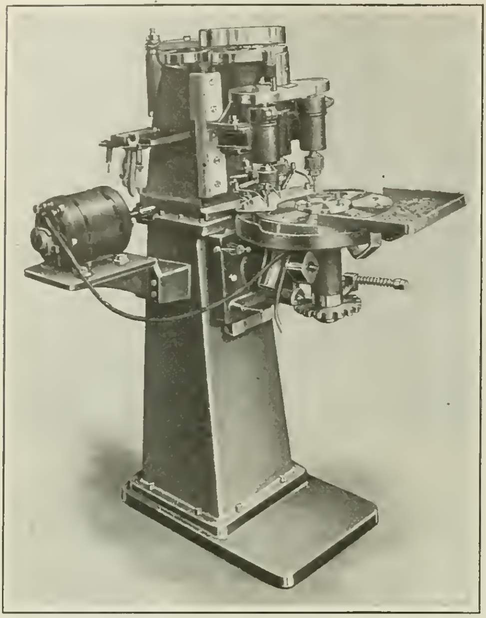


Fig. 1. Dial-feed Multiple-spindle Tapping Machine which is a Recent Development of the Anderson Die Machine Co.

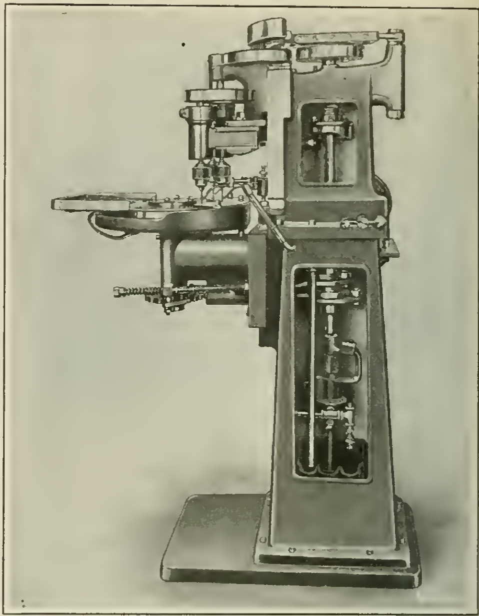

Fig. 2. Left-hand Side of Machine with Various Covers removed to show the Operating Mechanism

gears, while four speed changes for the traverse of the wheel carriage are effected by means of a lever on the front of the carriage. Eight speed changes are possible for this unit through the use of back-gears. An attachment adjustable to any radius up to 3½ inches is furnished for forming the corner of the grinding wheel to suit the grinding of fillets, while the truing device maintains the face of the wheel.

ANDERSON DIAL-FEED MULTIPLE-SPINDLE TAPPING MACHINE

To make possible high rates of production in the tapping of small steel and brass parts used extensively in the construction of electrical appliances, or in tapping nuts and other small pieces requiring a number of tapped holes, the Anderson Die Machine Co., Iranistan Ave. near Admiral St., Bridgeport, Conn., has produced a dial-feed multiple-spindle tapping machine which has a number of novel features incorporated in its design. The general appearance of the machine is shown in Figs. 1 and 2, from which it will be seen that it is equipped with three tapping spindles, while Fig. 3 shows the mechanism employed for alternately rotating the spindles in opposite directions. This alternate rotation is obtained by means of a crank disk mounted on the top of a vertical shaft located at the center of the machine and extending to the top. The crank disk moves a large gear tooth segment to and fro, the teeth of which engage a train of gears connecting with pinions at the top of the spindles.

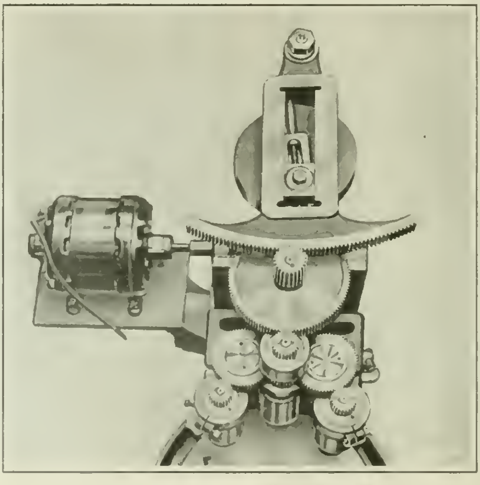

Fig. 3. Plan View of Tap-spindle Reversing Mechanism

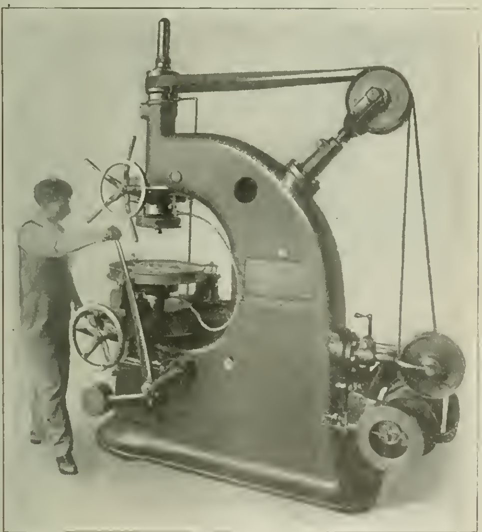
The work-holding dial is indexed by means of cams mounted near the middle of the vertical shaft, which lock the dial in position after each indexing. The ratchet that controls the dial operation is regularly furnished with eighteen teeth to correspond with the number of openings usually supplied around the dial for the work. The dial is made of relatively thin material, and the openings are made to fit the particular pieces to be operated on. Parts of various shapes may be accommodated by simply substituting a dial with openings of the necessary contour. Any piece requiring one, two, or three tapped holes can be tapped at one movement of the dial past the spindles, and on account of the construction of the spindles, three taps of entirely different leads may be employed at the same time.

The two end tapping spindles are adjustable so that holes in various positions may be tapped. Each dial is designed to suit the fixed central spindle and then is located and indexed in such a way as to make one hole register with the fixed spindle, the two auxiliary spindles being finally adjusted to suit the location of the other holes to be tapped. When the machine is used for tapping holes of the general sizes met with in electrical work, namely from No. 4 to 10, the taps are operated at the rate of fifty-six strokes per minute, which gives an hourly production of 3360 pieces having either one, two, or three holes.

On pieces where only one hole is to be tapped, it is possible to increase the production 100 per cent by doubling the number of work slots in the dial, which can be conveniently done by staggering them, and adjusting one of the auxiliary spindles to suit the work held in the staggered openings. With this provision, the production on single-hole tapping is approximately 112 pieces per minute. By furnishing a cam and slide which will work in conjunction with the dial, the machine may be modified so that round pieces can also be tapped without difficulty. Ball bearings are provided for all shafts that run at comparatively high speeds, and all gears are accurately cut. The machine is driven by a direct-connected motor mounted on a bracket attached to the left side of the column.

BLOMQUIST-ECK DOUBLE-FACING AND BORING MACHINE

The Blomquist-Eck Machine Co., 1146 E. 152nd St., Cleveland, Ohio, has designed the double-facing and boring machine shown in the accompanying illustration. The machine, as illustrated, is used for facing and boring automobile wheels at one setting, to insure that both sides of the wheel will be parallel. There is one cutter-head above the work and another below it in the base of the machine. After the wheel to be operated upon has been chucked, the hand-lever being actuated by the operator in the illustration brings up the lower head, which faces the under side of the wheel. As the spindle of this head moves upward, it brings a gage with it, which the operator locks upon the completion of the lower facing operation. He then brings down the upper facing spindle, which bores the hole and faces the hub simultaneously. As this spindle is brought down, a rod controlled by it strikes the gage referred to, at the time when the wheel has been faced to the right thickness, and prevents further downward movement of the spindle. The spindles are then moved to their original positions, the gage released, the wheel removed, and another wheel put in place, after which the operation is repeated.

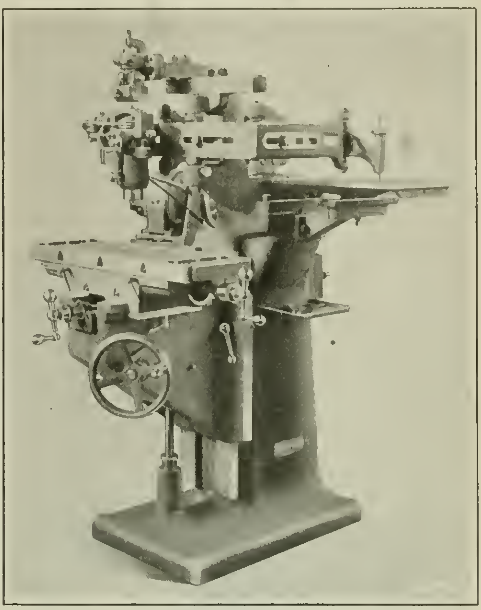


Machine developed by the Blomquist-Eck Machine Co. for boring and facing Automobile Wheels

The oiling system provides for lubricating the upper drive-pulley bearing, the upper spindle quill, and the lower spindle quill by one continuous flow of oil, a flexible tube connecting the upper and lower spindle quills. The pump can be adjusted to supply any necessary amount of oil. The machine is provided with S K F ball bearings throughout. The drive from the countershaft in the back of the machine to the spindle quills is through 3-inch single-ply belts.

GORTON HEAVY ENGRAVING MACHINE

To meet the demands for a heavy engraving machine suitable for cutting dies, steel stamps, and large-size letters, and for handling other similar jobs in steel, brass, and cast iron, the George Gorton Machine Co., Racine, Wis., has developed the No. 1-S engraving machine, which is heavier and has a greater capacity than the machines previously built by this concern. On the new machine the pantograph may be set for various reductions of from 1 to 1 down to 6 to 1. Both radial and thrust ball bearings are provided for the pivots, all other pantograph bearings consisting of hardened, ground, and lapped male and female cone-point centers. The tracing style is held in a ½-inch collet and the adjustable scales are mounted on the top surfaces of bars. The scales have engraved figures giving the settings for the various reductions, and are graduated the full length with twenty graduations to the inch.



Heavy Type Engraving Machine developed by the George Gorton Machine Co.

The cutter-head is an integral part of the heavier of the pantograph bars. Its spindle is mounted on ball bearings and regularly has a range of from 1800 to 8000 revolutions per minute, thus enabling small cutters to be used for fine work and finishing up corners. However, spindle speeds down to 600 revolutions per minute may be obtained by using special driving pulleys. The spindle nose has a straight hole ⅜ inch in diameter, and a collet nut for holding cutters. Extra bushings can be supplied for taking drill-rod cutters less than ¼ inch in diameter.

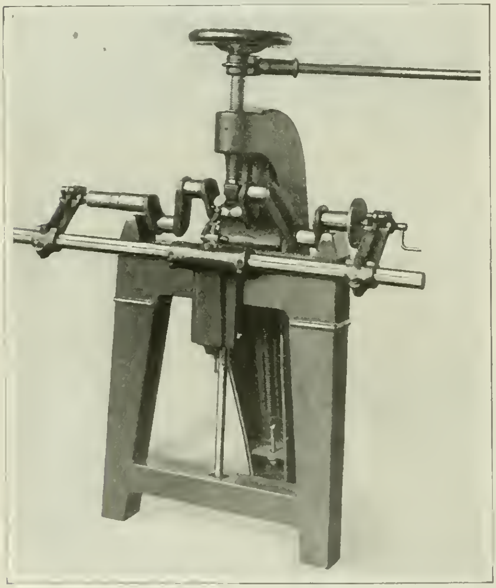
A heavy spindle running in bronze bearings and at slower speeds than those specified can also be furnished in place of the ball-bearing spindle or as an addition to the regular equipment. The table is 10 inches wide, 30 inches long, and provided with three T-slots. An oil-groove planed along each edge allows the cutter lubricant to drain into pockets at the ends of the table. This member is gibbed to take up wear, and a lock-screw provides for holding it in the desired position.

When engraving work of curved or irregular contour, the forming attachment used has six different adjustments which permit it to be set quickly and accurately relative to the work to be engraved. The lower member of the attachment is located directly over the center of the spindle and carries the former block, which is a hardened piece of steel of the same shape as the engraved surface except in the reverse. This block controls the vertical movements of the spindle. The copy-holder is mounted on a bracket at the right-hand side of the machine and is adjustable to compensate for changes in the reduction of the pantograph. The machine is regularly equipped with a copy-holder to suit the work to be handled, and a considerable variety of these can be furnished. Those who have smaller machines built by this concern can utilize any of their copy-holders on this machine through the use of an adapter.

Some of the important dimensions of the machine are as follows: Longitudinal feed of table, 17½ inches; cross-feed of table, 8¼ inches; minimum distance from nose of spindle to top of table, ½ inch; and maximum distance from nose of spindle to top of table, 16 inches. The approximate weight of a belt-driven machine is 1800 pounds, and that of a motor-driven machine 1950 pounds.

GEIER PRODUCTION STRAIGHTENING PRESS

A No. 2P straightening press intended for handling large quantities of parts without removing them from between centers has been recently developed by the P. A. Geier Co., Cleveland, Ohio. The round bar on which the center brackets are mounted is fitted to a sliding head provided with a roller bearing. The bar can be moved freely to the right or left to permit the straightening or bending of work at any point along its length. The sliding head unit is pivoted to the



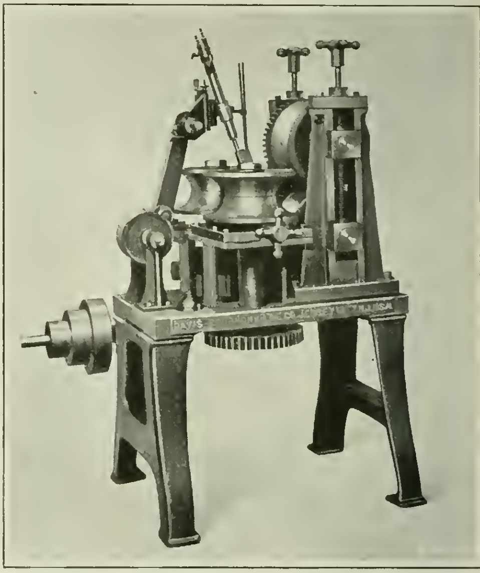
Production Straightening Press placed on the Market by the P. A. Geier Co.

frame of the press and held in a horizontal position by a vertical shaft equipped with a compression spring on both sides. The head also has an up-and-down movement obtained by means of a spring in the rear leg, which is connected by a cable. An adjustable stop-screw enables set-ups to be made that permit the work to clear the blocks.

The handwheel is graduated in twenty-five equal spaces and by turning it through one space a 0.0001-inch up or down movement of the pressure screw is obtained. The amount that a part is out of truth can be read in thousandths of an inch from a dial indicator supplied with the machine and used with the work placed between the centers. This indicator has a ¼-inch stroke. A few of the principal dimensions of the press are as follows: Length of bed, 26 inches; distance from center of screw to frame, 4 inches; maximum distance from bed to thrust block on screw, 8 inches; minimum distance, 2 inches; and maximum distance between centers, 40 inches. The net weight of the machine is about 500 pounds.

DAVIS-BOURNONVILLE TUBE-WELDING MACHINE

An oxy-acetylene tube-welding machine designed for the quantity production of large-diameter thin gage tubing has just been brought out by the Davis-Bournonville Co., Jersey City, N. J. This machine is especially intended for use in tube manufacturing plants where it will be set up and used



Quantity-production Tube-welding Machine added to the Line of Equipment built by the Davis-Bournonville Co.

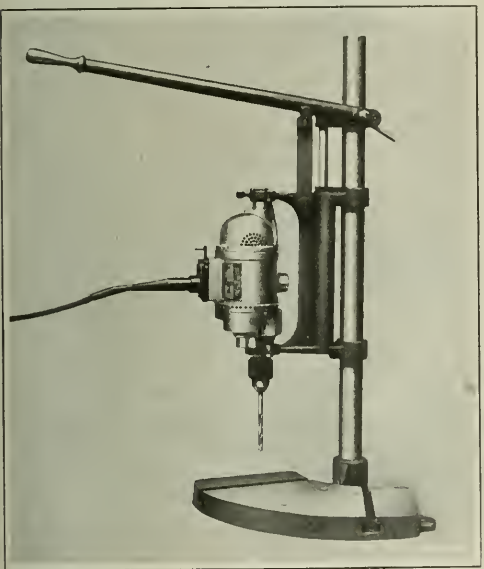
for long runs on one size of tubing. It has two pairs of rolls, one for feeding and the other for welding. The drive is by belt to a three-step cone pulley mounted on a shaft at the rear. This shaft also carries a pinion which drives a spur gear keyed to a shaft having two worms. Motion is transmitted to the feed and welding rolls through a worm-wheel on one spindle of each pair. The worm-wheel driving the feeding rolls is in a vertical position, and that for the welding rolls is in a horizontal position.

The back welding roll is fixed in place, while the one in front is adjustable, its spindle bearing being in a slide, the position of which is controlled through a screw and hand-wheel. The mating gears of the rolls have involute teeth of a comparatively large diametral pitch, which permit adjustments within the range to be made without affecting the smoothness of the tooth action. The upper and lower feeding rolls are geared together, and in this case adjustment is also made by moving one of the rolls and its mating gear. The welding rolls have annular depressions on top to receive cooling water, and a circulatory system can be provided when essential.

The welding torch is of the Davis-Bournonville multiple-jet water-cooled type. Both the tip and the barrel of the torch are cooled by the circulation of water to maintain the conditions necessary for successful continuous welding. The torch-holder permits vertical and horizontal adjustments of the torch and varying of the angle at which the tip is presented to the seam to be welded. The maximum capacity of the machine is for tubing 6 inches in diameter, made from No. 10 gage. Although designed and built for the quantity production of one size and gage of tubing, as previously stated, the machine can be set up for any diameter and gage of tubing within its capacity by employing rolls grooved to suit the desired tube diameter. All rolls, whether for large or small diameter tubes, are the same size over all, and the normal center distances of their mating gears are the same.

UNITED STATES DRILL STAND

To accommodate portable electric drills so that they may be used as bench machines, the United States Electrical Tool Co., Sixth Ave. and Mount Hope St., Cincinnati, Ohio, has



Stand for Electric Portable Drills made by the United States Electrical Tool Co.

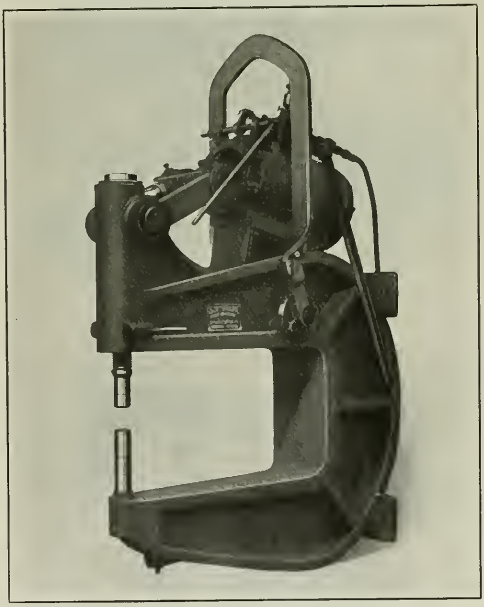
placed on the market the improved drill stand shown in the accompanying illustration. The unit to which the drill is attached may be clamped in various positions along the vertical bar to meet the requirements of the job. The drill is then raised and lowered for the operation through the manipulation of a long lever. The stand will accommodate the 3/8- and 1/2-inch drills manufactured by this company, and without a drill weighs approximately 68 pounds.

MILBURN OXY-ACETYLENE WELDING OUTFIT

An oxy-acetylene welding unit, which is also provided with a tube that adapts the apparatus for burning carbon from automobile cylinders, has been placed on the market by the Alexander Milburn Co., 1420-1428 W. Baltimore St., Baltimore, Md., for use in machine shops and service garages. In addition to the carbon-burning tube, the equipment consists of a welding torch, five welding tips, single-gage oxygen and acetylene regulators, oxygen and acetylene hose, and several other parts used in welding. The outfit is contained in a fiber case. The welding torch is 16 inches long, and of the balanced pressure type operating on approximately equal pressures of oxygen and acetylene. All mixing takes place in the tip. The seats of the regulators close with the pressure rather than against it, thus enabling them to be closed by the exertion of several pounds pressure. The carbon-burning tube fits into the torch-head similarly to a welding tip. It may be conveniently attached and replaced as it becomes worn out.

SOUTHWARK PNEUMATIC RIVETING MACHINE

A line of pneumatic riveting machines made in various capacities from 10 to 150 tons is now being built by the Southwark Foundry & Machine Co., Philadelphia, Pa. On these machines movement is given to the die through a toggle action which causes the die to advance rapidly to the rivet at a decreasing rate of speed and an increasing tonnage, after which the movement is at a uniform speed and pressure for a sufficient distance to drive the rivet tight, drawing the plates together and following up the shrinkage of the rivet with full pressure. It is unnecessary to drive the rivet at the end of the die travel or piston stroke, it being intended that the die be set for any run of work so that the rivet will be headed when the piston has moved through about three-quarters of its stroke, thus allowing a sufficient die travel at full pressure on either side of this position to take care of variations in lengths of rivets, thickness of plates, dimensions of holes, etc., without necessitating further adjustment of the die screw to be made.



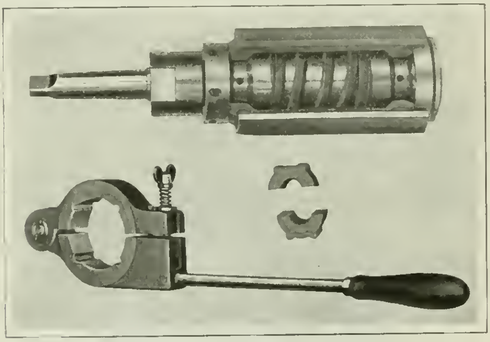
One of a Line of Pneumatic Riveting Machines developed by the Southwark Foundry & Machine Co.

The first inch of piston stroke results in a travel of 1 3/4 inches of the die, which, owing to the fact that the power delivered to the die is in inverse proportion to its movement relative to the piston, develops only four-sevenths of the power actually exerted on the piston. Thus, if a 5-ton pressure is exerted on the piston, only 2.85 tons will be exerted by the die in this position. In the second inch of piston stroke, the rivet die advances 7/16 inch, exerting a pressure of 11.4 tons, and in the third inch of piston stroke, the die advances 5/16 inch, exerting a pressure of about 16 tons. For the ninth and each succeeding inch of piston stroke, the die advances 1/12 inch and exerts a pressure of about 60 tons on the die, this pressure being maintained for ½ inch of die travel.

The operating valve is of the plain sliding type having a simple wick packing on the stem and a removable valve seat which permits ready regrinding. It is provided with means for using line pressure in the pull-back. Two separate pressures may be supplied to the rivet die by turning a plug cock in the valve plate to admit air at full pressure in the pull-back area. This reduces the pressure to the next lower tonnage rating, that is, a standard 50-ton machine will develop both 50- and 30-ton pressures on the die; a 75-ton machine, 75- and 50-ton pressures on the die, etc.

R & C INTERNAL AND EXTERNAL LAPS

The R & C Lap Co., Davenport, Iowa, has developed a line of internal and external standardized laps having interchangeable and replaceable soft metal shells charged with abrasive. The laps were designed especially for finishing parts of internal combustion engines, compressors, and similar apparatus. The shells are supplied in two grades to suit the speed of the operation and the type of work handled. It is stated that highly skilled labor and much experience are unnecessary in order to secure a satisfactory finish with these laps. They are made in various sizes above ¼ inch.



Cylinder and Crankshaft Laps brought out by the R & C Lap Co.

A cylinder lap is shown in the upper part of the accompanying illustration with one section of the shell removed to show the internal construction. This lap consists of a floating shank and expanding device that permits adjustment of the lap diameter and also adjustment to compensate for wear of the soft metal shell. While expanding the lap, the diameter is kept constant throughout the length to insure a true bore in the work. The lap is expanded to the required size by the adjusting nut, and this setting is maintained by a locking nut. The standard shank permits the use of the lap in lathes and drilling machines or by hand.

The lap shown in the lower part of the illustration is of the external type and is used for lapping crankshafts. Another interesting lap made by this firm is a small internal lap intended for tool-room use. The patented construction of this lap permits a slight contraction which prevents the lap from sticking while being used. After a contraction, it cannot expand beyond the original micrometer setting.

H & G SOCKET- AND RATCHET-WRENCH SET

The illustration shows a wooden carrying case containing ten wrench-sockets for hexagonal nuts, which accommodate all sizes of nuts from 7/16 to 1 inch, inclusive; adjustable T-handle; reversible ratchet; universal joint; extension piece; two screwdrivers; and a box wrench. This outfit is

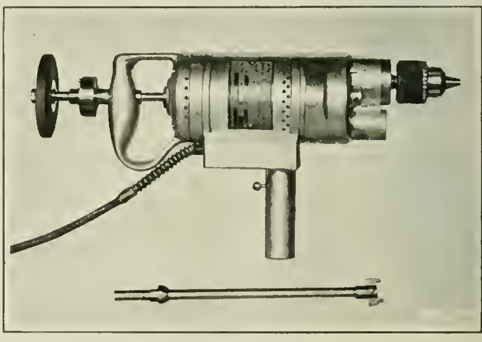
Socket- and Ratchet-wrench Set manufactured by the Eastern Machine Screw Corporation

now being introduced to the trade by the Eastern Machine Screw Corporation, 23-43 Barclay St., New Haven, Conn. Attention is called especially to the manner in which the sockets are manufactured. The hole in each one is first drilled to the dimension across the corners of the nut it is intended to fit, and then the hexagonal shape is formed by drawing in the surrounding metal. This procedure condenses the metal and produces a tough structure. The sockets are provided on top with hexagonal heads by means of which they are turned by the use of the wrench members.

The T-handle has an adjustable cross-bar which can be used in a central position or adjusted to obtain the maximum leverage. The ratchet may be set for use by either the right or left hand by simply raising and reversing the position of a ball-head pin. The extension piece is used between the T-handle and a socket to turn nuts that would otherwise be difficult to reach, or to bring the T-handle into a more favorable position, and the universal joint provides for turning nuts located at difficult angles. Each female part has a split-screw made from spring steel, which produces the necessary amount of friction to hold the parts together while being used.

LOUISVILLE COMBINED PORTABLE DRILL AND GRINDER

One of the distinctive features of the new ⅜-inch portable electric drill now being introduced to the industrial field by the Louisville Electric Mfg. Co., Louisville, Ky., is the grinding wheel attachment made to fit the armature shaft.

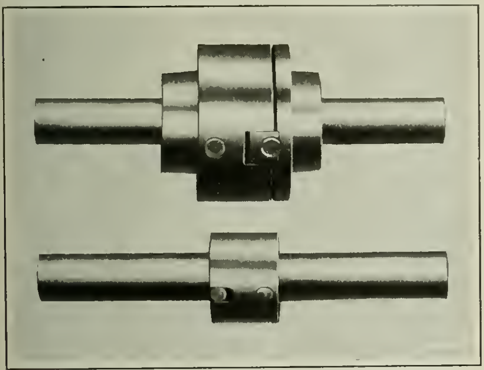


Portable Electric Drill with Grinding-wheel Attachment which is a Product of the Louisville Electric Mfg. Co.

This attachment extends through the handle of the drill into the body, and is equipped with ball bearings and a two- or three-inch grinding wheel running at the rate of 9000 revolutions per minute. The attachment can be inserted whenever the operator desires to sharpen drills or use it for grinding operations. The drill is adapted for use on a lathe. Built into the drill housing is an oscillating automobile-valve grinding device from which the bit holder can be removed at will. This provision makes the drill especially suitable for use in repair shops and garages. The drill motor operates on either direct or alternating current of 110 or 220 volts. The gears are made of heat-treated alloy steel, and aluminum castings are used throughout the construction in order to reduce the weight.

BARTLETT FLEXIBLE SHAFT-COUPLING

A patented flexible shaft-coupling which has a free turning motion around hardened steel pins and a sliding motion in a tongue and groove connection, is now being placed on the market by C. H. Breaker, 4226 Broadway, Indianapolis, Ind., under the name of the inventor, Bartlett. Two styles are shown in the accompanying illustration. The coupling maintains a uniform velocity ratio between the two shafts regardless of the amount of angular or lateral misalignment,



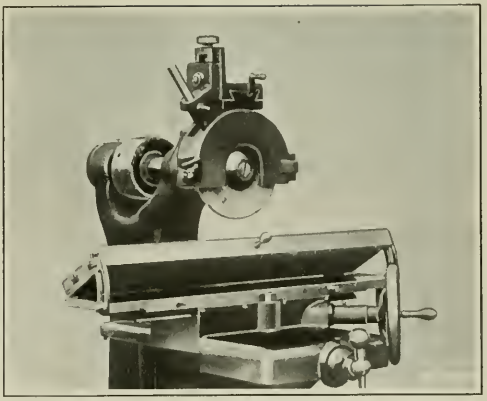
Two Styles of Flexible Shaft-coupling sold by C. H. Breaker

and allows the ample end float essential when couplings are used with alternating-current motor installations, the two sliding members of the coupling being simply pushed into or out of position as necessitated.

The style shown in the upper portion of the illustration consists of two hubs keyed to the shaft ends, two rings which engage each other by means of a tongue and groove construction, and bearing pins driven transversely into each hub. There is another style similar to this, except that the pins are driven directly into the shaft ends, and the hubs are omitted. With the style shown at the bottom of the illustration the pin in one of the shaft ends engages the slotted ring carried by the other shaft end. These coupling members are made of machine steel and heat-treated. With slight changes in the construction, a positive transmission can be had between shafts set at any angle up to 90 degrees.

WILMARTH & MORMAN SURFACE GRINDING MACHINE

In MACHINERY for December, 1921, was published an illustrated description of the No. 1 hand-feed surface grinding machine built by the Wilmarth & Morman Co., 1180 Monroe Ave., N.W., Grand Rapids, Mich., equipped with a swivel sub-table which adapted the machine for handling angular and irregular work. The same machine may now also be



Tilting Table now made for the No. 1 Surface Grinding Machine manufactured by the Wilmarth & Morman Co.

supplied with a tilting table, as here illustrated. Suitable T-slots are provided on this table to accommodate a magnetic chuck, vise, or other fixture. Graduations in degrees facilitate the setting of the table to the desired angle for the work in hand. This design of the table obviates the necessity of tilting or blocking up one edge of a magnetic chuck in order to grind work at an angle. The truing device is conveniently located on the wheel-head, which permits the grinding wheel to be dressed straight or at any required angle without removing the work from the table. A radial truing device operating from the table can also be supplied.

LOUISVILLE MOTOR-DRIVEN HACKSAW

The Louisville Electric Mfg. Co., Louisville, Ky., has added to its line of products a hacksaw driven by a motor which, together with its control switch, is built into the machine so as to be out of the way and at the same time be protected from injury. The slide of the hacksaw is located above the blade for the purpose of keeping the sliding surfaces free from chips and grit. The vise swivels and is provided with graduations to enable the convenient cutting of work at various angles. The stroke of the machine is adjustable from 5 to 7 inches, and there are two speeds, either 45 or 90

Motor-driven Hacksaw brought out by the Louisville Electric Mfg. Co.

strokes per minute. The machine takes a saw 16 inches long, the feed of the saw into the work being by gravity. The motor stops automatically when a piece of work has been cut through. Ball bearings are contained in the construction of the motor and it can be furnished for operation on any circuit. The machine may be equipped with an oil pump when desired, and may also be used as a portable equipment by mounting it on wheels. The weight of this hacksaw is approximately 450 pounds.

BROWN DUPLEX AUTOMATIC FORMING MACHINE

In the line of work classed as screw machine products there are many pieces that can be made most economically by the method known as "form and cut-off.". The duplex automatic forming machine shown in Figs. 1 and 2 has been developed by the L. P. Brown Machine & Tool Co., Attleboro, Mass., to produce parts rapidly according to this principle. The main feature of the machine is the use of two work-spindles which operate simultaneously as two separate single-spindle machines on different pieces of the same product. The machine will make any piece that can be produced with one forming and one cutting-off tool, or with a forming tool and a combined forming and cutting-off tool. This classification includes such parts as special shaped rivets, knobs, studs, handles, etc. By combining the productive capacity of two single-spindle machines in one machine, a saving in floor space, investment, and operating expense is realized.

The two spindles are placed side by side, and the duplicate sets of forming and cutting-off tools work together on two bars of stock so that two pieces are completed in the length of time that would be required for making one on a single-spindle machine. The tooling and setting-up of the machine can be accomplished quickly as a result of the adjustments provided in all directions. The members through which adjustments are obtained are graduated for the convenience of the operator. The rigidity of the machine enables heavy cuts to be taken at high speeds without vibration, and all parts are amply proportioned for strength and longevity. Simplicity was the keynote in designing the machine.

The spindles are hardened, ground, and lapped, and run in phosphor-bronze boxes provided with means of compensating for wear. Thrust is taken up at the rear end of each spindle by hardened steel and phosphor-bronze bushings. The spindles are driven from the shaft of a three-step cone pulley through spiral gearing, which is entirely enclosed and runs in oil. The pulley shaft is provided with roller bearings. Six changes of spindle speed in geometrical progression ranging from 240 to 1820 revolutions per minute are obtainable. The chucks are easily changed; they are adjusted by a nut at the rear end of each spindle, and are prevented from moving endwise when opening or closing.

The feeding mechanism is controlled by adjustable dogs conveniently located. It feeds the work rapidly in any length up to 3 inches, but by the use of extra dogs, lengths up to about 12 inches can be fed. The feeding may be accomplished at any time during the revolution of the camshaft. The forming tools are carried on cross-slides, and can be adjusted independently in any direction. The slides on which the cutting-off tools are mounted are set at an angle to provide clearance between the tools. These tools can be adjusted independently or in unison. Change-gears supplied with the machine enable a production of from 60 to 1800 pieces per hour, the rate, of course, depending upon the character and size of the part. The machine occupies a floor space 44 inches long and 26 inches wide.

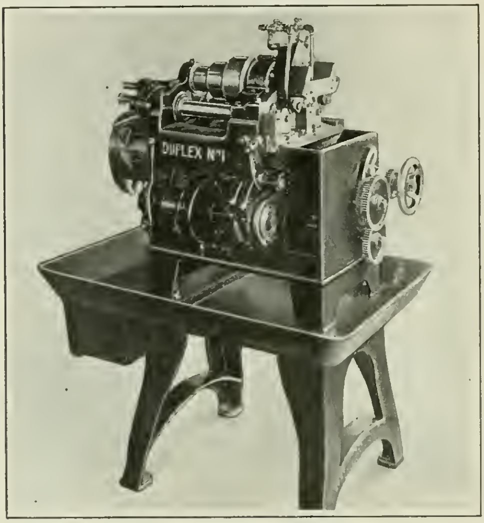


Fig. 1. Double-spindle Automatic Forming Machine made by the L. P. Brown Machine & Tool Co.

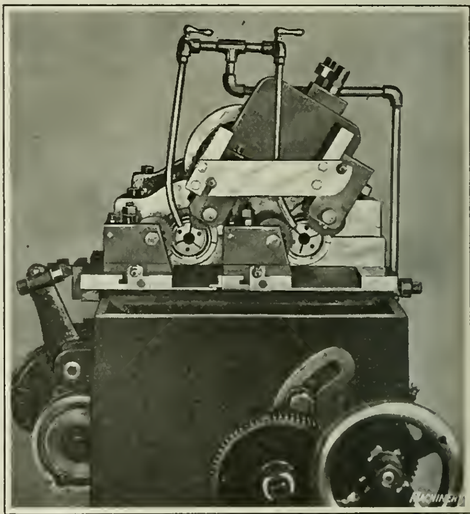

Fig. 2. Close-up View of Automatic Forming Machine showing Arrangement of the Two Work-spindles

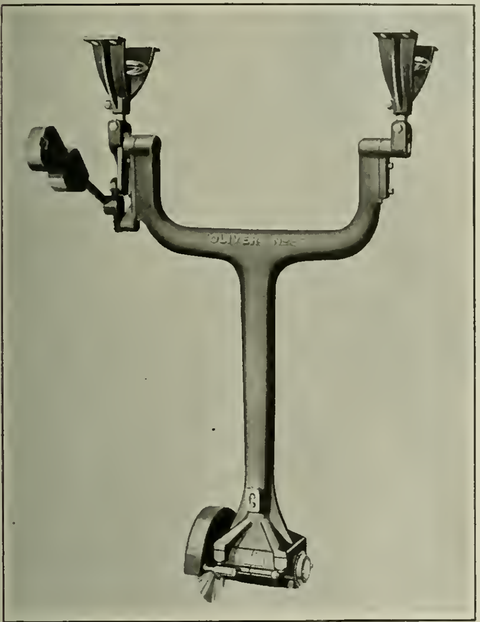
OLIVER SWING CUT-OFF SAW

A swing cut-off saw which may be driven either by belt or by a motor directly mounted on the saw arbor has been placed on the market by the Oliver Machinery Co., Grand Rapids, Mich. The motor-driven type is shown in the illustration, from which it will be seen that the push-buttons used to control its operation are conveniently located directly above the motor. The motor-driven arrangement is supplied only for two- or three-phase, 60-cycle, 220- or 440-volt, alternating current. The motor is of 3-horsepower capacity, and operates at 3600 revolutions per minute. A 16-inch diameter saw is fitted to the end of the saw arbor when the machine is motor-driven, and an 18-inch saw when it is belt-driven.

The frame is a cored casting with a single arm centrally located. The arbor unit is attached at the lower end of the frame by a tongue and groove connection. The frame is made in three standard lengths, 5 feet 5 inches, 7 feet 5 inches, and 9 feet 5 inches, respectively. The saw arbor is made of crucible steel and machine-ground to size. It is mounted in two self-oiling split bearings, and has a speed of 2000 revolutions per minute. The arbor frame is detachable from the main frame, and is adjustable vertically for taking up the stretch of the belt on belt-driven machines. A handle is bolted to the arbor frame for the convenience of the operator.

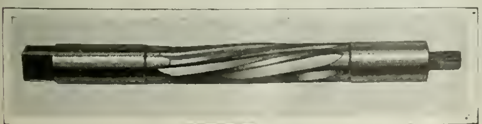
The saw is equipped with a counterbalance consisting of weights on a lever which tend to reduce the resistance of the equipment to the operator. On the belt-driven style, a countershaft extends between the bearings of the frame at the top, and a belt from one of the countershaft pulleys extends through the hollow arm of the main frame to connect with a pulley mounted on the saw arbor in place of the motor. June, 1921, MACHINERY contained a description of a table designed especially for use with a saw of the type described in this article, this table also being manufactured by the Oliver Machinery Co.



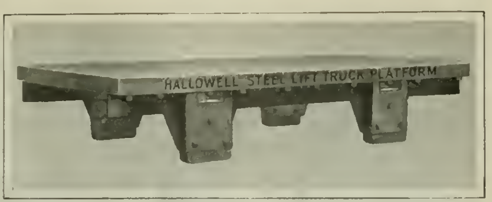
No. 36 Swing Cut-off Saw made in Motor- and Belt-driven Types by the Oliver Machinery Co.

MILLERSBURG HELICAL-FLUTE EXPANSION HAND REAMER

The helical-flute expansion hand reamer here illustrated has recently been placed on the market by the Millersburg Reamer & Tool Co., Millersburg, Pa. The cutting action of the teeth is said to be such that chatter is eliminated, and smooth and accurately sized holes are produced. A patent covering the construction of this expansion hand reamer has been applied for. It is made in various sizes.



Helical-flute Expansion Hand Reamer made by the Millersburg Reamer & Tool Co.



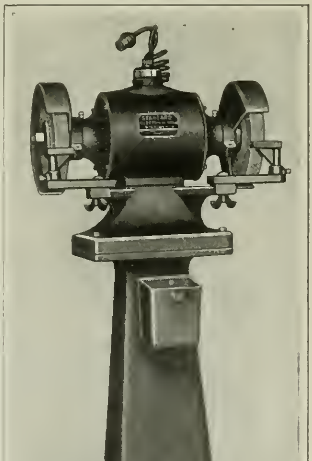
Steel-and-Wood Lift-truck Platform made by the Standard Pressed Steel Co.

"HALLOWELL" LIFT-TRUCK PLATFORM

A platform which may be adapted for use with either hand or power lift trucks is now being manufactured by the Standard Pressed Steel Co., Jenkintown, Pa., as shown in the accompanying illustration. The platform consists of wooden planks to the bottom of which are bolted two steel skids. Riveted to these skids are four steel brackets in each of which a wooden leg-block is bolted to support the entire platform. These blocks can be replaced as they become worn, and are made in different heights so that the clear height of a platform may be changed to suit the truck with which it is employed. An important feature of the skids is that they flare in an outward direction at each end, thus enabling a truck to be readily slid between them. There are also no projecting rivet- or bolt-heads or nuts that might come in contact with the truck.

BENCH AND FLOOR TYPE ELECTRIC GRINDER

A ½-horsepower alternating-current electric grinder of an improved type is now being manufactured by the Standard Electric Tool Co., Cincinnati, Ohio, in a bench style which may also be provided with a pedestal as illustrated. The grinder is fitted with double-row ball bearings and a Westinghouse motor suitable for operation on either 110- or 220-volt, single-, two-, or three-phase alternating current. The grinding wheels are 8 inches in diameter, ¾ inch in face width, and have a ⅝-inch hole. They are extended well away from the body of the motor to permit the grinding of comparatively long and irregular castings or bars. One coarse and one fine wheel are regularly furnished, the former being intended for castings and rough work, and the latter for tools and fine work. A quick make-and-break switch is located on top of the motor, in which position it is within easy reach of the operator. Ten feet of reinforced cord fitted with a plug is regularly furnished. The net weight of the grinder without a floor pedestal is about 110 pounds, and with a pedestal 225 pounds.



Grinder built by the Standard Electric Tool Co.

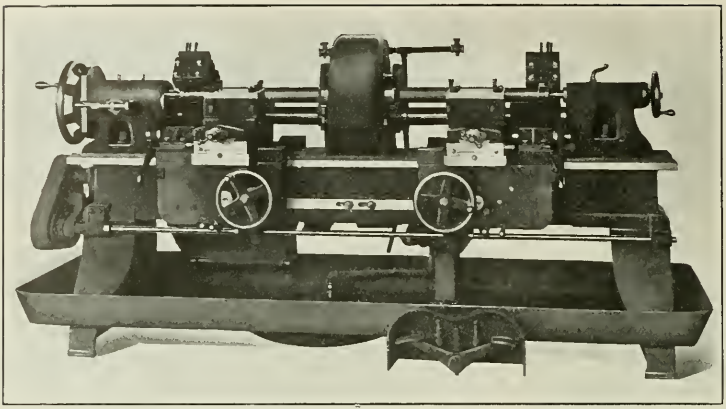


Fig. 1. Short-head Center-drive Lathe of an Improved Type built by the Reed-Prentice Co.

REED-PRENTICE CENTER-DRIVE LATHE

A lathe driven at the center, which was designed by the Reed-Prentice Co., 677 Cambridge St., Worcester, Mass., for turning both ends of Ford automobile driving shafts was described in an article published in May, 1918, MACHINERY. Another machine in which the same driving principle is employed has recently been built by this concern as shown in the accompanying illustrations. However, a considerable number of changes have been made in the general design. This class of machine has proved useful for turning both ends of axles and similar parts, the one limitation on such work being that the part to be machined cannot be turned at the middle portion, because it is held in the headstock at that point.

The headstock is equipped with two chucks, one at each end of the spindle, which are generally of the floating type. These position themselves relative to the outside diameter of the work when the jaws are tightened, at which time the chucks are securely clamped against shoulders on the spindle. By means of this construction the work is held rigidly, is positively driven, and maintains its natural position without deflection. In cases where the work is particularly short, one chuck is omitted to permit the carriages to come closer to the headstock.

The spindle is made of cast iron, has a large hole running its entire length, and rotates in cast-iron journals. It is driven by a motor of at least 7½ horsepower, which is mounted at the rear of the bed as shown in Fig. 2, and drives direct through a silent chain to a sprocket gear on the spindle. The driving mechanism is controlled by a foot-treadle at the front of the machine by means of which a clutch is actuated to engage or disengage the gearing to the headstock without stopping or starting the motor.

The left-hand tailstock has an extra large spindle with two holes running through its entire length, one of these holes being for the purpose of carrying a standard center, while the other is a clearance hole through which the work is telescoped in loading and unloading the machine. By withdrawing the index-plunger at the front of this tailstock, its spindle may be revolved to bring the clearance hole into proper alignment with the hole in the headstock spindle, after which work may be entered or withdrawn from the headstock. When work has been placed on the machine, the index-plunger is again released and the spindle rotated to bring the center once more into proper position for supporting the left end of the work. The withdrawal of the index-plunger is effected through the rotation of a large handwheel, there being a certain angle of free rotation during which a cam surface on the hub of the handwheel causes the plunger to be withdrawn. Then by continuing to rotate the handwheel the plunger picks up the motion and finally brings the center or the clearance hole into alignment with the headstock spindle.

There is no endwise adjustment for the spindle of the left-hand tailstock; however, the spindle of the right-hand tailstock may be moved longitudinally, the latter being similar to the standard type used on engine lathes. Either tailstock may be unclamped from the bed and moved along this member to the proper position to suit longer or shorter work than that for which the machine may be set.

The carriages have their bridges set off center to permit them to work close to the headstock, and their blocks are arranged to receive special magazine tool-holders. Each carriage is provided with an eccentric link motion, by means of which the operator feeds the tools to predetermined positions, at which points they are automatically locked. The longitudinal feed of the carriages is then engaged, and after turning the work to the desired length, a tripping mechanism automatically releases the link and cam actions, causing the tools to recede from the work so that they do not score the latter when they are returned to their starting positions. Each carriage has an individual automatic feed-trip, although they are both driven by a single set of feed gearing at the left-hand end of the machine. Both carriages feed simultaneously toward the headstock. On the particular machine illustrated, a back-arm attachment has been supplied for each carriage, so that the squaring of shoulders as well as the grooving of shaft ends can be performed simultaneously with the turning operation.

Several set-ups possible with this machine are as follows: (1) The machine may be arranged with front tool-blocks for diameter turning and rear blocks for shoulder and taper

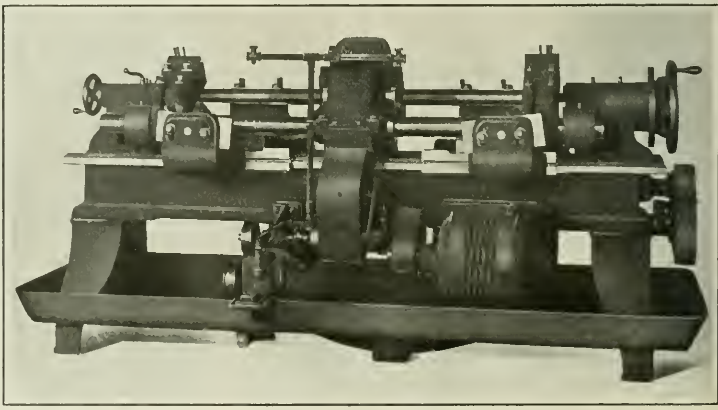

Fig. 2. Rear View of the Machine illustrated in Fig. 1 which is employed for turning the Ends of Shafts, Axles, etc.

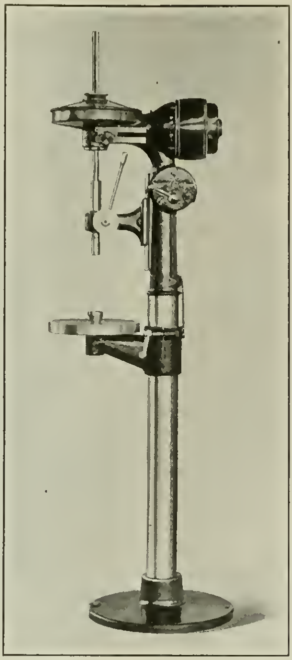
turning, the rear blocks being brought into position by hand after the diameter turning has been accomplished; (2) front tool-blocks may be supplied for diameter turning, and a back arm for use in shouldering, necking, chamfering or grooving simultaneously with the turning step; (3) auxiliary hand-operated tool-blocks may be introduced at the rear for shaving fillets or chamfering corners. On a machine designed for turning shafts up to 2⅞ inches in diameter and having a 9-foot bed, the maximum distance between centers is 72 inches.

LOUISVILLE SENSITIVE DRILLING MACHINE

A 12-inch sensitive drilling machine equipped with friction drive to which power is transmitted by a motor built into the top of a column is a recent product of the Louisville Electric Mfg. Co., Louisville, Ky., which is here illustrated. The motor rotor and the friction disk are mounted on ball bearings. The frictional pressure of the drive is governed by the weight of the disk, thus being constant and requiring no adjustment. The friction drive members are completely enclosed and so constructed that their frictional surfaces are kept free from oil. The spindle is counterbalanced by means of a spring, and its speed can be easily adjusted from 450 to 1200 revolutions per minute. The table is also counterbalanced by a weight within the column. The motor can be furnished for all circuits. Its controlling switch is also built into the machine.



Twelve-inch Motor-driven Sensitive Drilling Machine produced by the Louisville Electric Mfg. Co.

This drilling machine is made in both bench and floor types and supplied with V-blocks and cup and point centers. Some of its main dimensions are as follows: Greatest distance from table to nose of spindle, 39 inches; vertical adjustment of table, 32 inches; vertical adjustment of spindle arm, 8 inches; maximum height with spindle raised, 76 inches; diameter of spindle in sleeve, 13/16 inch; and diameter of table, 11½ inches. The spindle socket is a No. 3 Morse taper. The motor runs at a speed of 1725 revolutions per minute, and has a rating of ½ horsepower.

PRATT & WHITNEY GAGES

A set of automobile engine spark-plug thread gages made to S. A. E. standard limits and consisting of a double-end limit thread plug gage of the "Trilock" reversible-end type, a "Go" and "Not Go" templet gage, and a setting plug gage for the templet which has two threaded plug members and one plain plug for checking its root diameter is illustrated in Fig. 1. This gage set is now being introduced to the trade by the Pratt & Whitney Co., Hartford, Conn. The pitch diameters of the thread plugs are 0.841 and 0.843 inch, respectively, the tolerance for tapped holes being 0.002 inch. The templet pitch diameters are 0.836 and 0.839 inch, respectively, giving a 0.003-inch tolerance on the spark-plug body threads and a neutral zone of 0.002 inch between a maximum size plug and a minimum size hole.

The templet is of an improved type having a taper screw permitting fine adjustment of the pitch diameter. The "Go" and "Not Go" holes are located close together for convenience in placing on work and in handling. The "Go" side of the templet is cut away to permit a quick identification when using the gage in rapid inspection.

September, 1921, MACHINERY contained an illustrated description of a line of plain and thread plug gages made by the Pratt & Whitney Co., which had reversible ends held securely to the handle by means of three prongs on this member and corresponding grooves on the gage ends. The plain style was made in sizes from 5/16 to 2 inches. Fig. 2 of the present article shows a plain plug gage of similar type but which is made in sizes of 2½ inches and larger. As will be seen in the broken detail, the gage ends consist of a hollow ring into which two disks are forced on tapered surfaces before grinding. These disks hold a central tube, and the entire end is secured to the handle by means of a washer and a machine screw. Three prongs on the handle are forced into corresponding grooves in the bushing to provide the three-point self-centering support embodied in the design of the gages referred to in the previous article. The "Trus-

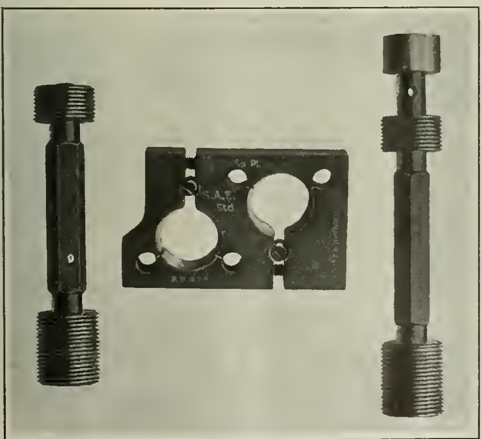


Fig. 1. Automobile Engine Spark-plug Thread Gage Set made by the Pratt & Whitney Co.

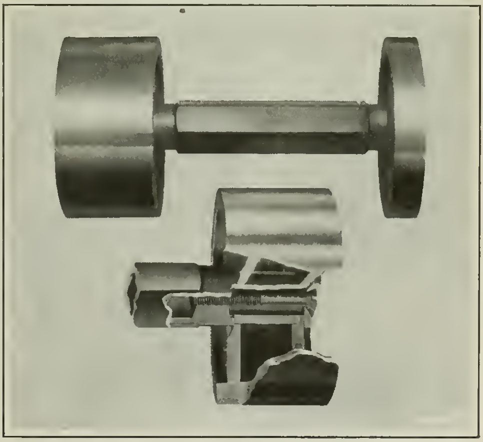

Fig. 2. Hollow- and Reversible-end Plain Plug Gage made in 2½-inch and Larger Sizes

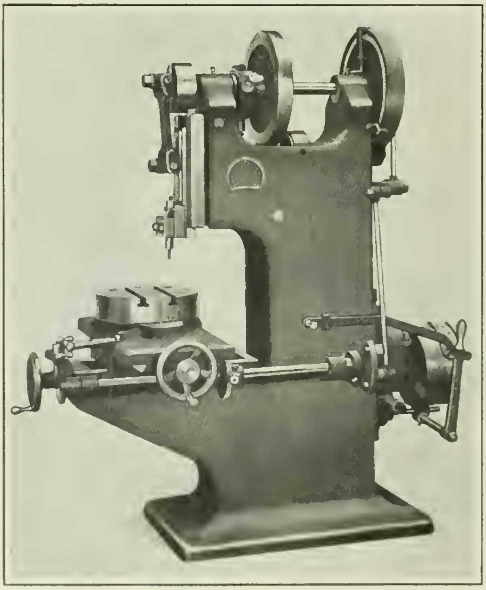
form" adjustable-limit snap gages also manufactured by the Pratt & Whitney Company were described in July, 1921, MACHINERY. These gages were constructed along the general lines of a roof truss and had round-head anvils. They may now be obtained with square-head anvils which are interchangeable with the round-head type.

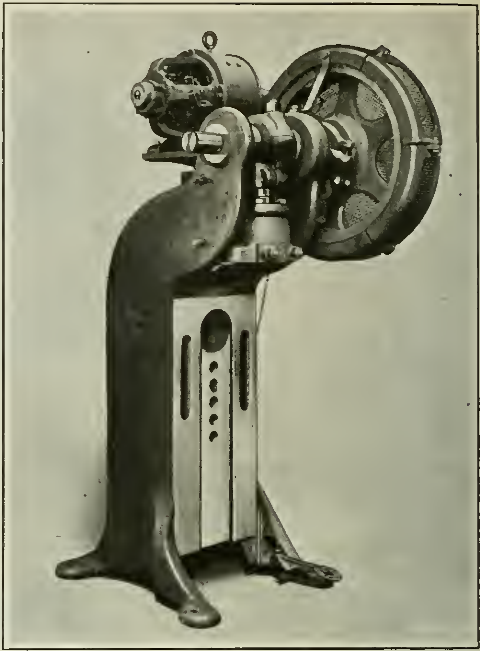
PETERS-BOSSERT DIE-SLOTTING MACHINE

A vertical slotting machine designed especially for machining round, square, and irregular shaped punches and dies has been recently developed by the Peters-Bossert Co., 617-619 E. Pearl St., Cincinnati, Ohio. As will be noted in the illustration, the ram is driven by a crank connected at the upper end to a crankpin on the main shaft at the top of the machine. This crankpin is adjustable so that any length of stroke up to 4 inches may be obtained. The member on which the ram slides, and to which it is gibbed, is hinged at the upper end in such a manner that it can be set at a slight angle relative to the face of the column in order to produce a clearance in die openings. The crank-arm at the lower end is attached to a pin located in a slot in the ram, the position of this pin being adjustable in order that the location of the ram path may be altered to suit the work in hand.

The lower end of the member on which the ram slides may be connected by the manipulation of a pull-pin to a toggle-joint mechanism operated by an eccentric on the main shaft. When connected, this mechanism moves the ram over a curved path on the down stroke, thus enabling curved cuts to be taken in dies. The mechanism also causes the tools to clear the cut on the up stroke, the amount of clearance being adjustable to suit requirements. When the toggle-joint mechanism is disconnected, the machine is set for taking straight cuts. Cross, longitudinal, and circular hand feeds of the work are each obtained through separate screws, but the machine can also be furnished with power feeds when these are desirable. A variable-speed gear-box mounted inside the column furnishes three changes of speed, which may be secured by shifting a lever on the outside of the column. The machine is supplied with tight and loose pulleys.



Vertical Die-slotting Machine built by the Peters-Bossert Co.



Special Horning Press built by the Ferracute Machine Co.

FERRACUTE MOTOR-DRIVEN HORNING PRESS

The Ferracute Machine Co., Bridgeton, N. J., has recently produced the special horning press illustrated herewith, which is driven by a motor mounted on a bracket bolted to the frame. The motor drives the press through a rawhide pinion which meshes with teeth cut around the flywheel. This method of driving is especially advantageous, as it is out of the way and economical as regards space. The flywheel is entirely surrounded by a guard, and, in addition, has wire mesh cast between its spokes so as to prevent any possibility of accidents when the press is in motion.

The hole provided in the frame for the horn is 7½ inches in diameter and located 43 inches above the floor. This is unusually high, but the press is intended for special work. The horizontal distance from the center of the ram to the planed surface on the front of the frame is 11 inches. Guides are machined on the planed front to enable an adjustable bed to be attached at different heights from the floor and square with the bottom of the ram. The connections are made by means of large bolts and dowels in a manner that insures parallelism between the bed and ram surfaces. The wide variation in the distance between the bed and the ram, together with the facilities for horning and the unusual height of the press, provide for a greater latitude of work than is customary with machines of this class. Presses of this design are also made in four other sizes.

HARRIS IMPROVED AUTOMATIC HOB GRINDING MACHINE

A few years ago a No. 815M motor-driven automatic hob grinding machine developed by the H. E. Harris Engineering Co., Bridgeport, Conn., was described in the technical press. A number of improvements have now been incorporated in the design of this machine, the more important of which will be enumerated in the following. The improved style is about 20 per cent heavier than the older machine, and

Hob Grinding Machine redesigned by the H. E. Harris Engineering Co.

the motor drive for the reciprocating parts is mounted on an integral bracket at the back of the machine instead of being placed on the floor as formerly. This new arrangement makes the machine self-contained. The maximum helix angle to which an 8-inch diameter hob can be ground has been increased to 47 degrees, in both right- and left-hand hobs.

In the old design, a sliding block was used to transmit the spiral action from an adjustable angular slide-way at the back of the machine, but ball bearings are now employed for this purpose. Heavy bronze bushings of oil-well construction, with a positive adjustment for wear are now supplied for the wheel-spindle. The overhang of the table from the bed of the machine at the end of its stroke has been decreased, the column is made heavier at the back, and the slides are longer. The overhang of the wheel has also been reduced to insure rigidity. The index-head is provided with larger bearings and has been redesigned so that, except for the heaviest hobs, it is unnecessary to support the outer end of the work-arbor by means of the tail-stock center. This possibility saves considerable time in changing from one hob to another.

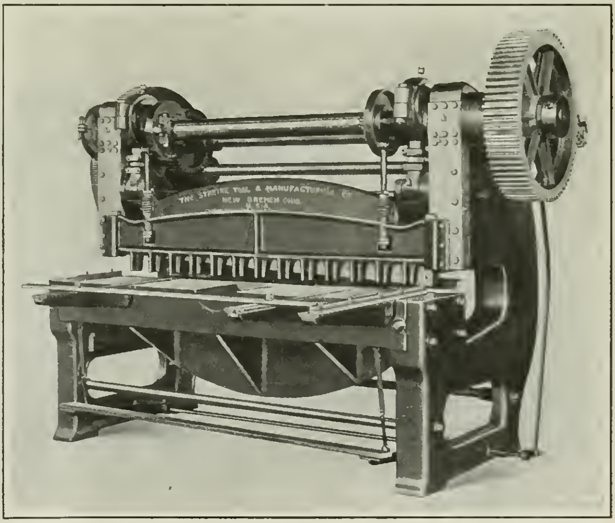
The arrangement for wet grinding has also been changed, larger valves and pipes and a deeper pan now being supplied so that about double the amount of the coolant can be used. The machine can be quickly set not only for radially grinding the faces of hob teeth but also to compensate for wear of the wheel. An adjustment provides for grinding hobs under-cut or with "hook" or top rake for the teeth. An improvement made in the arrangement of the control members enables all adjustments to be made by the operator while in position at the front of the machine. The majority of these adjustments can be made while the machine is running. The diamond truing device is now built into the head instead of being located on the work-table. The latter is driven by a clutch and gear mechanism connecting to a pinion meshing with a rack. Stops on the front of the table permit adjustments to suit the grinding of hobs of any length within the capacity of the machine.

STREINE GAP SHEAR

A newly designed shear having a gap in the housings which facilitates the splitting of long plates has been added to the line of shearing machinery built by the Streine Tool & Mfg. Co., New Bremen, Ohio. The illustration shows a 6-foot machine, but the same design is built in other lengths. It has a capacity for cutting annealed steel up to 3/8 inch in thickness. One of the features to which attention is particularly directed is the design of the cutter-bar, or, as it is commonly called, the cross-head. This cutter-bar is of double- and cross-ribbed box construction, and provided with long bearings fitted into the slides of the housings by means of adjustable hand-scraped taper gibs.

This construction obviates the necessity of providing a truss rod or some other similar device to keep the cutter-bar from springing or deflecting under strains. The long bearings by which the cutter-bar is attached to the housings, as previously mentioned, prevent the bar from tilting while cutting, and so enable sheets to be cut with a clean smooth edge. The cutter-bar is connected to the eccentrics by means of adjustable links; with this construction the shear knives may be set, by raising or lowering the cutter-bar, either to split long stock or to do plain shearing to the full length of the knives.

The eccentrics are double-keyed and shrunk on the eccentric shaft. The bearings of this shaft are split and can be readily adjusted or replaced. All shafts are of large diameter and all gears machine cut, the gears being made of semi-steel castings and the pinions of steel forgings. The clutch is also made of forged steel and fitted with a tool-steel clutch pin and finger. The hold-down or clamp is automatically operated and equipped with compensating springs to take care of unevenness of variation in the thickness of metal to be sheared. The bed of the machine can be adjusted to suit the requirements of the work.



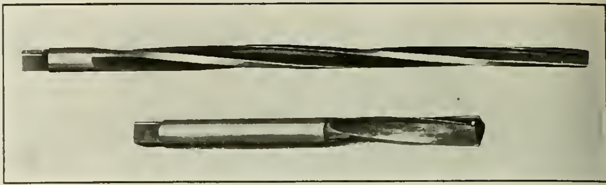
One of a New Line of Gap Shears manufactured by the Streine Tool & Mfg. Co.

A full set of front, side, and back gages is furnished, the back gage being of the parallel-screw and miter-gear operated type which is manipulated through a crank handle. The miter shaft is made in two pieces joined by means of a sleeve. This sleeve can be loosened and the gage set parallel with the blades or otherwise in a minimum amount of time. Parallel graduations in sixteenths of an inch are marked from the edge of the shear blades to the ends of the front gage supports to enable the operator to set the gages quickly and accurately. This shear can also be arranged with a motor drive and equipped with a long squaring arm. Some of the specifications of the size illustrated are as follows: Length of shear blades, 74 inches; size of flywheel pulley, 42 by 7 inches; speed of flywheel pulley, 280 revolutions per minute; strokes of cutter-bar, 18 per minute; and ratio of gearing, 16 to 1.

BICKFORD-SWITZER HELICAL-FLUTED REAMERS

The Bickford-Switzer Co., 50 Norwood St., Greenfield, Mass., is now manufacturing a line of "Cutwell" reamers, two of which are here illustrated. The taper pin reamer at the top of the illustration has three right-hand helical flutes on which the cutting lands are rugged and the hook or undercut generous. Two of the lands are relieved right up to the cutting edge, while the third land is relieved for only about two-thirds of its width, the remainder being a circular section which steadies the reamer and prevents the right-hand spirals and under-cuts from drawing the tool into the work. This reamer seems to work at its best in a drilling machine. and when used for cutting steel, the chips look like steel wool.

The principal claims made for this reamer are that it will not draw into the work, does not chatter, cuts similarly to a drill, and works best when used under power. The same principle of design has been applied to a chucking or hand reamer for straight holes, one of which is shown in the lower part of the illustration. In this case the reamer is made with three equally spaced and fully relieved cutting lands, and midway between two of these is a narrow and unrelieved land which steadies the reamer and keeps it from being drawn into the hole or chattering. It also serves, in connection with one of the cutting edges, to furnish a place for conveniently measuring the reamer diameter.



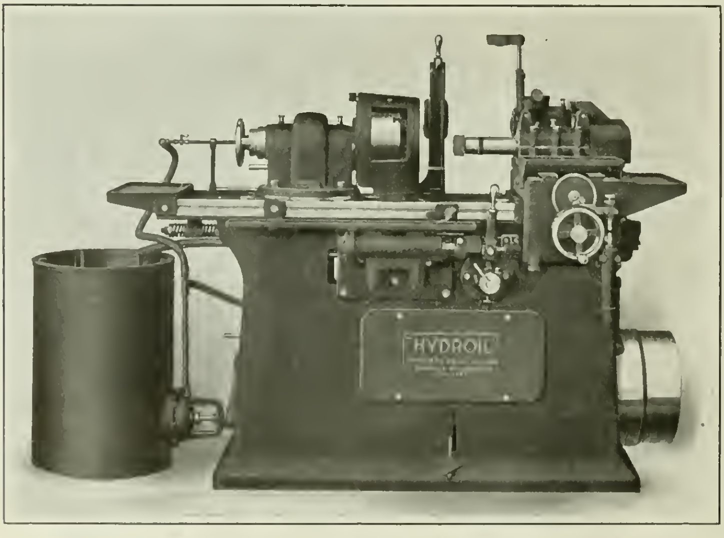
Two "Cutwell" Reamers made by the Bickford-Switzer Co.

GREENFIELD "HYDROIL" INTERNAL GRINDING MACHINE

A new internal grinding machine known as the "Hydroil" has been brought out by the Greenfield Tap & Die Corporation, Greenfield, Mass. The design of this machine is based on the principle of high traverse speeds. The wheel-spindle is carried on a slide controlled by a feed-screw which is calibrated for feed increments of 0.004 inch on the bore diameter of the work. The work-table reciprocates on ways located at right angles to the wheel-slide ways and carries a head for holding and rotating the work. The speed of the table traverse is controlled through a highly sensitive throttle valve, which admits oil under low pressure to a distributing valve controlled by table limit stops. From the distributing valve, oil is conveyed to either end of a double-acting cylinder-and-piston mechanism attached to a cross-head on the under side of the table. By the application of the hydraulic principle a flexibility of table control can be obtained which it is impossible to secure by mechanical means. The regular machine has a maximum speed of 50 feet per minute, although special designs provide for faster operation.

With the "Hydroil" control there are no definite stations of speed setting, and so minute differences of speed may be obtained without difficulty. The valve and piston designs provide for reversal of the table without shock, and the element of time involved in accomplishing a reversal is so small that on a ½-inch stroke the table will reverse 320 times per minute. A pressure-relief valve permits the table to stop without damage when overloaded. This feature also allows accurate positioning of the table for grinding against shoulders. A screw-adjusted stop is employed to locate the table, after which this member is held in place under oil pressure. By a combined use of reversing and locating stops, the table can be held to within limits of 0.0005 inch on reversal, without any sacrifice in the operating speed.

All table motions are controlled by a single lever. By pulling this lever toward the operator, the table is run back from the operating position. Another movement of the lever brings the table up to the operating position, where it automatically reciprocates between the working limit stops. A foot-treadle is employed to start and stop rotation of the work. The work revolves toward the operator at the top, the wheel turning in the opposite direction.



Internal Grinding Machine developed by the Greenfield Tap & Die Corporation, on which the Table Traverse Speeds are controlled by a Hydraulic Arrangement

The truing diamond contacts on the back of the wheel and so throws the dust downward. The fixture of the diamond-holder swings out of the way, but it may be quickly located in the truing position. Water is supplied for cooling the diamond.

The spindle bearing pressures are in the same direction whether the wheel is grinding or running free. The spindles provided on the standard machine are mounted in ball bearings so installed that a thrust adjustment eliminates vibration. Where an exceptional mirror finish is desired, the production rates are sacrificed to some extent, and special types of spindles are furnished. However, high operating speeds may be employed to advantage even in this class of work. The machine is especially suitable for removing stock rapidly in roughing operations. With holes three inches or more in diameter, at least one cubic inch of hardened steel can be removed per minute.

A special type of work-head is provided for large bearing races having straight holes. This head chucks several races end-to-end and holds them between a plunger operated by oil pressure and a mechanism similar to a camera shutter. The plunger ejects the load at the completion of an operation. By the use of loading pots this fixture may also be employed in grinding piston-rings and similar parts, a machine equipped in this manner having a capacity for grinding about 25,000 piston-rings per ten-hour day.

PRATT & WHITNEY HELICAL-FLUTED EXPANSION REAMER

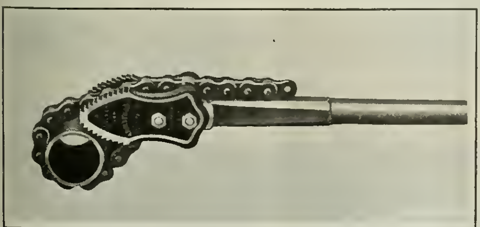
A recent addition to the line of small tools manufactured by the Pratt & Whitney Co., Hartford, Conn., is the helical-fluted expansion hand reamer here illustrated. Its adjustable feature enables one size to cover a range of diameters,

Hand Reamer of the Helical-flute Expansion Type made by the Pratt & Whitney Co.

it being possible to ream over- or under-size holes after making a simple adjustment. The reamer is equipped with a lock-nut to hold it to an adjusted size, and a safety stop which prevents over-expansion and indicates positively when the maximum limit is reached. The reamer is made in all regular sizes.

ARMSTRONG CHAIN PIPE WRENCH

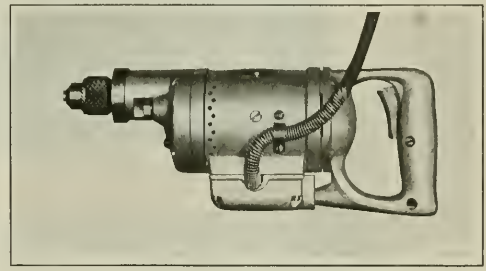
A chain pipe wrench having two drop-forged jaws and a length of either flat-link or cable chain is now being manufactured in seven sizes for pipes ranging from ⅛ to 16 inches, by the Armstrong Bros. Tool Co., 313 N. Francisco Ave., Chicago, Ill. The wrench shown in the illustration is provided with a flat-link chain. Through the use of hardened chrome-nickel steel bolts, the jaws are held solidly in place, the rear bolt being located directly under the chain socket where the strains tending to spread the jaws are most severe. Chain guides are provided on the jaws to protect the finished end of the bar from wear due to the action of the chain and to make the adjustment of the chain convenient. The handle is forged from high-carbon steel.



Flat-link Chain Pipe Wrench made by the Armstrong Bros. Tool Co.

"WILLEY" PORTABLE ELECTRIC DRILL

Under the trade name of "Willey" the James Clark, Jr., Electric Co., Inc., 522 W. Main St., Louisville, Ky., is placing on the market a portable electric drill made in 3/16-, ¼-, and 5/16-inch sizes, weighing 6½, 7 and 7¾ pounds, respectively.

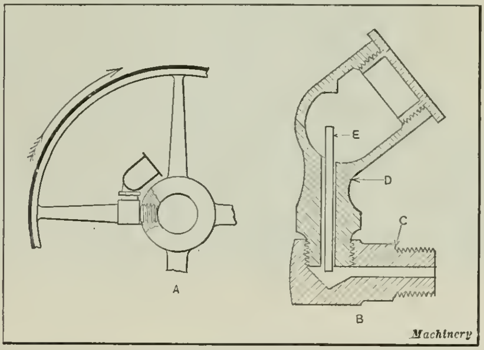


Portable Electric Drill made by the James Clark, Jr., Electric Co., Inc.

The drill is constructed of three units, consisting of the motor body, the drill spindle and gears, and the handle. The latter is provided with a mechanism for controlling the motor switch, which is actuated by the fingers of the operator in grasping the handle. By this arrangement the drill automatically stops rotating when hand pressure is released from the switch mechanism. All electrical connections and attachments are contained in the motor body. The tool is designed for use with high-speed drills only when drilling in steel or iron, it being intended that carbon-steel drills be used for the softer metals and wood.

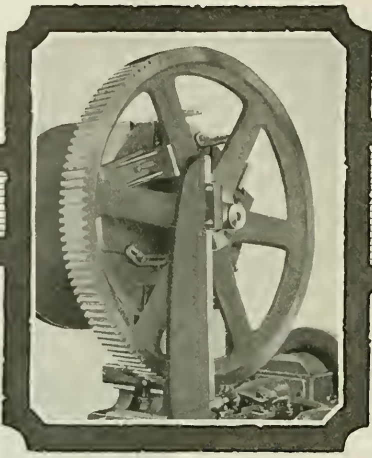
KAY LOOSE-PULLEY OIL-CUP

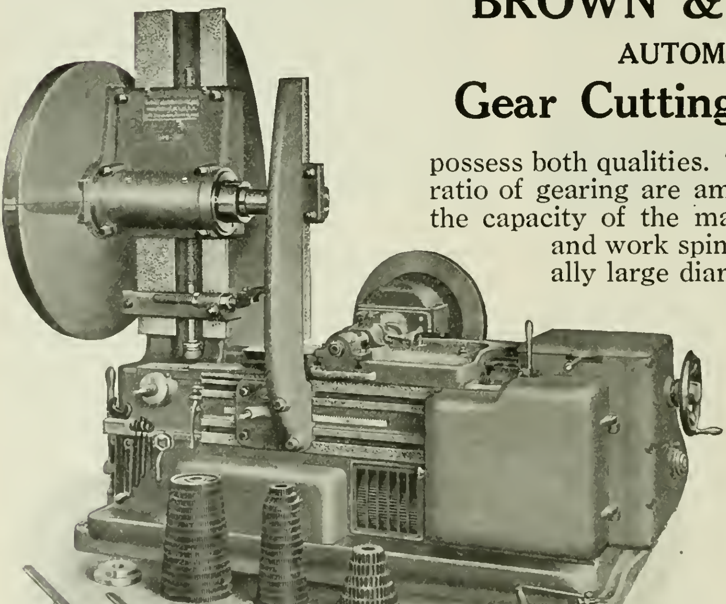
To accomplish the efficient and economical oiling of loose pulleys, Charles Kay, 5073 Burns Ave., Detroit, Mich., has brought out an oil-cup which is said to keep the pulley shaft well oiled while the pulley is revolving and does not allow the oil to empty from the cup and leak along the bearings when the pulley is stationary and the oil-cup is above the shaft center.



Loose-pulley Oil-cup manufactured by Charles Kay

The method of mounting the oil-cup on the hub of the pulley is shown at *A*, while the detail at *B* clearly illustrates the construction of the cup. The fitting *C*,



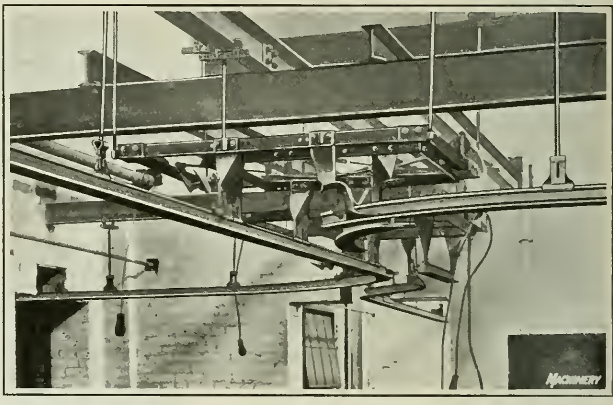


which has a hole drilled along its center line, is screwed into a hole that is tapped in the hub of the pulley, and the shank of oil-cup *D* is screwed into a tapped hole in fitting *C*. It will be seen that the hollow portion of the cup is at an angle to the shank, and that a sliding pin *E* is placed in a passageway through the shank. This pin has a movement in the passageway that is limited at one end by the pin striking against a lug on the wall of the cup, and at the other end by the pin coming in contact with fitting *C*. The pin is only moved when the pulley is started or stopped, serving to keep the passageway unobstructed and to regulate the flow of oil.

CLEVELAND TRAMRAIL OVERHEAD CARRYING SYSTEM

To reduce the time required for moving work from machine to machine and about the shop, the Cleveland Crane & Engineering Co., Wickliffe, Ohio, has developed a tramrail overhead carrying system in which the carrier may be operated by hand or electric power and the rail of which can be bent to a 4-foot radius so that practically all machines or locations in a shop can be reached. The rails are made of a special analysis high-carbon steel which can be bent cold on the job and are of a light section. The fittings employed in connection with the rail have been standardized to meet any requirements likely to be met with in wooden, structural or concrete buildings, and to permit the rail to be erected by the workmen of the plant in which an installation is made.

With the sliding switches furnished with this system, it is impossible for a carrier to run off the rail at an open switch, because of the provision of a safety stop which drops on the rail. The switches are locked in the closed position to prevent a carrier and its load from sliding the switch out of position. An additional safety feature can be added to make it impossible for an electrically driven carrier to run at full speed against a safety stop. This involves the use of trolley insulators which provide a dead section of the trolley wire that is energized only when the switch is in position to receive a carrier. Electrically driven carriers have ample power to carry a full load up a 12½ per cent grade.



Tramrail Carrying System developed by the Cleveland Crane & Engineering Co.

NEW MACHINERY AND TOOLS NOTES

Surface Grinding Machine: Badger Tool Co., Beloit, Wis. A surface grinding machine of the vertical-spindle type, which is equipped with a steel disk wheel, 42 inches in diameter, faced with a special abrasive compound, ½ inch thick. The machine is direct motor-driven, the shaft of the motor serving as the spindle of the machine. This machine is particularly adapted for grinding such parts as large tractor transmission cases and covers.

Spindle-type Grinding and Sanding Machine: Wonder Grinder Co., 612 W. 12th St., Erie, Pa. An internal grinding and sanding machine applicable to both wood and metal parts. The work-holding table is circular and can be tilted 45 degrees either side of the horizontal. It is automatically locked in position at right angles to the spindle. The spindle or roll for carrying the abrasive is mounted on a vertical shaft and driven directly from a vertical motor mounted in the base.

Hydraulic Forcing Press: Watson-Stillman Co., 192 Fulton St., New York City. A hydraulic press intended especially for forcing, pressing, and bending operations in railroad and large machine shops. The press is of the reversed cylinder type. The pump is employed only to actually apply the pressure, a handwheel being used to quickly bring the ram to and from the work. The pressure in pounds per square inch on the ram and also the total pressure in tons are indicated on a gage.

Burners, Furnaces, and Forges: Chicago Flexible Shaft Co., 1154 S. Central Ave., Chicago, Ill. A line of burners, furnaces, and forges for general shop use, including high-pressure, high- and low-pressure, and intermediate-pressure burners; a portable oil-burning rivet forge which employs compressed air for atomization; an oil-fired furnace designed for use in tempering punches, dies, tools, and knives; a crucible furnace employing either gas or oil as fuel and intended for use in lead or cyanide hardening, soft metal-melting, tinning baths, and galvanizing; a forge for use in welding and miscellaneous forging work; and a furnace for handling large forging work.

NEW BOOK ON PRODUCTION MILLING

PRODUCTION MILLING. By Edward K. Hammond. 278 pages, 6 by 9 inches; 177 illustrations. Published by THE INDUSTRIAL PRESS, 140-148 Lafayette St., New York City. Price, $3.

Recent years have witnessed the introduction of many improved methods of performing milling operations. On production work, where high rates of output are essential, the aim has been to reduce the non-productive time of the men and machines in the milling department. In the preparation of this treatise, attention has been given to methods of milling and the design of fixtures that will enable repetition operations to be performed economically. Information and illustrations relating to the latest developments in production milling practice have been gathered by personal studies of the methods used in many of the most progressive manufacturing plants; and acknowledgement is made to the large number of factory executives who have cooperated in this work. All the methods described have been successfully used under actual shop conditions.

It has been assumed that the readers of this book are familiar with the various types of production milling machines. Hence, only brief descriptions of the essential features of each type of machine have been included. It is the purpose of this book to explain the application of some of the more efficient methods of operating milling machines on repetition work, rather than to discuss milling machine design. In connection with the examples of machining operations performed on the various types of milling machines, information is included covering the speed and feed at which each operation is performed and the rate of production that is obtained. These data should prove of value to other manufacturers handling similar work. No attempt has been made to deal with work-holding fixture design, beyond explaining certain fundamental principles which must be observed in order to keep the ratio between the "loading time" and the "cutting time" down to a point where satisfactory rates of output can be secured.

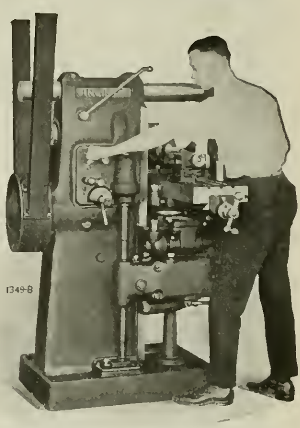
Who would expect it of a Universal?

The Cincinnati 1M and 2M Universals will take the same heavy cuts with the same quiet ease as the 1M and 2M Plains.

But more important is the story of the picture below. The toolmaker easily reaches the starting lever. The feed changes are at his finger tips. Feed changes are made while running. The feed trip is arranged to permit engagement of the feed forward or reverse without running off the dogs by hand. All controlled without leaving his seat.

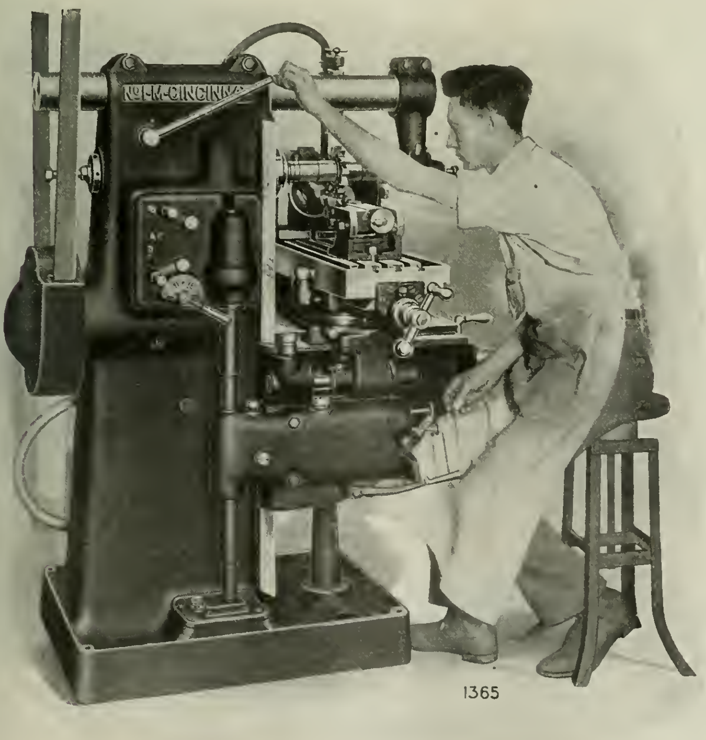
Do you know of any other Universal Miller that is so handy?

These are only a few of the good things in the Cincinnati. The catalog tells about all of them. Shall we send it?



The speed change levers can be reached from the operator's usual position. The belt is guarded 6 feet above floor. This meets the usual factory safety requirements.

Cincinnati 1M and 2M Universals



The Cincinnati Milling Machine Company
Cincinnati, Ohio
U. S. A.

The British Machine Tool Industry

From MACHINERY'S Special Correspondent

London, January 12

THE present outlook in the machine tool trade is encouraging. An effective stabilizing influence is the withdrawal of the 12½ per cent bonuses, effective January 1, which was referred to in the December article, as selling prices can now be calculated on a definite wage basis.

Demand for Machine Tools

There is a fair demand for certain classes of machine tools, for example, planers, punching and shearing machines, and three-operation automatics, and a few orders are being received from industries that have not been in the market for many months. Firms who make a specialty of tooling equipment and manufacturers of small tools report a slight improvement in the market, although naturally the actual amount of business is much below full capacity.

The continued disposal of surplus government stocks at prices that often are actually less than scrap value has led the Machine Tool Trades Association to send a committee to the Disposals Board with certain proposals, among which is the suggestion that the Government hold its stocks until any small demand there may be at the present time has been satisfied direct from the maker to the user and more normal conditions obtain. It is believed that there is some prospect that these proposals will be put into effect.

Conditions in the Automobile Industry

The automobile exhibition held at Olympia was of considerable importance from many points of view, as not only were the first real post-war designs in evidence, but the amount of business done came as a surprise to everyone. There are instances of makers whose whole output for 1922 has been spoken for. One large manufacturer is said to have disposed of cars to the value of over three million pounds, and it is anticipated that this particular firm will produce over ten thousand cars during the present year. The automobile manufacturers are beginning to take on additional help, and there is contemplation of an increase in the number of working hours.

As the automobile factories have represented, in the past, an average of as much as 50 per cent of the domestic trade of the machine tool maker, this revival of the automobile industry is of considerable importance. Automobile works are generally well equipped with machinery, but there are instances in which new equipment will be required to complete work started at the beginning of the general trade depression, but which has been held up until conditions should improve. Both Colonial and Continental markets are displaying great interest in buying, and inquiries have been received for machine tools and accessories, particularly from Australia and Czecho-Slovakia.

Iron and Steel Trade

In the iron and steel trades, British makers continue to receive their full share of orders. Costs are being reduced and a general expansion of business is hoped for. In all but a few instances British iron and steel makers are now offering their products at prices which successfully meet foreign competition, and substantial orders have been the result of this reduction in prices. British iron and steel makers are also finding it easier to obtain orders in the home market, although most buyers still find it necessary to limit their orders strictly to those called for by immediate needs. A feature of the general situation, which is basic to recovery in the machine-building trades, is the gradual improvement of the British output in pig iron. At the end of October there were eighty-two blast furnaces in operation, as compared with sixty-eight at the end of September. While Continental competition is still being experienced, the situation shows signs of improving, especially in view of the slight fall in transportation rates and fuel prices.

Whatever the ultimate advantage gained by the withdrawal of the orders for battleships, as the result of the negotiations that have taken place in Washington, there has been little short of consternation at the tentative suspension of work, and the iron and steel industry has felt the effect in common with the engineering and shipbuilding trades. Forging plants that were reopening in order to cope with the requirements of shipbuilders have again had to close down.

Exports and Imports

The overseas trade in machine tools during November shows some improvement over the previous month. The total value of exports rose to over £175,000 for a tonnage of 1250. The imports again are low, amounting to only a little over £18,000 for a tonnage of 112. The exports of small tools were valued at £44,000. Over £64,000 of the export value was represented by lathes, of which 197 were shipped to the overseas markets. More than £49,000 worth of the heavier type of metal-working machinery, such as bar-cutting and plate bending machines, steam hammers, ingot cropping and swaging machines were exported, while drilling machines, planing and shaping machines, and grinding machines were imported and exported in about equal quantities.

It seems likely that the year 1921 will show a total export of about 1¼ times pre-war exports in tons. Taken as a whole, imports are slightly below the pre-war level, so that the ratio of exports to imports has considerably improved, as compared with pre-war trade, the ratios being approximately 3 to 1 in 1914, and 4 to 1 at present. The export trade also shows signs of improvement in other lines besides machine tools.

Materials and Prices

Overseas buyers are generally taking more interest in the materials market, and, although orders are spasmodic, business of fair proportion is being done. The difficulty of obtaining reasonable delivery from Continental works increases, and the general opinion is that France, Belgium, and Germany are unlikely to be able to improve upon the situation in this respect for some time. Arrangements as to minimum prices fixed by the Scottish and English Tool Makers Association have been terminated, and a return has been made to the pre-war competitive system. It is expected that this will lead to the placing of orders which have been held in abeyance.

Compared with a month ago, the prices of most raw materials show a further decline. Pig iron generally has dropped 15s per ton, and finished steel also shows a drop of from 20 to 30s per ton. Castings are quoted at substantially lower prices than have prevailed for a considerable time; thus 16-inch lathe castings are now offered at 20 to 25s per hundredweight, and the lighter grades at 28s per hundredweight. Reeled bars have again dropped considerably, the price of £14 10s prevailing a month ago being now down to £12 10s.

ANNOUNCEMENT

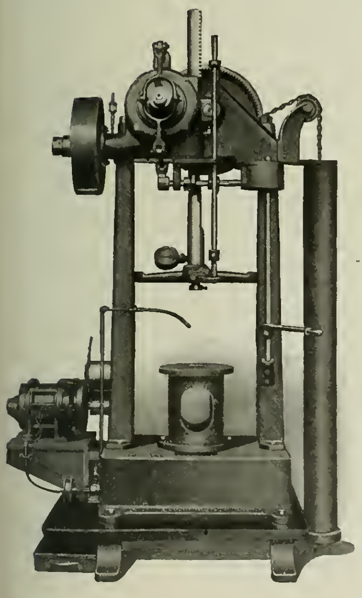
SOMETHING NEW

Yet tested and tried

The Lucas Vertical Push-Broaching Machine

(A modification of the Lucas Power Forcing Press)

Has been in successful operation for over two years on *vertical push-broaching* and *production assembling.*



Send for Special Circular C-26-M.

ADVANTAGES:

- Shorter, and therefore less expensive broaches.
- Better lubrication of cutting edges.
- Easier setting of work, easier manipulation of broaches.
- More production.
- A choice of fixed positions for the operator.
- Lever Control (adjustable for height).
- Less Floor Space Required.

WE ALSO MAKE THE

"PRECISION"

BORING, DRILLING AND MILLING MACHINE

LUCAS MACHINE TOOL CO. NOW AND ALWAYS OF **CLEVELAND, OHIO, U.S.A.**

FOREIGN AGENTS: Alfred Herbert, Ltd., Coventry. Societe Anonyme Belge, Alfred Herbert, Brussels. Aux Forges de Vulcain, Paris. Allied Machinery Co., Turin, Barcelona, Zurich. Benson Bros., Sydney, Melbourne. V. Lowener, Copenhagen, Christiania, Stockholm. R. S. Stokvis & Zonen, Rotterdam. Andrews & George Co., Tokyo, Japan.

OBITUARIES

James A. Brady, who was president and general manager of the James A. Brady Foundry Co., Chicago, Ill., up to the time of his retirement about ten years ago, died January 9, age seventy-four years. At the age of twenty-five he became connected with the foundry business at Beaver Falls, Pa., and in 1899 organized the James A. Brady Foundry Co. in Chicago.

George Baldwin Selden, inventor of the first gasoline-propelled vehicle and a pioneer in the automotive industry, died in Rochester, N. Y., January 17, aged seventy-seven years. Mr. Selden was president of the Selden Motor Co., of Rochester. He was graduated from Yale University in 1869 and later studied law, being admitted to the bar in 1871. Most of his legal work was in connection with patent legislation. Mr. Selden made his first gasoline driven engine in 1873.

T. C. DILL

T. C. Dill, president of the T. C. Dill Machine Co., Inc., Philadelphia, Pa., died suddenly on January 6 from heart failure, at the age of fifty-seven. Mr. Dill was well known in the machine tool industry, the slotting machine which bears his name being widely used in machine shops throughout the country. He founded the T. C. Dill Machine Co. in 1888 for the manufacture and sale of the Dill slotter. Prior to patenting his slotter, he had manufactured and marketed a connecting-rod, but the slotter business grew so rapidly that it became necessary to devote the entire efforts of the organization to this line. This growth of the slotter business was due largely to the efforts of Mr. Dill in developing a machine with unusual features, embodying the traveling head, which is the most striking feature of the Dill machine. These slotters are particularly well known in railway shops, and Mr. Dill's name will long be remembered in this field as well as in the machine-building industries in general, not only because of his mechanical achievements but also because of his attractive personality. The business will be continued by his widow, Mrs. Matilda J. Dill, who will become president of the company. His daughter, Mrs. Matilda Dill Moore, has been the company's secretary for several years.

THOMAS P. EGAN

Thomas P. Egan, president of the J. A. Fay & Egan Co., Cincinnati, Ohio, manufacturer of woodworking machinery, died January 10 at the Good Samaritan Hospital in Cincinnati, after a long illness. Mr. Egan was born in Ireland in 1848. Early in his life his family emigrated to Canada, where he obtained employment for a time. Later he came to the United States, going directly to Cincinnati and was naturalized there. Starting his career as a lathe hand in the employ of Steptoe, McFarland & Co., of Cincinnati, he rose to a position of leadership in the machine tool industry. The accidental loss of his arm caused him to be transferred from the shop to the office, where he advanced quickly and made a remarkable record as a salesman. In 1874 he went into the woodworking machinery business, and a few years later organized the Egan Co. which was consolidated in 1893 with the J. A. Fay Co. under the name of J. A. Fay & Egan Co. The firm grew steadily until it is now the largest woodworking machinery plant in the country. He was one of the founders of the National Association of Manufacturers and its first president, and when the association held its twenty-fifth annual meeting in New York a year ago, Mr. Egan was guest of honor. He is survived by his widow and seven children.

PERSONALS

Daniel Cushing, metallurgical engineer of Boston, Mass., has moved from 40 Court St. into larger quarters at 50 Congress St.

H. P. Losely, formerly industrial engineer with the James E. Morrison Co., Detroit, Mich., has gone into business for himself, having opened an office as industrial engineer at 414 Peter Smith Bldg., Detroit, Mich.

W. H. Patterson, who has been associated with the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., for the last sixteen years has become vice-president of the Kaestner & Hecht Co., Chicago, Ill., electric elevator builder.

Arthur Jackson, engineering representative of the Potter & Johnston Machine Co. in Japan, has been elected a regular member of the Japan Society of Mechanical Engineers. During the war Mr. Jackson was demonstrating Gridley automatics in Great Britain.

George C. Kimmel has resigned as mechanical engineer from the Cincinnati Grinder Co., Cincinnati, Ohio. Mr. Kimmel had been connected with this company since its inception in 1910 and previous to that was associated with the Heald Machine Co. and the Norton Co.

W. B. Wachtler, until recently manager of the Chicago district for the Industrial Bearings Division of the Hyatt Roller Bearing Co., has been promoted and transferred to the New York headquarters of the division at 709 Sixth Ave., as engineer in charge of general applications.

W. O. Renkin has become associated with the Hardinge Co., Inc., 120 Broadway, New York City, in the capacity of managing engineer of the Quigley pulverized fuel department, since this department of the Quigley Furnace Specialties Co. has been acquired by the Hardinge Co., Inc.

W. D. Blatz has been appointed general sales manager of the Bridgeport Brass Co., Bridgeport, Conn. Mr. Blatz joined the selling organization of the company in 1915, and during his connection with the company has made a thorough study of the brass industry in all its various branches, having traveled extensively.

A. H. Bauman has been elected vice-president and director of the Cleveland Duplex Machinery Co., Cleveland, Ohio. Mr. Bauman was formerly general foreman of the Gun Division of the American Brake Shoe Works, Erie, Pa. For the last three years he has been associated with the Cleveland Duplex Machinery Co. as sales engineer.

O. M. Rau, formerly consulting engineer to the Philadelphia Rapid Transit Co., has now become associated with the Hardinge Co., Inc., 120 Broadway, New York City, and will specialize in the handling of Quigley pulverized fuel systems as applied to boilers. This change took place with the acquirement by the Hardinge Co., Inc., of the pulverized fuel department of the Quigley Furnace Specialties Co.

James E. Gleason of the Gleason Works, Rochester, N. Y., was installed as president of the Chamber of Commerce of Rochester at a meeting of the Chamber on January 16. The principal speaker at the annual dinner, given in connection with the meeting, was Henry J. Allen, governor of Kansas who addressed the Chamber on the Kansas Industrial Court. A large number of factory foremen, who had been invited to attend, were present.

Zeno D. Barns has been appointed manager of the Cleveland office of the Ajax Metal Co., Philadelphia, Pa., to fill the vacancy made by the death of Louis E. Purnell. The Cleveland office, which is located at 429 Schofield Bldg., takes care of the business in the states of Ohio and Michigan. Mr. Barns has been connected with the Westinghouse Electric & Mfg. Co., and the Westinghouse Air Brake Co for some years past.

* * *

The University of Illinois maintains a number of research graduate assistantships in the Engineering Experiment Station to assist in the conduct of engineering research and to extend and strengthen the field of its graduate work in engineering. These assistantships, for each of which there is an annual allowance of $600, are open to graduates of approved American and foreign universities and technical schools who are prepared to undertake graduate study in engineering, physics, or applied chemistry. An appointment is made for two years, and upon the satisfactory completion of the work, the degree of Master of Science is conferred. There are now several vacancies to be filled, and applications should be sent to the director of the Engineering Experiment Station, University of Illinois, Urbana, Ill.

COMING EVENTS

February 13—Winter meeting of the American Boiler Manufacturers' Association at the Fort Pitt Hotel, Pittsburg, Pa. Secretary and treasurer, H. N. Covell, 191 Dikeman St., Brooklyn, N. Y.

February 14—Meeting of the Engineering Society of Buffalo at the Iroquois Hotel, Buffalo, N. Y. Secretary, N. L. Nussbaumer, 80 W. Genesee St., Buffalo.

February 20-25—Spring meeting of the American Institute of Mining and Metallurgical Engineers in the Engineering Societies' Bldg., New York City. Secretary, Frederick F. Sharpless, 29 W. 39th St., New York City.

February 22—Conference of practicing engineers under the auspices of the American Association of Engineers, in Chicago, Ill.; headquarters, Congress Hotel. Public information service of the American Association of Engineers, 63 E. Adams St., Chicago.

February 27-March 10—British industries fair in London and Birmingham, organized by the Department of Overseas Trade. Address of secretary for London, 35 Old Queen St., London, S.W. 1. Address of secretary for Birmingham, Chamber of Commerce, 95 New St., Birmingham. Further information can be obtained from the British Consulate General in New York City.

April 19-20—Annual meeting of the National Metal Trades Association in New York City; headquarters, Hotel Astor. Secretary, Homer D. Sayre, Peoples' Gas Bldg., Chicago, Ill.

April 22-May 2—Sixth annual Swiss sample fair at Basle, Switzerland, in the Great Exhibition Bldg. For further information apply to F. Dossenbach, Director of the Official Information Bureau of Switzerland, 241 Fifth Ave., New York City.

April 24-29—Annual convention and exhibit of the American Foundrymen's Association in Cleveland, Ohio; headquarters, Cleveland Public Hall, Lakeside Ave. and E. 9th St. Secretary, C. E. Hoyt, 140 S. Dearborn St., Chicago, Ill.

May 8-11—Spring meeting of the American Society of Mechanical Engineers in Atlanta, Ga. Assistant Secretary (Meetings), C. E. Davies, 29 W. 39th St., New York City.

June 26-July 1—Twenty-fifth annual meeting of the American Society for Testing Materials in Atlantic City, N. J.; headquarters, Chalfonte-Haddon Hall Hotel. Secretary, C. L. Warwick, 1315 Spruce St., Philadelphia, Pa.

NEW BOOKS AND PAMPHLETS

Fifth Biennial Report of the Department of Labor and Industry of the State of Maine for 1919-1920. 159 pages, 6 by 9 inches. Published by the Department of Labor and Industry, Augusta, Maine.

Structure and Related Properties of Metals. 104 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Circular No. 113 of the Bureau of Standards. Price, 25 cents.

Twenty-fourth Annual Report of the Bureau of Labor and Industrial Statistics of the State of Virginia for 1921. 139 pages, 6 by 9 inches; 10 charts. Published by the Bureau of Labor and Industrial Statistics, Richmond, Va.

The Distribution of the Forms of Sulphur in the Coal Bed. By H. F. Yancey and Thomas Fraser. 94 pages, 6 by 9 inches. Published by the Engineering Experiment Station of the University of Illinois, Urbana, Ill., as Bulletin No. 125.

Annual Report of the Director of the Bureau of Foreign and Domestic Commerce to the Secretary of Commerce for the Fiscal Year ended June 30, 1921. 148 pages, 6 by 9 inches. Published by the Department of Commerce, Washington, D. C.

NEW CATALOGUES AND CIRCULARS

Bausch & Lomb Optical Co., Rochester, N. Y. Price list of microscopes, microtomes, and accessories, effective January 2.

Whitman & Barnes Mfg. Co., Akron, Ohio, manufacturer of twist drills and reamers, is distributing a calendar for 1922 to the trade.

Wagner Electric Mfg. Co., St Louis, Mo. Bulletin 129, descriptive of the main features of the new Wagner polyphase motor known as the "Pow-R-full."

Goulds Mfg. Co., Seneca Falls, N. Y. Bulletin 123, descriptive of Goulds steam turbine driven centrifugal pumps, for use in paper mills, textile mills, steam power plants, mines, etc.

Rockford Milling Machine Co., Rockford, Ill., has recently issued complete circulars describing cutters, collets, arbors, and small tools, for use in connection with Rockford milling machines.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Leaflet 1825, illustrating and describing applications of the arc-welding process for repair and reclamation work as well as for manufacturing processes.

Carrier Engineering Corporation, 750 Frelinghuysen Ave., Newark, N. J., is issuing a monthly publication known as the "Weather Vein," containing information relating to air conditioning, drying equipment, etc.

Holophane Glass Co., Inc., 342 Madison Ave., New York City. Bulletin 343, descriptive of the Holophane lightmeter, which is a portable instrument designed for the accurate measuring of light and for color matching.

Weimer Machine Works Co., Lebanon, Pa. Circular, 12½ by 11 inches, containing full-page illustrations of Weimer patent cinder cars, styles J and K, which may be operated either by hand power, steam, air, or electricity.

Ohio Cultivator Co., Bellevue, Ohio. Pamphlet descriptive of the Ohio automatic belt-power baling press, for use in salvage departments for handling all classes of compressible materials, including the lighter gages of sheet metals.

Hydraulic Press Mfg. Co., Mount Gilead, Ohio. Catalogue 43-B, covering the H-P-M line of hydraulic high-pressure valves and fittings. The pamphlet contains sixty-four pages of illustrations, descriptions, and tabular material. In addition to the standard line of valves a few special types are shown.

Wardwell Mfg. Co., Cleveland, Ohio. Catalogue of machinery and tools for sharpening woodworking and metal-cutting saws. Illustrations and data are given covering band-saw filing, setting, and jointing machines; band-saw grinders; lap grinders; circular saw setters and filers; circular saw grinders, etc.

Electric Controller & Mfg. Co., 2700 E. 79th St., Cleveland, Ohio. Bulletin 1016A, containing description, illustrations and tables of ratings for E. C. & M. automatic motor starters for non-reversing direct-current motors. New price lists have also been issued by the company effective December, 1921, covering E. C. & M. apparatus.

V & O Press Co., Glendale, Long Island, N. Y. Bulletin 6-B, containing illustrations and brief descriptions of automatic feeding attachments for power presses, including standard single- and double-roll feeds, grip feeds, and dial feeds. The illustrations show the wide field of application for which these attachments are adapted.

Union Switch & Signal Co., Swissvale, Pa. Pamphlet entitled "Forging Ahead," containing a large number of illustrations of typical forgings produced by this concern. A brief statement is made of the equipment and capacity of the concern, and a chart is included giving S.A.E. steel specifications and recommended heat-treatments for the steels listed.

General Electric Co., Rock Drill Department, Fort Wayne, Ind. Circular 68980 illustrating and describing the boom mounting designed by the company for the Fort Wayne electric rock drill, which is designed for installation on mine cars, to take the place of the tripod type of mounting and to reduce the manual labor of handling the drill to the minimum.

Arthur A. Crafts & Co., 125 Summer St., Boston, Mass. Catalogue 22, entitled "Diamonds Used in Tools," treating of the use of diamonds for truing carborundum, alundum, crystolon, and other types of hard grinding wheels. Price lists are given for this company's line of diamond tools, including grinding wheel dressers, lathe turning tools, drills, glass cutters, engine turners' tools, wire drawing dies, etc.

Joseph T. Ryerson & Son, 30 Church St., New York City, has made a change in its bi-monthly "Stock List," having added a magazine feature in the front and a machinery and small tools section in the back of the book, which doubles the number of pages. It is hoped that the magazine section will serve as an exchange for suggestions and ideas, as well as a clearing-house to assist customers in disposing of odd stock and used machinery.

Bastian-Blessing Co., 125 W. Austin Ave., Chicago, Ill., is issuing a monthly publication called "Sparks" which will deal with the subject of welding or cutting by the oxy-acetylene or oxy-hydrogen process. In the first number is described a new "Rego" outfit known as the "Rego Little Six," which is particularly applicable for welding, cutting, brazing and decarbonizing in garages or small repair shops. Copies will be sent to anyone interested in this subject.

Goddard & Goddard Co., Detroit Mich., is issuing a series of pamphlets entitled "Real Production Tools," the first of which gives data on the "Go & Go" half side-mill which is designed to be used in pairs, right and left. No. 2 of the series gives information on the "Go & Go" plain mill. The third pamphlet is on the "Go & Go" inserted-tooth mill which consists of an alloy steel body and high-speed steel blades, and is intended for work requiring cutters 10 inches in diameter or larger.

R. K. LeBlond Machine Tool Co., Cincinnati, Ohio. Catalogue containing a detailed description and a large number of illustrations of LeBlond heavy-duty crankshaft lathes for the rapid production of automobile, gas engine, airplane, air compressor and other crankshafts. These machines are built in universal and duplex types for finishing crankpins either singly or in pairs, according to the design of the crankshaft and the requirements of the customer. Complete specifications are included.

Norton Co., Worcester, Mass. Pamphlet entitled "Metal Polishing," containing an article giving considerable information on the polishing of metal, including the correct abrasives to use; methods of setting up grinding wheels; drying wheels; size of grain used for different operations; polishing wheels; balance of wheels, speed, etc. Pamphlet entitled "Factors Affecting Grinding Wheel Selection," containing a definite outline of the conditions governing the correct selection of grinding wheels. Four tables are given listing the factors influencing the selection of the abrasive, grit, grade, and process respectively. A valuable feature of the booklet is the tabular material giving the abrasive process and the correct grade and grain of wheel to be used for different classes of work and operations.

TRADE NOTES

Cutler-Hammer Mfg. Co., Milwaukee, Wis., has moved its Boston office from the Columbian Life Building to Rooms 403 and 404 Harvey Building, Chancy St. C. W. Yerger is manager of this office.

Nickel Engineering Works, Saginaw, Mich., manufacturers of agitator equipment for chemical tanks, have leased a portion of the Schemm Brewing Co.'s plant, 920 N. Hamilton St., for machine shop purposes.

W. S. Rockwell Co., 50 Church St., New York City, furnace engineers and contractors, announce that Gibbons Bros., Ltd., Dudley, Worcester, England, has been appointed representative of the company for the British Isles.

Surface Combustion Co., Inc., 366 Gerard Ave., Bronx, New York City, has been awarded the contract for an automatic heat-treating furnace to be installed at the Naval Ordnance plant in South Charleston, W. Va., for heat-treating 16-inch armor-piercing shells.

American Motors Service has been organized in Pittsburg, Pa., by G. E. Burroughs and I. V. Conneely, for the purpose of distributing motor parts, tools, machines, and appliances for the complete equipment of garages. The temporary address of the concern is Lock Box 447 N.S., Pittsburg.

C. F. Davis Machine Co., Inc., 133 Andrews St., Rochester, N. Y., announces that it is and has been a separate and distinct organization from the Davis Machine Tool Co., also of Rochester. The similarity of names has caused some misunderstanding in the past and the announcement has been made to clear the matter up.

Reed-Prentice Co. and associate companies, the **Becker Milling Machine Co.** and the **Whitcomb-Blaisdell Machine Tool Co.,** have removed their New York office from the Grand Central Palace, 480 Lexington Ave., New York City, to Room 536, Singer Bldg., 149 Broadway, New York. The New York office is under the direction of P. K. Dayton, New York sales manager.

McCabe & Sheeran Machinery Corporation, Singer Bldg., New York City, has been organized by Harry P. McCabe and P. Frank Sheeran to deal in new and used machine tools and to act as manufacturers' direct representatives. Mr. McCabe was associated for twenty-five years with the J. J. McCabe Lathe & Machinery Corporation, the last three of which he was vice-president. Mr. Sheeran was connected with the same concern for twenty-three years, latterly as treasurer and chief of sales and advertising.

Morley Machinery Corporation (successor to the W. A. Wilson Machine Co., and the Rochester Boiler Works), manufacturer of iron planers and special machinery, has recently purchased and is now located in the plant formerly occupied by the Defiance Check Writer Corporation at 792-814 St. Paul St., Rochester, N. Y. New equipment has been purchased, and as the new property has a railroad siding the plant now occupied offers excellent manufacturing facilities.

Reading Machinery Exchange, 437 Washington St., Reading, Pa., has changed its firm name to Reading Machine & Tool Co. This change has been made because of the fact that the company some time ago discontinued handling used machinery, and since then has been devoting its entire time to the sale of new metal-working and woodworking machinery and tools, electric motors, and industrial furnaces. The new name has therefore been adopted as being more descriptive of the firm's present activities.

Warren F. Fraser Co., Westboro, Mass., manufacturer of cylindrical grinding machinery, plain cylinder grinders, special machine tools, and metal products, has been reorganized. The officers of the reorganized company are as follows: president, Warren F. Fraser; vice-president, Frank H. McClaskey; general manager, Sidney Player; sales manager, Joseph N. Bethel; treasurer, Maurice J. Cashman; assistant treasurer, Richard S. Staples; consulting engineer, Herbert S. Indge; and factory superintendent, Alfred E. Box. Messrs. Player, Bethel, Staples, Indge, and Box have also become stockholders in the company.

MARCH MACHINERY 1922

Hot Swaging

Description of Swaging Operations, Based on the Practice and Recommendations of the Langelier Mfg. Co., Providence, R. I.

By FRED R. DANIELS

In Machinery for June and July, 1921, a description of the cold-swaging process was published, including the equipment used, the effect of the process on the quality of the material being swaged, and the manufacture of swaging dies. In the present article, similar information is furnished regarding the hot-swaging of metal, based upon the use of the equipment manufactured for hot-swaging by the Langelier Mfg. Co. The process has been found especially economical in the making of carbon steel drills and end-mills and for the manufacture of motorcycle pedal pins and spinning spindles used in the cotton industry.

Operation of Hot-swaging Machine

The rolls that impart a radial movement to the dies of a cold-swaging machine are carried by a cage having a floating or slow rotary movement. This construction causes a sliding blow to be delivered to the work, which is suitable for the cold-swaging process, but not for hot-swaging. Fig. 1 shows the design of a hot-swaging machine head in which the rolls rotate on their axes while held in a fixed position; as a result the blows are delivered directly and quickly to the work without producing any torsional effect.

Rolls *A* have fixed bearings in a gun-iron ring, which is forced into the head of the machine, and they are arranged diametrically opposite each other in pairs and in such relation to the center that as the hammer blocks *B* revolve, the rolls carried in the ends of these blocks will strike against the fixed rolls and close dies *D* which are held in a slot in each of the hammer blocks. As the hammer blocks pass from roll to roll, they are moved radially outward by centrifugal force until they again contact with the next pair of rolls. This operation is similar to that of the cold-swaging machine described in June Machinery, with the exception of the fixed-roll feature.

On a twelve-roll machine a spindle speed of about 170 revolutions per minute is employed, thus delivering approximately 2100 evenly distributed blows around the work per minute. These machines are built in a variety of sizes and are fitted for swaging both solid and tubular work, the maximum capacity for solid work being 2½ inches in diameter, and for tubing, 5½ inches in diameter.

There is one simple and important feature in connection with the adjustment of the dies to obtain the desired opening, to which special attention should be called. In setting up the machine, shims are used back of the dies at *E* to obtain the proper force of blow, and the die opening is adjusted by means of the two cone-point headless set-screws shown in the spindle plate *C*. The points of these screws enter corresponding conical holes in the hammer blocks, and to change the die opening it is only necessary to adjust these screws.

The amount of die opening is of great importance. For solid stock, ¼ inch in diameter, it should be about 1/32 inch; for ⅝-inch stock, about 1/16 inch; and for larger sizes, in proportion. The idea is to allow enough opening so that the stock can be fed easily through the dies. Restriction of feed movement will produce inferior work, and if the work is not gripped securely, it is likely to twist. Too great a die opening permits stock to be fed fast, and for solid work this will result in chewing the material or cracking it. A large opening on tubular work will cause it to be swaged out of round.

The severe service imposed upon a machine by the swaging of hot metal demands a heavily constructed machine and means for keeping the dies cool. In the Langelier type of machines this is accomplished by placing a water jacket around the head roll bearing, which enables the machine to be kept in continuous operation, and increases its productivity. The oil from the machine and the heat produced by the hot work cause smoke, which must be carried away. This is done by providing a flue in front of the machine above the dies, and running a jet of compressed air through the hollow spindle from the rear, which forces the smoke through the flue, and at the same time carries scale and oxide away.

Arrangements for Heating the Work

Obviously some convenient arrangement must be provided for heating the work prior to swaging. In the Langelier equipment this consists of a special rotary heating furnace, such as illustrated in Fig. 3. The oven is circular, and is supported in a framework so that the stock to be heated may extend up from beneath and enter the heating chamber a short distance. The blanks to be heated are held in suitable holders arranged in a circle. The furnace is equipped with a powerful gas burner *A* which drives the flame around the circular firebrick oven, and the feed-plate in which the work-holders are carried revolves at the required operating speed. This passes the blanks into the oven from an opening at one end and out of a similar opening at the other end where they automatically drop to a lower platform, and are then successively removed by the operator and placed in the work-holder of the swaging machine.

The speed of delivery of the heated blanks is regulated to agree with the time required for the swaging operation, so that the operator is constantly supplied with hot blanks and the swaging machine kept in continuous operation. This special equipment provides for handling work up to 20 inches in length and 1½ inch in diameter. For work of this size, the maximum distance that the blanks must be heated from the end is 5 inches. The furnace can be adjusted to heat the blanks to 1800 degrees F. and deliver the work at the same rate that the swaging machine operates. For example, on ¾-inch diameter blanks which require to be swaged 4 inches from the end, the output is about eight per minute, which is about the same as for the swaging operation.

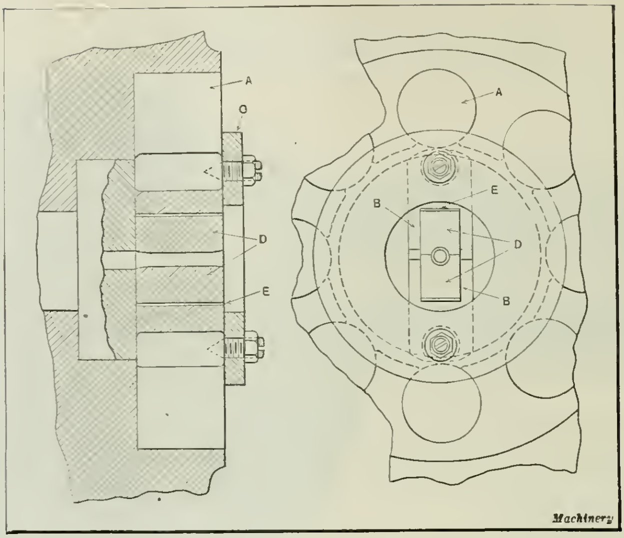


Fig. 1. Construction of the Fixed-roll Type of Swaging Machine Head

The circular opening on the inside of the furnace oven is narrow enough to accommodate the maximum diameter work and does not allow an excessive loss of heat. The rotary speed of the feed-plate is varied by suitable gearing at the lower end of the vertical shaft to which the feed-plate is attached. The furnace is located conveniently and in any position relative to the swaging machine that is best suited to the working conditions. The work is removed by tongs, placed in the work-holding chuck, and fed into the dies.

Work-holding Devices

Figs. 2, 6, and 7 show types of hot-swaging machines equipped with various designs of work-holding chucks and feeding devices. The chuck shown in Fig. 2 is of the self-opening spring type and is operated by compressed air. The compressed air forces the piston on the inside of cylinder *A* forward, resulting in a gripping action of the chuck. The work is firmly held by this means until the operation of swaging has been completed and the work withdrawn sufficiently from the dies to automatically shut off the air pressure and permit the spring to operate and release the jaws. The illustration shows the air connection *B* and the position occupied by the holder just before the automatic release of the air.

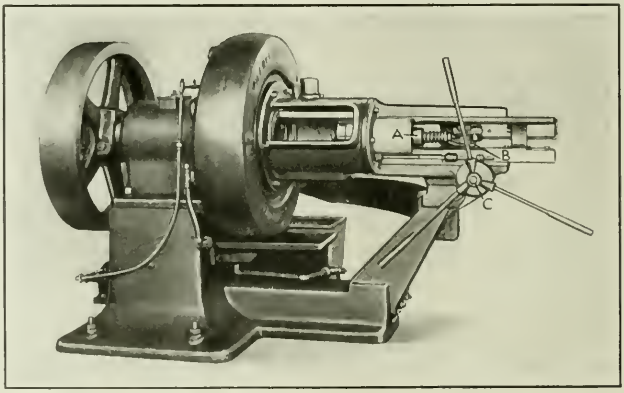

Fig. 2. Swaging Machine with Hand Feed and Compressed Air Work-holder

This machine has a hand feed, operated by a pinion on the capstan wheel shaft *C*, which meshes with a rack on the under side of the tubular holder in which the chuck is carried. The hand feed and automatic chucking device are particularly suitable for medium-sized work, but for the heavier work it is advisable to employ a more positive feed arrangement than that shown.

The holder and feed used on the machine shown in Fig. 7 are fully automatic in operation. The work is chucked pneumatically, the clamping jaws being bolted to a saddle which is fed forward and backward on the ways by hydraulic pressure, the feed being controlled by a hand-lever. The hydraulic feed is employed because it furnishes a steady movement for heavy work. The entire holding and feeding device is attached to the cover that encloses the swaging rolls, and this cover may be swung on its hinge to give easy access to the working parts of the machine.

Fig. 8 shows the cover opened, revealing the ends of the swaging rolls and the spindle plate *A* in which the two conical-point adjusting screws for obtaining the desired die opening are carried. When the cover is open, a support must be provided for the overhanging weight of the holding and feeding attachments. This is taken care of by a curved rail *B* which provides the necessary outboard support and permits the entire mechanism to be swung to the position shown. The holder is provided with a positive stop *C* for regulating the length to which the work is to be swaged.

The machine illustrated in Fig. 6 is furnished with a holder operated by a hand-lever *A*, and is extensively used on smaller classes of hot-swaged work. The feed is also hand-operated, and is of the rack and pinion type, the hand-lever for the feed being shown at *D*. This illustration also shows the smokestack *B* for the smoke caused by the hot dies burning the oil on the work, as well as the drainage receptacle *C* under the holder support into which this oil drips, and which contains a strainer for removing foreign particles from the oil, after which it drips back to the source of supply. In hot swaging operations considerable scale is produced by the rapid hammering of the hot metal, and it has been found necessary to provide for removing this foreign matter before the oil is fit to be used again.

Amount of Reduction in Hot Swaging

Small work cannot be reduced as much proportionately as larger work, due to the fact that the former does not retain the heat as well. The hot-swaging process is more particularly adapted to the production of large work than small work (which is better handled by cold-swaging), and for large heavy work a reduction of 1/8 inch on the diameter per pass is permissible, this being about twice that recommended for cold-swaging. The length of the blank also influences the amount of reduction permissible, because the distance between the dies and the holder must not be great enough to allow the work to twist due to the torsional strain produced by the die action.

In determining the length to which the blanks are to be heated, it should be borne in mind that it is not necessary to heat the blank as far from the end as it is desired to swage it, since the heat from the hot end radiates into the colder metal so that the blank is heated with a uniform decrease from the end, corresponding to the taper produced by the bell-mouthed entrance to the opening of reduction dies, or by regular taper-swaging dies. That is, the blank does not need to be as hot at the end of the swaged portion as it does at the end that is subjected to the greatest reduction. Practice must determine the length to which the blanks should be heated; other factors to be considered, besides the length of the blank, are the diameter, physical qualities of the metal, type of machine, etc.

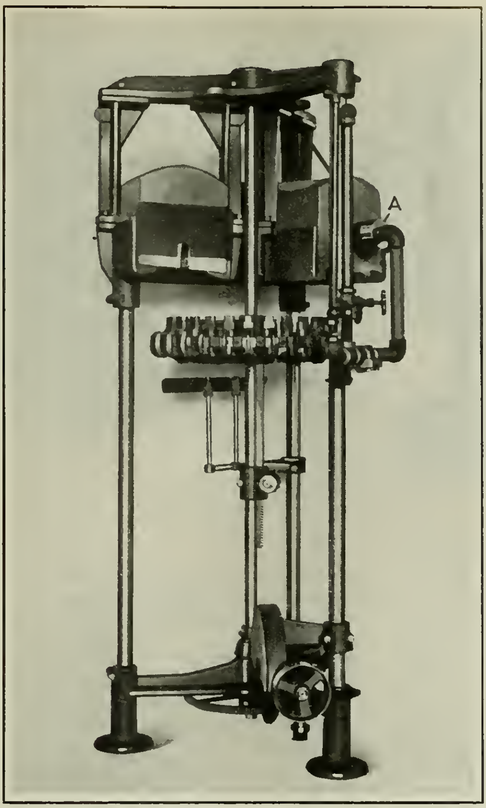

Fig. 3. Rotary Gas Furnace in which the Blanks are heated at the End prior to swaging

Examples of Hot-swaging

A number of examples of hot-swaged work are shown in Fig. 4. The piece shown at *A* is a bicycle pedal-shaft made from a piece of machine steel, 0.875 inch in diameter and 4 inches long. The length to be reduced by swaging is 1 3/32 inches, the first operation producing a diameter of 1/2 inch, and a length of 3 1/8 inches. Piece *B* shows the second operation on the bicycle pedal-shaft, in which the 3 1/8-inch length of the first operation is tapered to 5/16 inch at the small end. The length of the reduced portion is then 4 3/8 inches. Similar operations are performed on the opposite end of this blank, and the piece is then cut in two to make two bicycle pedal-shafts. The time required for the first operation is ten seconds and for the second operation seven seconds per piece. The piece shown at *C* was produced from a piece of drill rod, 1/2 inch in diameter, and swaged straight to a diameter of 0.290 inch for a length of 4 3/4 inches.

Example *D* is similar to that shown at *C* except that the straight reduction is 5 1/4 inches long, and this piece shows a second operation which consists of taper-swaging the 1/2-inch diameter end. It was made from a blank 4 inches long and is swaged with a standard Morse taper, at the rate of four per minute. This piece is a drill blank. The piece shown at *E* is a steel tooth for a hay rake, and is made of machine steel, tapered in one operation for a length of 1 1/2 inches to a blunt point. The production time is eight per minute. In connection with this operation, it should be mentioned that it is impracticable to attempt to produce a sharp point by hot-swaging, since a narrow die opening will tend to flatten the point rather than produce a uniform taper.

The swaged piece shown at *F* is a live axle end, made from axle steel 1 1/8 inches in diameter and 5 inches long. The taper is 2 7/8 inches long, the reduction being 0.74 inch in diameter at the shoulder. The small end is 1 3/32 inches long and 0.625 inch in diameter. Two operations are re-

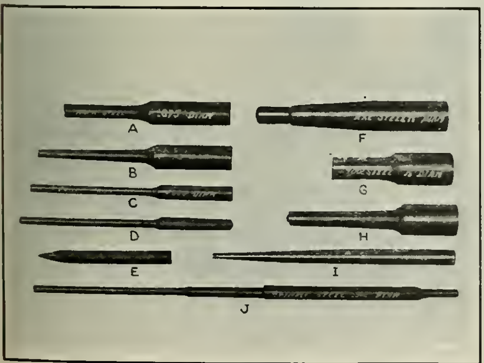

Fig. 4. Examples of Work produced by the Hot-swaging Process

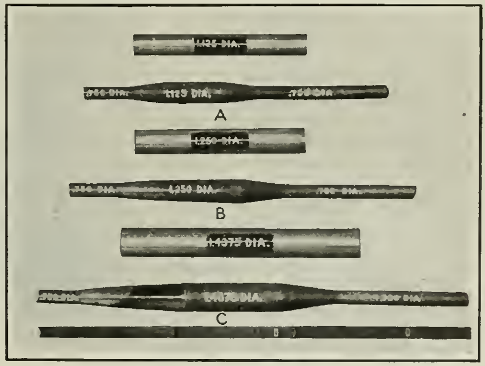

Fig. 5. Three Insulator Posts and Blanks from which they are swaged

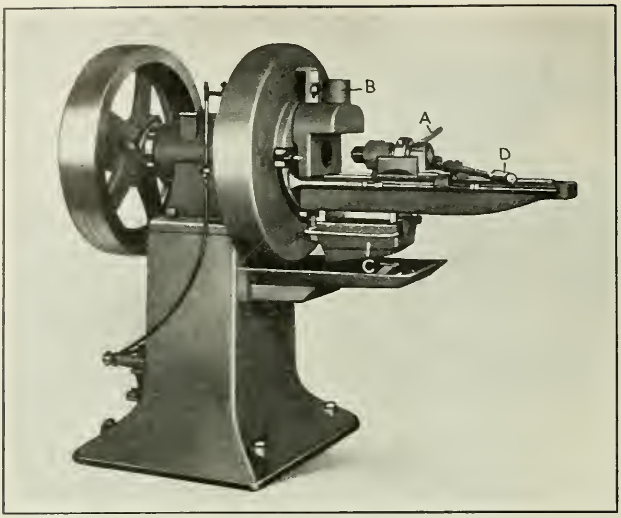

Fig. 6. Machine with Smokestack, Hand-operated Work-holder and Rack and Pinion Feeding Device

quired to produce this piece. The first operation in swaging an end-mill blank is shown at *G*, and the second operation at *H*. The material is tool steel, 1¼ inches in diameter by 3¼ inches long, and is reduced to a diameter of 27/32 inch, the length of the reduced section being 2¼ inches. In the second operation, the reduced end is tapered to 4 inches in length and a diameter at the small end of 9/16 inch. A butcher's steel is shown at *I*, this piece being made from a blank of 0.60 per cent carbon steel, 7¼ inches long and 9/16 inch in diameter. The two tapers are produced in one operation, the total taper length being 5 inches and the diameter of the small end 15/64 inch.

Example *J* is a spinning spindle used in textile machinery, and is made from special spindle steel. Three operations are required to produce this part from a blank 10 inches long and 0.562 inch in diameter, two of these operations being on the long end and one on the short end. The two diameter reductions on the long end are 0.40 and 0.27 inch, respectively, and the lengths 2⅞ and 5¾ inches. At the opposite end the stock is reduced to 5/16 inch in diameter for a length of 1½ inches. The increase in length from the original blank size is 5⅞ inches, that is, the spindle is elongated to 15⅞ inches during the three swaging operations.

Fig. 5 shows three sizes of insulator posts used for metal electric wire towers. The post shown at *A* is made from a piece of machine steel, 8¾ inches long and 1¼ inches in diameter, which is reduced at each end, in separate operations, to 0.750 inch in diameter, the short length being 1¾ inches and the long length 6 inches. The work shown at *B* is made from a 1¼-inch diameter blank, 8½ inches long in two operations, the left-hand end being tapered to 1 inch in diameter and reduced to 0.750 inch in one operation. The length of the straight portions on this insulator post is the same as in that shown at *A*.

The third example shown in this illustration is made from a blank 1 7/16 inches in diameter and 11¾ inches long, the length and diameter of reduction and the taper being the same as in the previous case. The various lengths to which these insulator posts are made may be determined by comparison with the extension rule shown below sample *C*. These posts were made on a machine of the design shown in Fig. 2 which was operated at a flywheel speed of 190 revolutions per minute, producing the three pieces of work in ten, eleven, and twelve seconds per operation, respectively.

Additional examples of work performed on the machine shown in Fig. 2 are illustrated in Fig. 9 at *A* and *D*. The spinning spindle *A* is reduced to the dimensions given at the rate of five spindles per minute for the two operations required to produce it. This rate of production is much greater than can be realized by forging these spindles in a trip hammer, the method frequently used on this kind of work. Under test it has been shown that a hot-swaged spindle is 9 per cent stronger than a hammered spindle. A drag-link socket used in automobile construction is shown at *D*, and is produced on the machine illustrated in Fig. 2 by equipping the holder for handling tubular work. The socket is swaged in one operation at the rate of four or five a minute, being made from a piece of steel tubing 1⅜ inches in diameter, having a wall thickness of 0.124 inch.

A sample of work produced on the machine and equipment illustrated in Fig. 6 is the case-knife blank shown at *B* in Fig. 9. The work is made from a blank of 0.60 per cent carbon steel, 2½ inches long by 0.518 inch in diameter, and swaged in two operations to the dimensions shown in the illustration. For this job, as for other jobs specifically referred to in this article, the rotary gas furnace described in connection with Fig. 3 is always used with the swaging machines, although it is not shown in the illustrations. In making the case-knife blanks by the hot process, the machine is operated at 375 revolutions per minute, the output from the first operation being seven or eight a minute, and from the second five or six a minute. The small diameter end of the work is the tang of the knife, and the large end is flattened between dies to form the knife blade.

Hot-swaging of Tubular Work

In swaging tubular work, it is advisable to use a mandrel to maintain the shape and the size, except on tubing with very thick walls. At *C*, Fig. 9, are shown two examples of tubular swaging, each of which was produced in one opera-

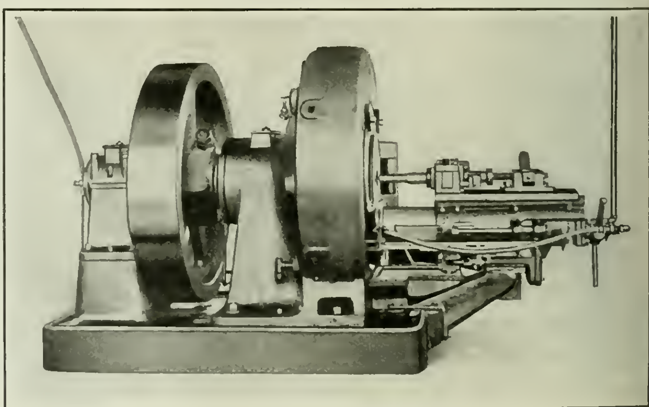

Fig. 7. Swaging Heavy Work on a Machine having a Pneumatically Operated Work-holder and Hydraulic Feeding Mechanism

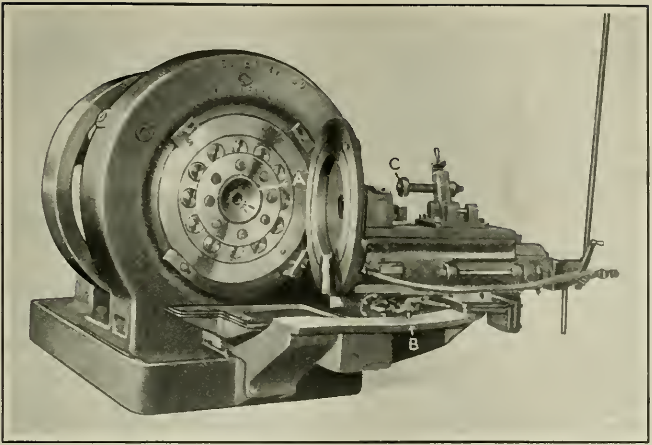

Fig. 8. View of the Machine shown in Fig. 7 with the Roll Cover and Attached Feeding and Holding Devices swung back

tion, the machine being equipped with an automatic holder and a hydraulic feed. With these attachments and with the spindle speed running at 150 revolutions per minute, the output was two pieces per minute for each part. The amount of reduction and the wall thickness are shown in the illustration. In testing the horsepower requirements for this job, it was found that 11 horsepower was required to start the machine, 5 horsepower to run without the dies, 14.8 horsepower to run with the dies without load, and from 24 to 26.5 horsepower for operating the machine under load.

A collection of tubes that have been swaged to various shapes at different times and with different equipment is shown in Fig. 10. The piece shown at *A* is produced in two operations, one being performed at each end, from tubing 21¾ inches long, with a wall thickness of ¼ inch. An example of heavy tube swaging work is shown at *B*, the wall thickness in this case being 21/32 inch. This piece was produced in one operation. An example of two-operation work is shown at *C*, the dimensions given on the sketches being self-explanatory. Three operations are required to produce the work shown at *D* from a piece of tubing 3¾ inches outside diameter, having a wall thickness of 5/32 inch. All the operations required to produce the various parts shown in this illustration were accomplished at the rate of about two pieces per minute. The type of feed and method of chucking the work will influence the rate of production as much as, if not more than, any of the other governing factors.

Making Hot-swaging Dies

The dies with which the Langelier swaging machines are equipped are made from a high grade of high-speed steel. It is proposed to outline briefly the procedure followed in making these dies, but the details will not be described here, as the manufacture of dies for hot-swaging does not differ radically from that used in making dies for the cold process, which was described in July, 1921, MACHINERY. The bars are squared up by planing, and then cut to convenient lengths on a power saw. They are next milled to die length and finished on the sides, and a pair clamped together preparatory to drilling the die groove or blade. For taper work, two or three sizes of drills are used successively to rough out the blade, so as to expedite the removal of the metal during the taper-reaming operation that follows.

For taper-reaming, a special six-flat reamer is used, similar in design to a watchmaker's broach. The rate at which the metal is removed by reaming is very slow, due to the lack of clearance on the tool, but it has been found that tools of this type produce a very accurate hole which requires little subsequent hand work when finishing the grooves or blades in the dies. Straight reduction dies are machined with an ordinary rose reamer. The tool marks produced in

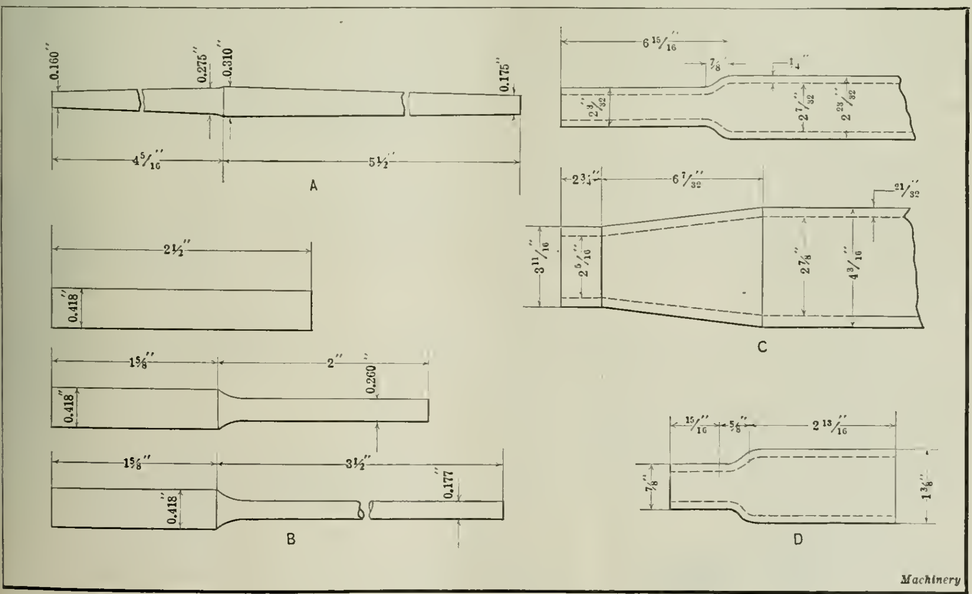

Fig. 9. Examples of Hot-swaged Solid and Tubular Work

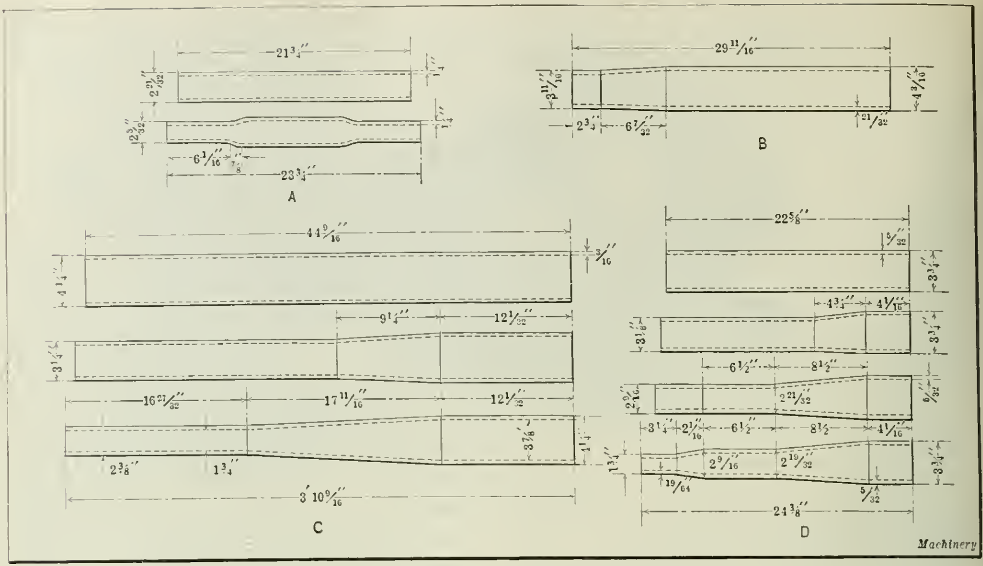

Fig. 10. Specimens of One-, Two-, and Three-operation Hot-swaged Tubular Work

reaming are then removed at the bench, and clearance at the sides of the groove is provided by means of a file. This clearance is of vital importance to allow the metal to flow as it is swaged, since the grooves are less than semicircular in contour, as was explained in describing the manufacture of cold-swaging dies in the July article.

A brass lap, turned up at the same time that the reamers are made, is then used to lap the groove, the abrasive being a mixture of a very fine carborundum and oil. After the dies have been nicely finished they are hardened by preheating to 1600 degrees F. and then to 2300 degrees F. They are quenched in Houghton's No. 2 soluble oil which is kept at an atmospheric temperature, and are then drawn to a temperature of 1100 degrees F.

In making the dies for multiple-operation taper work, care is taken to see that the die grooves in successively used dies are of such size as to cause an overlapping of the operations. This maintains the desired taper and prevents ridges and uneven places from being produced.

PIECE-RATE AND LAY-OUT CARD

By JOHN J. BORKENHAGEN

A piece-rate and lay-out card which the writer found of great help in his work as a rate-setter is shown in the accompanying illustrations. The front of the card, Fig. 1, contains information pertaining to the manufacture of the article, while the back of the card, Fig. 2, contains a record of changes made in the manufacturing methods and in piece rates. On the front of the card are given the part number; part name; material from which the part is made, and the weight of 100 parts; number of cards required to cover the operations; operation number; department in which work is done; description of operation; piece-rate per 100 pieces; production output per hour; name of machine and factory number; actual running time per piece; and date on which piece-rate was set. With these cards, cost data can be had on short notice. As the cards show the production labor costs and the weight per 100 pieces of material, it is only necessary to know the cost of the raw material and the overhead, to obtain the cost figures for any piece.

Formed Milling Cutters and Hobs with Top and Side Rake

By HARRY E. HARRIS, President, Harris Engineering Co., Bridgeport, Conn.

COMPETENT mechanics and mechanical engineers have realized for years that it is essential, in designing cutting tools, to consider carefully the amount of top rake or hook, side rake or shear, (also known as the back and side slopes, respectively) and clearance that should be provided in order to enable the tool to remove the maximum amount of metal with the least heating and damage to itself, the work, and the machine members. Consequently no skilled mechanic would think of making a lathe, shaper, planer, or slotter tool without rake. Inserted teeth of high-power milling cutters are now also made with side and back slopes amounting to as much as 15 degrees and more, and, according to experiments recently made, milling cutters with a hook of as much as 30 degrees have a more efficient cutting action than cutters with a less angle to the hook.

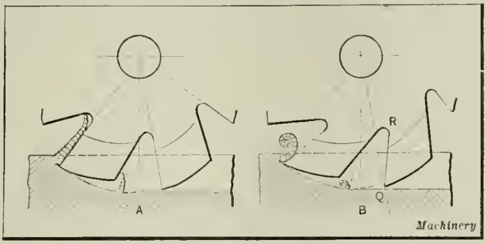

Fig. 1. Relative Cutting Actions of the Radial-tooth Hob at A and the Hook-tooth Hob at B

Instead of the chip consisting of a semi-fused distorted mass which presses against the top face of the tool, offering resistance and keeping the cooling lubricant away from the cutting edge, thus causing a severe rubbing action between the tool and the work, the chip is removed without undue distortion in the form of a curl. This results in a clean cut with much less tendency for the tool to chatter and with less power consumption. It also allows the lubricant to cool the cutting edge of the tool.

Since it is recognized that cutting edges properly ground with regard to hook and side rake have increased the efficiency of taps, face mills, broaches, lathe and planer tools, milling cutters, formed tools, reamers, counterbores, drills, etc., from at least twenty to several hundred per cent, the question arises as to why formed milling cutters and hobs without hook and side rake should be used in many shops otherwise up-to-date. Conservatism is perhaps the answer.

For instance, taking a similar case with taps, it was the general practice up to 1912 to make the face of the teeth radial to the center. With this design big losses resulted to tap users because the taps were broken, twisted, and worn out due to the hard cutting action and the jamming of chips. In a series of tests made by the writer, prior to the year mentioned, it was proved that a tap on which the teeth had top rake or hook required less power for a cut, made a cleaner job, and broke up the chips in small sections without jamming. The results of these tests were submitted to a meeting of the American Society of Mechanical Engineers at which the leading tap manufacturers were present. In a discussion following the presentation of the paper, the arguments were chiefly in favor of the practice that then prevailed of machining the taps with radial-face flutes, but in spite of the opposition, in the course of a few years there was practically no tap-maker of repute still manufacturing radial-face fluted taps.

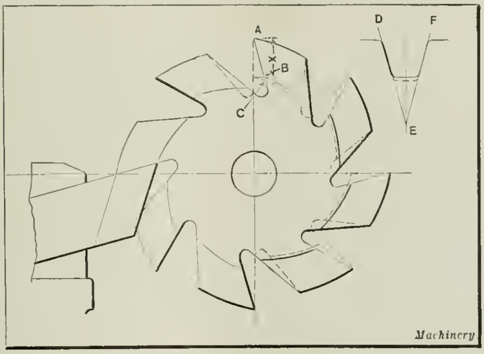

Fig. 2. Manner of tilting Cutter when relieving Under-cut or Hooked Teeth of Hobs and Formed Milling Cutters

The same thing may be expected to happen with regard to hobs and formed cutters, though some firms are now making their hobs with hook and side rake. The angle of the front face of the tooth from a radial line varies from 5 to 9 degrees in the practice of different concerns. The writer favors an angle within the limits of 7 and 8 degrees, but states that he does not know just how much greater this angle could be made with efficient results. There is no question but that an angle best suited for cutting one material under certain conditions might not be suitable for cutting the same material under different conditions or another material under the same conditions. The tooth-face angle of a hob should be made, if possible, to suit the general average of the work it is expected to do.

Fig. 1 shows at *A* an old-style hob in which the top faces of the teeth coincide with radial lines, while at *B* is shown a hob with hook teeth. The flanks of each tooth along line *QR* also have the shear or side rake feature. This is due to the fact that the hob tooth flank is angular and not truly perpendicular to the axis of the hob, and so there is actually a combined hook and side rake all along line *QR* producing an efficient cut on the working portion of the gear teeth machined by such a hob. This clean cutting action is almost impossible to obtain when the hob teeth are ground radial.

In some experiments it has been attempted to give the edge at *Q* a shearing action as well as a hook by using an even number of flutes and varying the angle of the flutes, that is, making every other flute have an angle less than the helix angle of the hob, and those in between a correspondingly greater angle. This has also been done with single gear-cutters by gashing the successive teeth at slight opposite angles. The writer has no definite data on the action of these alternate-angle cutters, but thinks that their advantage might be offset by the greater difficulty in making and grinding them, and while the action of one flank edge of the teeth would be improved by the increased angle of rake, that of the opposite flank edge would not be as good because the angle is obtuse.

It is as easy to produce hobs and cutters of the hook-tooth type as it is to produce radial-tooth hobs, when the hob is backed off by a relieving machine. The relieving tool merely has to be tilted about 7½ degrees to get the proper tooth shape for an 8-degree hook, instead of setting the tool to the center. The way the tool is tilted is shown in Fig. 2. This also gives the advantage of a hook and side rake to the cutting edges of the relieving tool itself. In hobs made without this allowance for hook, that is, with the depth and tooth angle correct in a radial plane, the effect of under-cutting the teeth is to give them a slightly greater depth *AC* instead of the proper depth *AB*. This will result in somewhat deeper teeth being cut in a gear than is necessary. The change in the resulting gear-tooth angle is so slight as to be ordinarily negligible, and some firms grind old stock hobs in this way without experiencing any disadvantages.

Another point for consideration is the fact that there seems to be no definite angle or amount of clearance adopted for hobs at the present time. Different manufacturers back off the same size hobs various amounts, and the same manufacturer will sometimes back off hobs of different diameters and pitches in amounts that do not vary in proportion to their size. In some cases manufacturers back off the same size hob different amounts at different times, probably because another machine is used or because a cam of a different throw happens to be in the relieving machine. It seems that since hobs and formed gear-cutters are fairly well standardized in other respects, the angle or clearance should also be standardized. If this were done, the correct tipping of the tool as illustrated in Fig. 2 could be worked out mathematically, as could also the exact foreshortening of the teeth, or the distance *X*, and the slight change in the angle *DEF*.

It is well known that cutting tools on which the teeth are hooked require less clearance than tools on which the teeth are not under-cut. The chief advantages of providing a hook on hob and cutter teeth may be briefly summarized as follows: Greatest possible production due to the ability to take heavier cuts at greater rates of feeds and speeds; more output between the hob grindings; less metal to remove from the hob when ground; smoother cutting action and less chatter; less power required and consequently less strain on the machine members and the hob teeth; and less clearance required for the teeth. Some materials on which it was found impossible to obtain a smooth finish when using radial-face hobs have been satisfactorily machined after grinding the hob teeth to the hook style.

FORMULAS FOR PRESSURE REQUIRED FOR SHEARING METAL

By D. C. OVIATT, D. C. Oviatt & Co., Cleveland, Ohio

The amount of shear or inclination necessary either for a shear blade or for shearing and trimming dies is variable and depends jointly on the physical condition of the metal being sheared or trimmed and the length of cut or distance around the die opening.

Shear may be expressed either as a fraction of the thickness of the stock to be sheared or as inclination of the shear blade in inches per foot. When expressed as a fraction of the thickness of the stock, the terms ¼ shear, ½ shear, 1½ shear, etc., are used. This is diagrammatically shown in the accompanying illustration. The thickness of stock is indicated by *X*, and the shear as a fraction thereof. For example, two cases are shown at *A* in which the shear blades are provided with ½ shear, that is, a rise of blade equal to one-half the thickness of the stock. Likewise, the blades shown at *B* are provided with ¾ shear. A blade having any given shear, as explained in the foregoing, will require the same pressure to force it through a plate, regardless of whether the blade presents one cutting edge or several. For instance, the pressure required would be the same for both cases shown at *A*, or for both shown at *B*, although the blades at the right have three points in contact, while those at the left have but one.

Pressure Formulas for Shear Calculation

When the shear is expressed as a fraction of the plate thickness, the following formula may be used to determine the pressure required to force the blade through the plate:

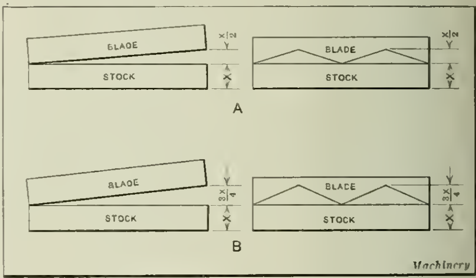
$$W = \frac{ldf}{c}\left(t - \frac{dt}{2}\right) \qquad (1)$$

When the shear is to be calculated without regard to the length of cut, or the boundary line of the die opening, but rather with relation to the inclination of the die face in inches per foot, the following formula should be used:

$$W = \frac{6dt^2f(2-d)}{s} \qquad (2)$$

In these formulas

- W = pressure in pounds required to force blade through plate;
- l = length of cut in inches in a straight line or in a line bounding an opening to be cut;
- f = ultimate shearing strength of material in pounds per square inch;
- t = thickness of plate in inches;
- c = shear, expressed as a fraction of the thickness of the flash;
- s = shear, expressed as inclination of the die face in inches per foot;
- d = constant.



Diagrammatic Illustration of ½ and ¾ Shear for Trimming Dies and Shear Blades

The constant d is that fraction of the plate thickness through which the shear blade must be forced before the shearing resistance of the material is overcome. The value may usually be taken as 1/3 for cold steel, but may vary from ¼ to ½, or even more, according to the condition of the shear blades or to the nature of the material being cut. Obviously this factor will be less for hot material than for cold, and greater for steels of higher shearing strength.

Application of the Formulas

Considering first the shear as expressed as a fraction of the plate thickness, what pressure will be required to shear a plate ¾ inch thick, 18 inches long, the blade being provided with ½ shear? The ultimate shearing strength of the material is 50,000 pounds per square inch.

The values for the different factors are: $t = 3/4$; $c = 1/2$; $d = 1/3$; $l = 18$; $f = 50{,}000$; so by applying Formula (1)

$$W = \frac{18 \times 1/3 \times 50{,}000}{1/2}\left(3/4 - \frac{1/3 \times 3/4}{2}\right)$$

$$= 600{,}000 \times 5/8 = 375{,}000 \text{ pounds.}$$

In applying Formula (2) to the solution of the same problem,

$$W = \frac{6 \times 1/3 \times (3/4)^2 \times 50{,}000\,(2 - 1/3)}{1/4}$$

$$= 7.5 \times 50{,}000 = 375{,}000 \text{ pounds.}$$

Planing Large Spur Gears

Application of Gear Planers which Cut Gear Teeth by Reproducing the Shape of a Templet

By FRANKLIN D. JONES

LARGE gears of coarse pitch may be cut either by planing on a templet or form-copying type of machine, by milling with a formed cutter, or by hobbing. Most gear manufacturers use the templet planer for the very large gears. One advantage of this type of machine is that simple, inexpensive tools are used, and this is very important, as often only one of these large gears is required, and the cost of making a formed cutter or hob would be prohibitive.

Gear-cutting machines of the templet type are also used for cutting large bevel and herringbone gears; in fact, gear planers of this class are used invariably for cutting very large bevel gears. Some gear planers are designed for cutting spur gears exclusively, but there are also combination types which may be applied to either spur or bevel gears.

A characteristic feature of the templet planer is the templet or master former which serves to guide the planing tool, thus causing it to plane teeth having the correct shape or curvature. When the planer is at work, a slide or head which carries the tool is given a reciprocating motion, and as the tool feeds inward for each stroke, the path it follows is controlled by the templet. The traversing movement of the tool-slide is derived from a crank on some gear planers, whereas others have a reversing screw. Still another method of traversing the head is by means of a rack and pinion, the latter being arranged to rotate in opposite directions.

There are two general methods of machining the teeth on one of these planers. One is to rough out the teeth with a single-pointed tool and then finish with a formed tool which removes the feed marks and gives the teeth a smooth finish. The other method is to take both roughing and finishing cuts with single-pointed tools. The use of the formed tool for finishing is impracticable for the larger pitches which are finished by a single-pointed tool. The number of cuts required depends upon the size of the tooth, amount of stock to be removed, and the kind of material.

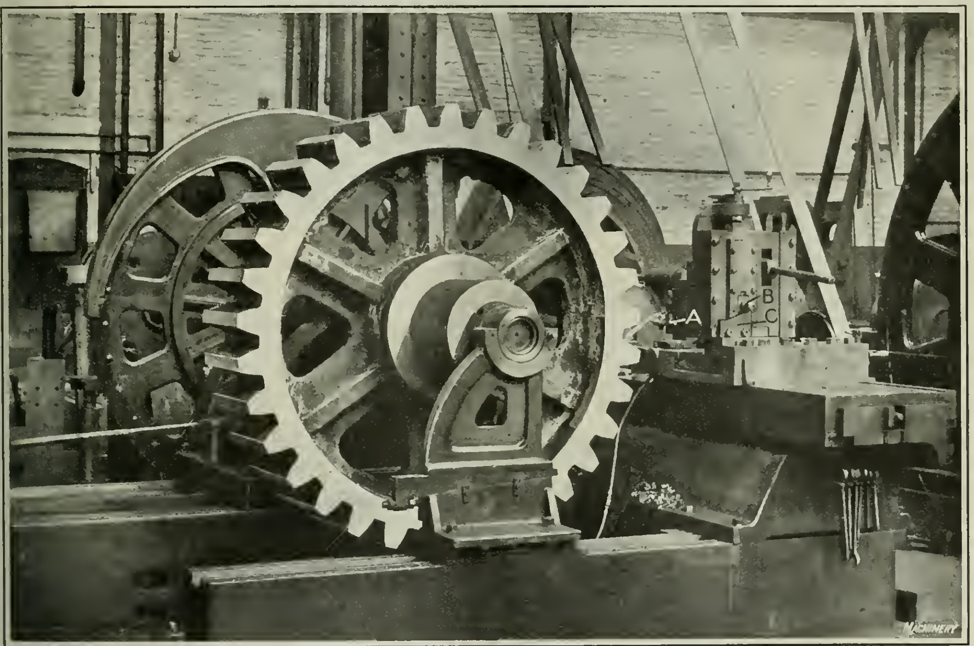


Fig. 1. Gear Planer of the Templet or Form-copying Type with Finished Spur Gear in Position

Operating Features of Templet Type Gear Planers

One of the Gleason planers of the type designed exclusively for cutting external and internal spur gears is shown in Fig. 1. The tool *A* is held by a slide which can move vertically. This slide is connected with another slide that is given a horizontal feeding movement after each cutting stroke of the tool. A roller *B* attached to the vertical slide, rests upon a templet *C*, which is stationary. When the horizontal slide feeds inward for taking a finishing cut, the tool planes one side of the tooth to the required curvature, because the path it follows is controlled by the shape of templet *C*. Sets of these templets are supplied with a gear planer, one templet of each pair being for the upper sides and the other for the lower sides of the teeth. Each pair of templets in the set covers a certain range of diameters and can be used for planing any pitch from the smallest up to the pitch stamped on the templet, which requires the full length of curve of that templet. The entire tool is mounted upon a large main slide that is traversed by a crank type of drive on the particular machine shown in Fig. 1.

The indexing mechanism may be seen in Fig. 3 which shows another machine of the same general type set up for cutting a larger gear. The large dividing wheel D is engaged by a worm connecting with a mechanism for controlling the indexing movement. After one side of a tooth is planed, the index mechanism is tripped by the operator, and then the gear is automatically rotated an amount equal to the circular pitch of the gear being planed. The power for this indexing movement is supplied by a small auxiliary motor M forming part of the indexing mechanism. The tool-slide of the machine shown in Fig. 3 is also motor-driven.

The thrust of the cut on these gear planers is taken by a rim support mounted on brace E. This support, which bears directly against the rim while the planing tool is at work, must be withdrawn slightly to permit the gear to swing freely while indexing. This is done by hand, by means of handle F. Gears of different diameter are accommodated by shifting along the main bed, the head carrying the work-spindle and also the bearing (see Fig. 1) for the outer end of the work-arbor.

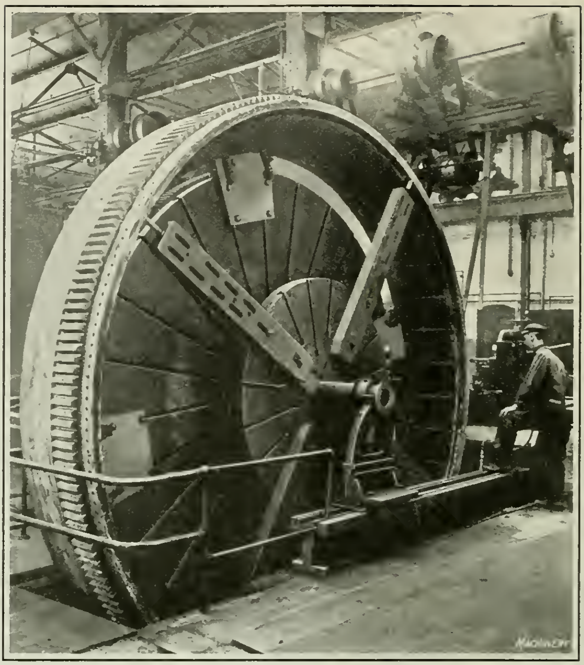

Fig. 2. Gear Planer provided with a Pit for swinging Large Gears

As a general rule, gears having a circular pitch of two inches and smaller are planed with tools which are used for both the sides of the teeth and the fillets at the bottom, but for coarser pitches, different tools are used for the sides and the fillets. A line representing the root circle is marked on one side of the gear blank, preferably by using a sharp-pointed tool at the time the blank is turned. When these gear planers are used for cutting internal gears, a special attachment is employed, which will be described in a subsequent article in connection with the cutting of internal gears.

Examples of Large Spur Gear Planing

When gear planers are used for gears having a larger radius than the distance from the center of the work-spindle to the floor, a pit is provided in order to increase the capacity of the machine. Figs. 2 and 4 show front and rear views of a planer at the Gleason Works, Rochester, N. Y., cutting a large gear which enters a pit beneath the floor. This machine is similar to the type just described. The gear teeth are on a large ring-shaped casting. In order to hold this casting, a large auxiliary faceplate was mounted on the work-spindle. The regular faceplate is located in front of the auxiliary faceplate. Four supporting arms are bolted to each of these faceplates for holding the ring-gear in position. As Fig. 4 shows there are gear teeth on the rim of the auxiliary faceplate to permit revolving it by a direct drive when it is necessary to turn the rim of a large gear which is beyond the capacity of machines generally used for turning operations. These planers for large gears are equipped with

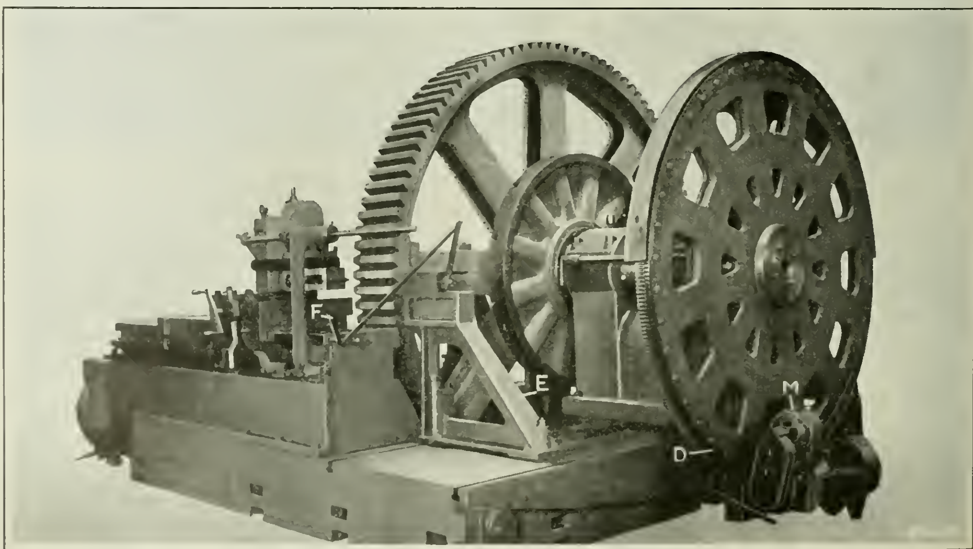

Fig. 3. View of a Spur Gear Planer showing the Indexing Mechanism and Large Dividing Wheel

dividing wheels of large diameter (see the illustration Fig. 4) to minimize indexing errors.

Another example of large spur gear planing is shown in Fig. 5. This illustration was obtained from the plant of the Farrell Foundry & Machine Co., Ansonia, Conn. An idea of the size of this gear may be obtained by comparison with the operator. The pitch diameter of the gear is 16 feet 10½ inches, the circular pitch 6 inches, and the face width 18 inches. This is another operation illustrating the use of a pit to provide room for swinging a large gear. It will be seen that this planer is of the same design as that illustrated in Fig. 1.

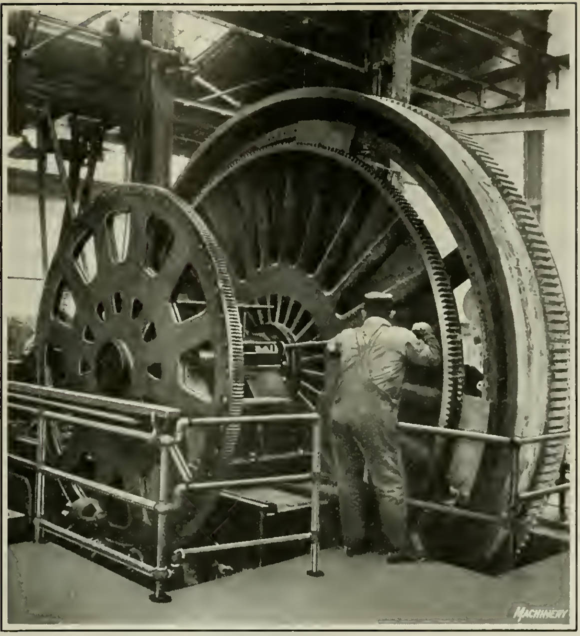

Fig. 4. Rear View of the Planer shown in Fig. 2. Note Large Dividing Wheel at Left-hand End of Work-spindle

Combination Gear Planers

Planers designed for cutting either spur or bevel gears differ from the type used for spur gears only, especially in regard to the arrangement of the main slide upon which the head is traversed. One end of this slide is provided with both vertical and horizontal bearings. The vertical bearing permits it to swing horizontally, and the horizontal bearing provides for a vertical movement. A feeding mechanism controls the horizontal motion, whereas the vertical movement is controlled by a former engaged by a roller attached to the outer end of the main slide. These combined horizontal and vertical movements cause the tool to follow the converging form of a bevel gear tooth. The toolholder used for bevel gears does not have a cross-feed relative to the main slide, but when planing spur gears another tool-head having this lateral feeding movement is used and then the main slide is held stationary in a position parallel to the axis of the gear. On planers of the combination type, the head which carries the gear blank has not only a side adjustment to care for different diameters, but also an adjustment that makes it possible to set bevel gears of different angles so that the apex of the pitch cone of the gear will coincide with the "center of the machine."

Gear Teeth Cast to Approximate Shape

Rough or unplaned blanks for large gears, such as are cut on the templet type of gear planer, ordinarily have rough-cast teeth, which are left thick enough to allow for planing. When the teeth are cast, it is not necessary to remove so much metal when machining them, although these cast teeth have a hard scale which offsets, more or less, the advantage men-

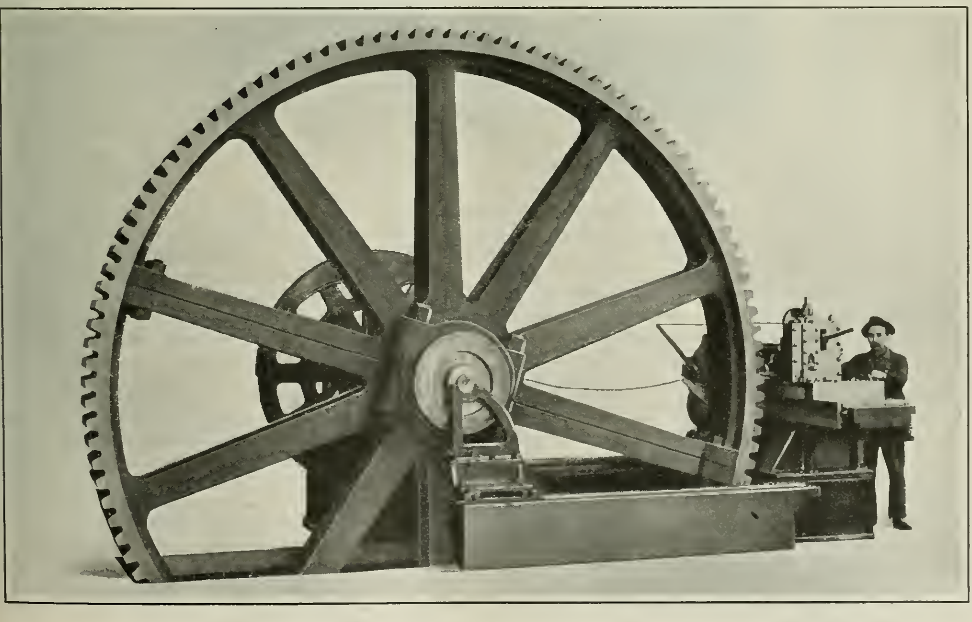

Fig. 6. Planing a Spur Gear having a Pitch Diameter of 16 Feet 10½ Inches and a Circular Pitch of 6 Inches

tioned. Because of this fact it is easier to cut the teeth "from the solid" in some cases; however, there is a good reason for casting the teeth to the approximate shape required. When the teeth of large gears are cast, this tends to insure soundness in the rim of the casting and tooth surfaces free from defects. On the contrary, if coarse teeth are cut from a solid rim, blow-holes or other interior defects might be encountered, especially in those rim sections adjoining the spokes or arms. According to one authority, there is no advantage in casting the teeth if they are smaller than one diametral pitch.

Cutting Large Gears on Templet Planer of Vertical Design

Another design of gear planer adapted for machining large spur gears is illustrated in Fig. 6 which shows a machine built by the Newton Machine Tool Works, Inc., Philadelphia, Pa. The tool-slide has a vertical reciprocating movement when the machine is at work. This traversing motion is derived from a rack and spiral pinion drive, the latter being rotated in opposite directions by open and cross belts similar to the arrangement of a planer drive. The vertical column may be adjusted along the horizontal bed to suit the diameter of the gear, and this machine will plane gears up to 40 feet in diameter.

The templets controlling the path followed by the tool as the latter feeds inward are attached on each side of the tool-slide. One templet controls the tool movement when planing one side of the teeth, and the templet on the other side of the tool-slide is used when planing the opposite sides of the teeth. When the planing tool is at the top of its stroke, it feeds inward for taking the next cut and at the same time the tool-slide is given a lateral movement under control of whichever templet is in use. This lateral movement is obtained from a "star feed" in conjunction with a friction device, that allows for whatever slipping may occur after proper contact with the templet has been obtained. The indexing movement is derived from a motor which transmits motion through change-gears and worm-gearing to the work-table. This indexing mechanism is controlled by simply releasing a hand-operated plunger which allows the motor to rotate the work-table and gear an amount equivalent to the circular pitch.

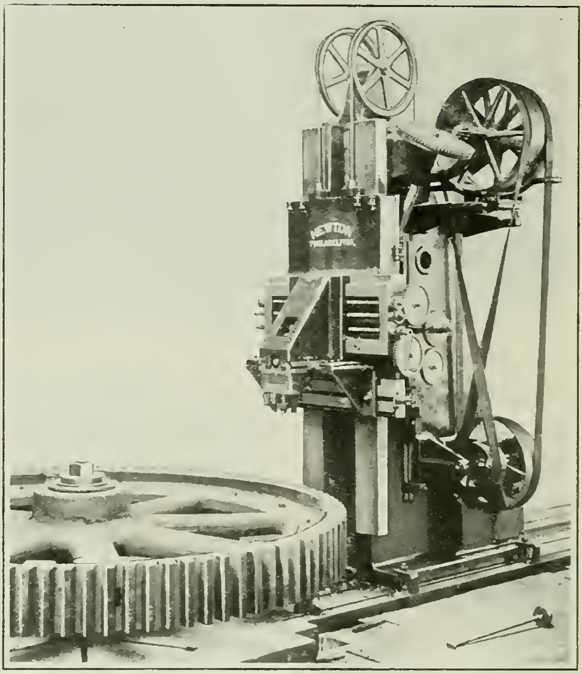

Fig. 6. Spur Gear Planer of Vertical Design

* * *

France is now the leader among European nations in tonnage of iron ore reserves, having 35 per cent of the total tonnage for the Continent; the United Kingdom follows with 18 per cent, Sweden with 12.5 per cent, and Germany with 11 per cent. Central and southern Russia, Spain, and Norway are the only others possessing more than 2 per cent of the total, according to a recent report (Bulletin 706) issued by the Geological Survey.

NUMBERING TOOL DRAWINGS

By JOHN E. COLLINS

Having twice been called upon to devise and install a drawing number system, and believing that the simplest way of doing anything is always the best, the writer developed the following method of numbering tool and pattern drawings. No cross-index systems are required to find the tool drawing for any part, or to determine from a tool drawing what parts are to be machined with the tool shown on that drawing.

The part number the tool is designed for is used in all cases as the base for the tool number. Thus if the part number is 4500, the tool number will also contain the number 4500. This ties the tool number up with the part it is to be used on. To take care of tools of different sizes, it is necessary to have the drawings on sheets of various sizes. This makes it desirable to include some method of noting the size of the sheet on which the drawing is made, as a separate file is preferable for each size drawing regularly used.

The tool numbers for the various operations on any one part are distinguished from one another by simply using the operation number of the part. On the tool drawing sheet a space is provided at one side of the general title for the model and part number. If at any time a new model is released for manufacture and the tool can be used on this model also, this information is noted on the tool drawing. It should be remembered that the details must be drawn on sheets which are the same size as those used for their tool lay-out drawings.

For example, let the tool number 4-4500-6 be selected. The first number 4 identifies the sheet size. In the plant under consideration there are four sizes. The number 4 indicates that the sheet is 24 by 36 inches. The number 3 would indicate a sheet 18 by 24 inches, number 2 a sheet 12 by 18 inches, and number 1 a sheet 9 by 12 inches. Therefore, if we have the tool number we also have the sheet size, which in turn indicates what cabinet and drawer it is filed in.

The next number is the part number 4500, which identifies the tool with the part. By knowing the part number it is an easy matter to find the tool number, or vice versa. The last number 6 identifies the operation number on the part 4500 and at the same time serves to distinguish between tools used on the same part. If more than one tool is used for one operation letters A, B, C, etc., are used to identify them.

Tool pattern numbers are the same as tool drawing numbers. If more than one pattern is required for any one tool, the pattern numbers have a prefix attached, thus: A, B, C, etc. The operation-sheet forms are typed on very thin paper with carbon paper backing up the letters on the rear side This allows any number of duplicate blueprints to be made from the original operation sheets.

Operating a Factory with a Reduced Force

By JOHN C. LEASE, General Superintendent, Houston, Stanwood & Gamble Co., Covington, Ky.

THE organization and methods for operating a factory economically when run at full capacity are not always applicable when the factory is running at only 25 or 30 per cent of capacity. Many manufacturers have become keenly aware of this fact during the past year. At the Houston, Stanwood & Gamble plant the problem arose of operating the factory profitably at 30 per cent capacity. By adopting a unique method of control and enlisting the interest and co-operation of the employes, it has been possible to accomplish noteworthy results in this direction, and the factory has been run on a paying basis in spite of the reduced business.

Chart Showing Productive and Non-productive Labor

In any scheme of management the secret of success is to reduce the non-productive labor hours to a minimum, while maintaining the productive labor hours at a maximum. The first thing to be done in running a factory on a reduced scale is to investigate the proportion between productive and non-productive labor hours. The term "productive labor hours" means time spent in directly producing such products of the company as are sold to customers. The expression "non-productive labor hours" designates time spent on maintenance and equipment, experimental work, store-rooms, supervision, shipping, watchmen, etc. If an investigation is made in the average shop during the period of depression when the shop is engaged at but a small percentage of capacity, it will be found that non-productive working hours run up to an unexpected figure, as compared with productive hours.

Fig. 1 shows what such an investigation revealed in the plant of the company referred to, when the system of control to be described was first put into operation. There were 1750 non-productive hours per week, as compared with 2450 productive hours. The first step was to reduce to a minimum the amount of non-productive labor being performed about the shop, and, as will be noted from the chart, in three weeks' time the non-productive time was reduced to 618 hours. Meanwhile the productive hours decreased also, due to a lack of orders, but the proportion between productive and non-productive hours was far more favorable at the end of the three weeks than at the time when the chart was begun. At the end of each week the total number of productive and non-productive hours is noted on the chart, and the entire scheme of holding down the non-productive work is explained to the employes, so that they take a remarkable interest in seeing the productive curve rise while the non-productive remains either stationary or falls. It has been explained to the employes that only by increasing the productive labor hours in proportion to the non-productive can the firm expect to do a business profitable enough to keep them permanently employed, and the interest taken in this matter by everybody in the entire factory is an indication of the possibilities of teamwork within an organization, when all the problems pertaining to the manufacturing program are explained and understood by the employes.

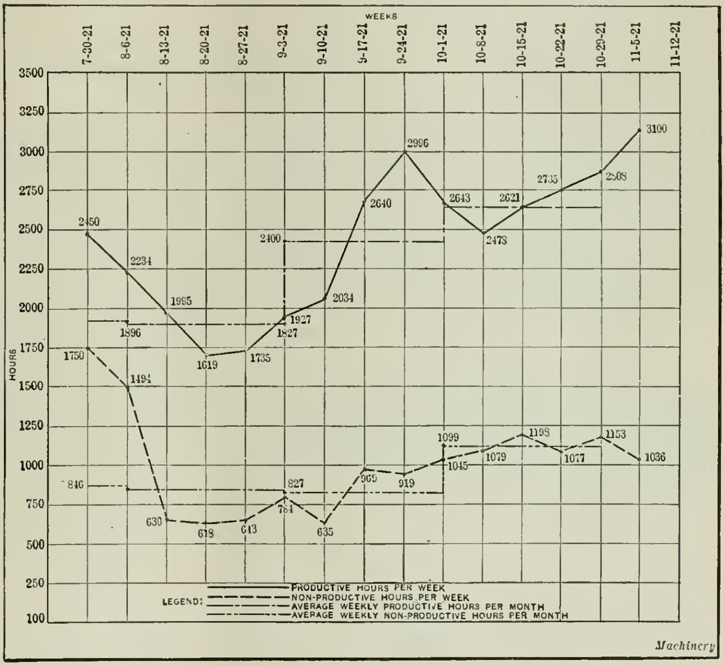

Fig. 1. Chart showing the Relation between Productive and Non-productive Hours, Weekly and Monthly

Operation of the System

Besides the general superintendent, two men are employed to keep the system running. One is the production supervisor, who makes every effort to increase the productive hours. The other is the employment manager and timekeeper, who acts as a clearing house for the hours spent both in productive and non-productive work, and who, in addition, is directly responsible for holding down the non-productive hours. The employment manager, of course, has a complete record of all men employed in the plant. If a foreman in a given department finds that he will be short of work for a certain number of men within a few days, he notifies the employment manager, who then transfers these men to some maintenance work that may have been held up for the time being but with which it may seem advisable to go ahead, employing the men temporarily idle. Should there be no non-productive work to be done, it will be necessary to reduce the force. However, one of the objects of the system of transferring men from productive to non-productive work is to keep the men permanently employed as long as possible, giving them a steady job in the shop, even though they have to do a variety of work in the course of their employment.

Reports on which the Chart is Based

Each day a shop labor report is prepared by the two men who have charge of the productive and non-productive labor, respectively, and this report is added to the records of the employment manager from which the chart shown in Fig. 1 is constructed. This shop labor report is arranged as shown in Fig. 2. It gives the number of hours spent on productive work, on standard machinery orders and special orders, and the number of non-productive hours spent on maintenance and equipment, experimental work, etc.

Shop Labor Report								
Description	Daily Time Entries							Total for Week

Stores and Traffic								
Watchman & Supervision								
Total Non-productive Hours								
Number of Men Employed								

Fig. 2. Daily Shop Labor Report of Productive and Non-productive Hours, used in laying out Chart shown in Fig. 1

Record of Productive and Non-productive Men in the Shop

A record of the number of productive and non-productive men in the shop is kept by the employment manager on a chart which shows the plan of the shop, as indicated in Fig. 3. Each circle indicates a productive man, and each black dot a non-productive man. A dot within a circle indicates a working foreman. The dots and circles are not put in with ink but with crayon, so that they can be easily removed and replaced, and in this way a graphic index of the number of productive and non-productive men in every department is always before the eyes of the general superintendent, the production supervisor, and the employment manager.

Transferring the Men from One Job to Another

The employment manager keeps a list of all the machines and occupations within the plant, which gives the names of the men capable of performing the work under each head. This list is known as a key sheet, a sample of which is shown in the accompanying table. From this sheet it can be quickly determined which men are capable of operating several machines, so that when work on one machine runs out, they can be transferred to a job that is waiting to be done on some other machine. In this way it is possible to run the shop efficiently with a greatly reduced force, and to retain men capable of operating a number of different machines so that all the required work can be handled without hiring a great number of men that are specialists on one machine only. The key sheet helps to solve the problem of operating a plant with a small force of men during a period of depression.

Every plant would have to devise some modifications in a system of this kind to suit its peculiar conditions, but it is believed that the outline given will suggest to the managers of machine shops in general how an effective control may be established to prevent the overhead due to unproductive labor from becoming too large during times of depression. The key sheet also indicates how, by employing not more than, say, twenty-five men, it is possible to fill the jobs for which eighty-five men would normally be required. It is evident that such a key sheet is very valuable in determining which men should be laid off in case there is not enough work to be done. The men who have the best all-around experience would naturally be kept, and those that could not be transferred readily from one machine or job to another would have to be dispensed with first. The details of the system can be readily worked out for each shop according to the local conditions. No attempt has been made to explain anything but general principles. At this time, when so many plants are operating on a reduced schedule, an idea such as outlined should prove especially valuable. It is not a mere theory, but has proved its applicability.

COUNTERBORING ATTACHMENT

By D. A. NEVIN

Seventy-five thousand brass parts like the one shown at *A* in the illustration were required to have the 0.437-inch hole counterbored or burred to a square bottom and sized concentric with the outside diameter. This could not be done economically on the automatic screw machine employed for the preceding operations, because of the loss of time resulting from the slow feed for which the automatic machine was set, and the necessity for frequent sharpening of the counterbore. Rechucking in the hand screw machine was undesirable, as it would tie up a high production machine on a comparatively simple job which required the use of but one tool. Also the amount of unnecessary floor space which would thus be devoted to this operation, and the inaccuracy which would probably result from the use of a counterbore held in the turret without a pilot were also factors to be considered.

There were several small lathe heads in the store-room which had been used a number of times for tapping and burring. One of these heads was mounted on the bench with the chuck facing the operator and the counterboring attachment added as shown. The bracket *B* is attached to the lathe head and carries the bearing *C*. The spring-operated work-holder *D* is retained in bearing *C* by the collar *E*. Part *D* is keyed to bearing *C* by the key *F*, and the work is driven by the pin *G*.

This and other similar jobs were performed very rapidly by the use of the attachment, as the work is simply placed in the pocket and pushed against the cutter with the thumb. In the sectional view the work is shown in position with the counterbore or cutter at the bottom of the cut. There is probably a considerable amount of hand screw machine work in various factories that could be performed with this device. For general use, it would be necessary to employ interchangeable work-holders, and provide longitudinal adjustment for stop-collar *E*.

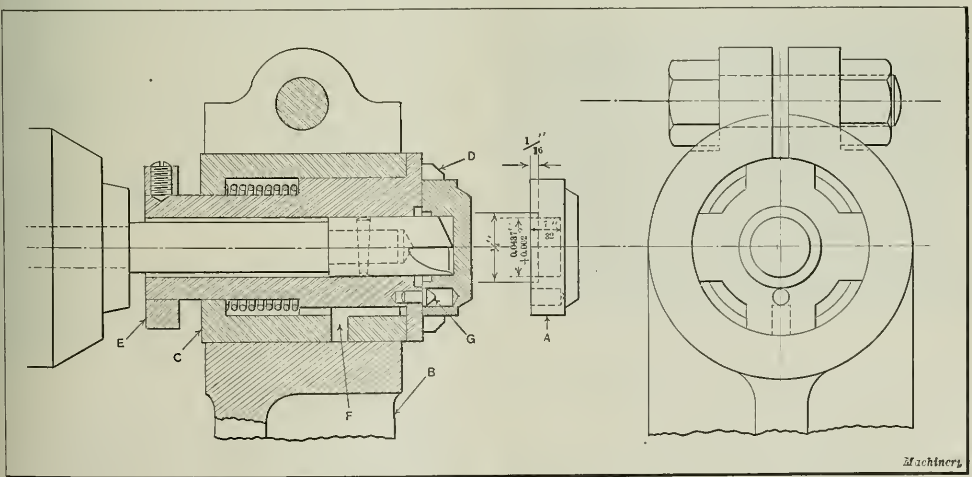
FOUNDRYMEN'S CONVENTION

Announcement has been made that the annual convention and exhibit of the American Foundrymen's Association which was scheduled to be held during the week of April 24 in Cleveland is to be held instead in Rochester, N. Y., from June 5 to 9. All activities of the association will be centered at Exposition Park, which is located a mile and a half from the center of the city.



Counterboring Attachment for Lathe Head

Price and the Machine Tool Salesman

By a Machine Tool Sales Manager

EVEN in the best of times most salesmen are somewhat reticent when they must talk price. They will talk about their product ardently and demonstrate it enthusiastically, until they create an interest and the prospective customer begins to view the article with an eye to its possession. When he wishes to learn the consideration necessary to possess it, the tone of the salesman often changes from one of aggression to one of hesitation. This change frequently makes the prospective customer feel that while the salesman has confidence in the product, he has no confidence in its price.

This lack of confidence is sometimes expressed as well as implied. Recently a buyer needed a collet for a machine previously purchased. When he asked the salesman the price of the collet, he replied: "I am almost ashamed to tell you; it is $11." The collet was not purchased—not at that time.

The salesman's reason for his attitude on price may be that he wishes his customer to notice that he is looking out for the customer's interest. If machine tool prices are or were at any time exorbitant, this would be a commendable attitude on the part of the salesman, but machine tool prices are not high—a fact that may easily be proved by comparative figures—and for the salesman to intimate this in any way borders on misrepresentation. It also creates a misconception in the mind of the buyer that sooner or later must be corrected.

The Salesman's Attitude toward Price

The price of every article is always a factor in its sale, but at no time should this be the sole factor. It is not good salesmanship to dwell too much on the price or even to quote it before explaining the value of the machine itself. On the other hand, there is no reason why the salesman should fear to talk price. Price is a feature of the product. It is so related to the quality of the product that any salesman should feel free to speak of it in bold-face type instead of whispering it in parentheses.

Some machine tool salesmen avoid quoting a price at the time of an interview and state that they will make a formal quotation. This puts too small a value on the importance of price and postpones a decision on the part of the buyer. It is human nature to procrastinate in the spending of money (at least for useful purposes). The salesman generally is not present when the formal proposal is studied, and he has no opportunity to answer questions relative to price. Simply stated, the salesman puts up a fight for the mechanical features of the machine and runs away to let the price shift for itself.

The Relation of Price to Output

In most products there has been a sad lack of stability of price that has caused buyers to be reluctant in placing orders. In the machine tool industry there is uo just basis for hesitancy. It is one of the salesman's problems, however, to bring this phase before the buyer in its true light, and to explain the conditions to the customer. Back of every machine tool there is usually some definite proof that may be presented to show the buyer that the price is a reasonable one—not to say a favorable one.

The builder of a production machine tool recently decided to talk to his prospects in terms of output only. Instead of merely stating that the price of the equipment is so much, he also quotes the cost of the operation per piece. The cost of the equipment—the "cost of ownership"—was figured at 6 per cent interest on the original outlay, with depreciation at the rate of 10 per cent per year. Two thousand production hours in a year were assumed. The interest and depreciation divided by 2000 represents the cost of the machine per production hour. Then there are the items of overhead, aside from the interest on the investment and depreciation —such items as rent, light, heat, power, and upkeep. These miscellaneous items were assumed and added to the "cost of ownership." This particular concern allows 30 cents per hour for the miscellaneous items per machine. A $3000 machine on this basis would equal cost, in total, 54 cents per hour. To this cost is added the operator's rate, and this sum, divided by the production per hour, gives the cost per piece.

The whole problem may be expressed by the formula:

$$x = \frac{(A + B) \div C + D + E}{F}$$

in which

x = cost of production per piece, in dollars;
A = interest on investment (6 per cent of cost of equipment);
B = depreciation (10 per cent of cost of equipment);
C = production hours per year (assume 2000);
D = cost of overhead per production hour, in dollars;
E = operator's rate per hour, in dollars; and
F = number of pieces produced per hour.

This method of arriving at the cost per piece may seem somewhat roundabout, but it is more effective than merely assuming a fixed rate per hour, because it shows what items the salesman has taken into consideration in arriving at the cost per piece. Also, the methods of computing shop costs vary widely and are understood often only by the auditor or the cost department, and these departments ordinarily are not consulted in the selection of new equipment.

Another way of justifying the price of machine tools is by the use of comparative figures. Take the composite price of 327 commodities as published by the United States Department of Labor, and compare this with the price of machine tools, in 1914 and in 1922. This comparison will show that machine tools have closely followed the general price curve, and the salesman can prove that any delay in the purchase of a machine tool is unwarranted. Besides, there have been improvements in design and workmanship in most machine tools, and the price will never be as low as before such improvements were made.

Another comparison that is worth while is the relative prices of machine tools and pig iron. Beginning with 1915, and assuming that pig iron and machine tools then had a definite relation in price, it can be shown by a chart that during the years 1917, 1918, and 1920 pig iron rose to a much higher level than machine tools, while in 1919 the two followed closely together, and in 1921 both showed the same downward trend. Pig iron, on account of the conditions, fell somewhat more rapidly, but recovered, while machine tools show a steady decline commensurate with the reductions in raw materials and wages.

Improvement in Quality and its Relation to Price

An example of the effect of improvements on price recently came to the writer's attention. A machine tool manufacturer who formerly used cast iron and soft steel gears is now using heat-treated steel gears that cost five times as much to produce. Such great changes should be pointed out to the buyers of machine tools in order to explain to them thoroughly the reason why improved quality must demand a higher price.

It is doubtful if any machine tool salesman who studies the problem of manufacturing costs can come to any other conclusion than that machine tool prices today are low in proportion to prices of most other manufactured products. When he has thoroughly studied the subject and come to this conclusion, he is prepared to speak authoritatively on the price question. He may even come to share the opinion of many manufacturers in the machine tool field that some prices of machine tools are now too low and that renewed activity will bring about increases. At this point his real work today begins—to prove and to transmit to the buyers of machine tools the information that he has gathered as to machine tool prices. Armed with the actual facts in the case, he need have no hesitancy on the question of price when making a sale.

STRAIGHT PIPE THREADS

By J. R. SHEPPARD

Referring to the article on straight pipe threads, appearing on page 492 of February MACHINERY, the writer offers the following additional information:

When hydraulic pressures of 2500 pounds per square inch and over are used, the best practice demands the use of straight threads. In this case a double extra heavy pipe is used, and the gasket placed between the ends of the pipes. The flanges then act simply as connections to hold the ends of the pipes together, the pipe protruding through one flange, while the other flange is counterbored to form a pocket that confines the gasket. With this arrangement, there is only one joint; whereas, if taper threads were used, there would be three joints for each flange connection. The same is also true for plugs for these high pressures, straight pipe threads being used and the joint made with a gasket at the bottom of the plug.

THE FOREIGN MARKETS FOR MACHINERY

The Industrial Machinery Division of the Bureau of Foreign and Domestic Commerce has issued a review on the expanding markets for machinery, pointing out that while the flow toward Europe represents a smaller percentage than formerly, the demand in certain other sections is rapidly rising. While Asia absorbed only 7.4 per cent of the American machinery exports in 1910, this market absorbed about 25 per cent in 1921. The statistics indicate that the markets that have shown the greatest activity in 1921, compared with pre-war years, are to be found in British India, Dutch East Indies, Japan, China, Mexico, Argentina, Brazil, and Cuba. Considering the machinery field as a whole, it appears that there is reason to be optimistic regarding the machinery markets in these countries as well as in Australia and South Africa. In certain lines of machinery, these markets have absorbed much of the exports that normally would have gone to Europe.

* * *

A joint meeting of the Virginia sections of the American Society of Mechanical Engineers, the American Society of Civil Engineers, and the American Institute of Electrical Engineers was held at the Virginia Polytechnic Institute at Blacksburg, Va., February 17 and 18. The subjects dealt with pertained particularly to the distribution and production of coal, and papers were read on the transportation of coal, the electrification of railroads, and coal combustion. A visit was made to the power station at Bluestone Junction, where experiments are now being made with pulverized coal fuel equipment, and a trip was also made to Pocahontas, Va., to see the coal mining operations in this well-known mining region.

CHAMFERING RING BEVEL GEARS

The chamfering of the outer edges of bevel gear teeth is sometimes an advantage, but in doing this work, it is often difficult to produce a neat-looking job. As the result of some experimenting, the Illinois Tool Works of Chicago, Ill., have made successful application of the hobbing process for this purpose. A special hob has been developed, as illustrated in Fig. 1, where a No. 18 Gould & Eberhardt hobbing machine is shown engaged in beveling the teeth of a spiral bevel ring gear. A section of this gear with a number of teeth is

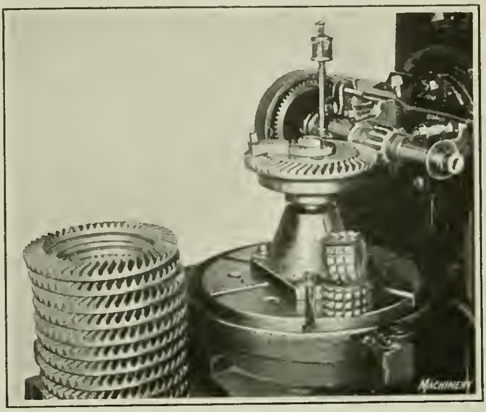

Fig. 1. Chamfering Gear Teeth on the Hobbing Machine by the Use of a Special Hob

shown in Fig. 2, from which it will be noticed that the work presents a neat appearance and that all teeth are uniform.

Owing to the continuous generating action of the hobbing process, and to the fact that very little stock is removed in the operation, the work may be performed with considerable speed. For example, in a recent trial, ring bevel gears having fifty-five teeth were chamfered in forty-five seconds each, floor to floor. It is believed that this performance can be duplicated by using these special hobs with any suitable hobbing machine. It is necessary to provide a work-holder having a quick-releasing feature, by means of which the ring gears may be located accurately and held securely, and this is the only extra equipment required for handling work of this kind. The hobs, except in the very coarse pitches, are

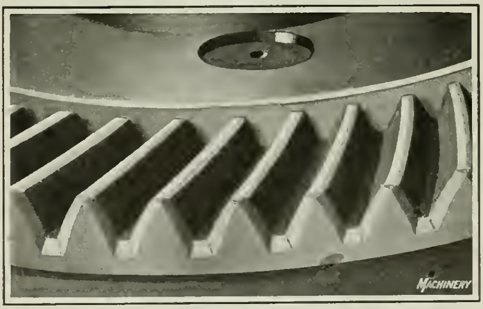

Fig. 2. Section of a Ring Bevel Gear showing Teeth which have been chamfered

of standard dimensions, that is, 3½ inches in diameter and 3 inches long, as this size is best suited for the purpose. Hobs of this length allow for shifting into several positions to make use of all the teeth before they need to be removed for regrinding. The life of a hob used for this work will extend over a long period of time, because it is only necessary to sharpen the hobs at intervals of several days.

BALL BEARINGS FOR LINESHAFTS

It has long been claimed by manufacturers of ball and roller bearings that considerable saving in power would result from the use of such bearings for lineshafts, and recent experiments made by one of the well-known ball bearing manufacturers have demonstrated the justice of these claims. The experiments referred to were made in textile mills, where it was found that when the lineshafts were running idle the power saving due to the use of ball bearings amounted to from 9 to 25 per cent. When the spinning machines were running, the load on the lineshaft being fully thrown on, the saving amounted to from 6 to 7 per cent of the total load.

The saving of so comparatively small a percentage is not a small item in dollars and cents. One of the installations, where the experiments were conducted, paid for itself within a year on account of the saving in power, and another paid for itself in six and one-half months. With coal selling at high figures these power savings are well worth while; and, generally speaking, after the first year the saving is all "velvet."

The economy resulting from the use of ball and roller bearings for lineshafts is applicable to small installations as well as large ones. In a small factory where the power cost averaged between $36 and $40 a month, and $200 was spent on installing ball bearings, the power cost was reduced to from $23 to $26 a month. In other words, the saving in a single month was sufficient to pay a large annual interest on the first cost of the bearings, or, figured in another way, the entire cost of the installation was repaid in about eight months.

TRAINING FUTURE EXECUTIVES

The president of a large locomotive company recently said that quite a number of executive positions in his organization remain vacant because of the difficulty of finding men capable of filling them satisfactorily. Had young men of the requisite ability and energy been trained in time to fill the higher positions as the opportunities arose, capable men would have been ready. But the management is by no means entirely responsible for this condition, for usually the heads of large businesses are constantly searching for and trying out men who apparently have the making of future executives. Those they try out line up from mediocre to fairly good. Seldom is a star executive developed. In one concern more than a hundred outside young men were looked over in a careful but vain effort to find an office executive. The head of one of our largest concerns recently said that he never expected to find one hundred per cent men. He felt lucky if he found eighty-five per centers, and this is true generally, especially among shop men, who are less likely than office men to have the advantage of education in their youth.

It is usually difficult to obtain from the outside a thoroughly trained and satisfactory executive. Such men lack the necessary familiarity with essential details of the business, and they must be engaged for a long period at high salaries, which they are not always worth. The ideal method is to train men taken from the organization, because those who have worked for a concern for a period of years usually possess a more thorough knowledge of its product, policies, methods and needs than an outsider.

A large manufacturer in the Middle West is at present endeavoring to develop executives by means of a series of meetings and studies which bring the plant superintendent and a number of the other executive heads of the company in close contact with the foremen and others in minor executive positions. During these conferences such subjects as principles of inspection, production management, time and motion study, wage payment systems, duties of foremen and other minor executives, and methods of handling men efficiently, are brought up. In this way the management is afforded an opportunity to form a sufficient estimate of the judgment and ability of some of the subordinates to warrant trying them out further.

* * *

MECHANICAL AND MARKETING PROBLEMS

The head of a large machine tool plant, when recently asked what in his opinion were the most important questions for machine tool builders to consider during present conditions said that they should devote their time principally to three distinct problems:

First, they should develop the design of their machines to the highest point of productive efficiency, profiting by their experience during the high productive period since 1915. If they do not feel warranted in spending money on actual development and experimental work, they should at least give all the thought possible to working out designs carefully on paper, so that the resulting improvements can be quickly turned into concrete form when the market warrants.

Second, machine tool builders should study the methods used in their own plants with an eye to reducing manufacturing costs and to improving the accuracy of their product. Machine tool builders could often profit, this manufacturer said, by applying in their own plants methods of interchangeable manufacturing which some of them have developed for their customers. By applying the unit system of design and construction to a line of machine tools, it would frequently be possible to produce many parts of the machine in greater quantities and at a reduced cost.

Third, they should not lose sight of the possibilities of foreign trade in non-European countries. It is not likely that Europe will buy many machine tools for several years; but there is a constantly increasing market in other parts of the world. Japan, China and India, for example, imported, in value, more metal-working machinery in 1918 than England and France combined imported in 1910, and almost as large an amount as England, France, and Germany combined imported from the United States in 1909. In 1919 and 1920 the imports of metal-working machinery into Asia were greater than in 1918, and it is expected from present figures that in 1921 the entire value of our metal-working machinery going to Asia will be nearly $6,000,000—three times the value of the metal-working machinery sold to England and France in 1910. Australia also offers a growing market, and the same is true of South America. These markets may offset the important pre-war European markets, now dormant, and competition with England and Germany will undoubtedly be keen in all of them. For that very reason our machine tool manufacturers should study them carefully and prepare themselves to meet the competition there.

The Supply of Used Machine Tools

DURING the war period, machine tools were built in much larger quantities than would have been required for the normal needs of the country in peace time. For much of this machinery there appears to be no immediate use; hence it is generally believed that large quantities of such machinery are for sale—a quantity vastly greater than was normally on the market in pre-war years. Manufacturers as well as users of machine tools share this belief, which is a logical inference from past and present conditions. Nevertheless, there were many indications that the supply of used machinery was not materially greater than in pre-war years, and MACHINERY undertook to get the facts from the War and Navy Departments and from dealers in used machinery, and others, throughout the country. The results we are now able to place before the machine-building industry and the users of machine tools in other fields.

It is generally believed by manufacturers as well as buyers of machine tools that there are very large stocks of used metal-working machinery which will seriously affect the market for new machine tools. MACHINERY has investigated the situation, and the results are given in the present article. There is no substantial foundation for the belief that large stocks of used machinery are available. Neither the War and Navy Departments nor the dealers in used machinery have any abnormally large stocks of such machinery.

The Effect of the War

While enormous quantities of machine tools were built during the war, thousands of machine tools were used up during that period. Machines of older types considered adequate up to that time were found useless for the hard service required by war conditions, so that while there was a tremendous increase in the number of machine tools built, there was also a great increase in the number of machine tools scrapped; and at the end of the war, many of the machines bought specifically for the manufacture of munitions and other war supplies had been used so severely that they were not marketable as used machinery. An instance may be cited: One of the largest plants in the country advertised for sale early in 1919 a large quantity of machine tools used in its munitions plants, but the prospective buyers found them so far below par that most of them had to go to the scrap heap.

Furthermore, much of the machinery built at that time was special in nature, and while it added to the curve that showed an increase in machine tool production, it did not add to the available supply of machine tools for general purposes. We have seen several hundred shell turning lathes in the yards of a large plant ready to be broken up for scrap, there being no further use for them; and recently the Government offered for sale some fifty lathes of a well-known make built for a special purpose, having neither lead-screws nor carriages. It is easy to imagine how much sale there will be for lathes of this kind in the used machinery market.

Present Government Stocks

The War and Navy Departments have nothing like the big stocks of machine tools on hand with which they are generally credited. Most of the machinery to be disposed of by these departments, where the machines are of general applicability, has been sold. Machines built for special purposes, and obsolete machines for which there is no market, are still available, although many have been scrapped, especially by the Navy Department.

In addition to the machine tools sold by the War Department in this country since the war, large quantities were sold abroad, and a considerable percentage was acquired by the schools and colleges under the provisions of the Caldwell Act. To be sure, there are still War Department machine tools on the market, and additional ones will doubtless be offered for sale, but the quantity is not such as to warrant any apprehension on the part of the machine tool industry.

The Navy Department's records do not show any considerable quantity of machine tools for the market. Such machines as turning and boring lathes, and special single-purpose tools, which were required during the war period, have been absorbed by the various naval shops, or otherwise disposed of. A considerable quantity has been scrapped because there was nothing else to do with them. It is stated by the Navy Department that machine tool manufacturers need not be apprehensive about any large offerings of machine tools by the Navy.

Stocks of Dealers in Used Machine Tools

A canvass of the used-machine tool trade shows that most of the leading dealers in used machinery have no larger stocks (by volume) of such machine tools at present than they considered normal in pre-war days. A few have a smaller stock by volume—if not by value—than they carried before the war, and a small percentage have larger stocks—two or three considerably larger stocks. There are some exceptions, of course, but the fact is that the dealers, generally, have not stocked up to an extent appreciably exceeding their pre-war supply.

As compared with a year ago, about one-half of the dealers report that they are keeping their stocks at about the same level. Most of the remainder report smaller stocks, and only a few report larger stocks than a year ago. It is also found that the dealers have difficulty at the present time in obtaining good first-class used machinery to add to their stock. What is offered are mainly obsolete machines or those for which there is not a ready sale.

Machine Tools Available in the Used Machine Tool Market

Referring specifically to different classes of machine tools, it may be stated that while there is a fair quantity of production lathes in the used machinery market, there is a scarcity of good precision lathes. Some dealers state that it is almost impossible to buy lathes of certain well-known makes known for their quality. Only in the centers where there were an unusually large number of tool and contract shops, some of which have gone out of business, are used machines of this type available. There are but few heavy lathes available except those having unusual bed dimensions, in which case some are for sale, with no buyers, because the machines were designed for special purposes, such as for boring gun tubes. There is a fair quantity of turret lathes on the market, but few machines of the best known makes. The same is true of the smaller sizes of automatic screw machines—in fact there is a great scarcity of the best makes; but of larger sizes of automatics there is a fair quantity available.

In the milling machine field, there is a scarcity of universal machines, a fair quantity of plain machines, and a considerable number of Lincoln and semi-automatic milling machines. The supply of planers is practically normal. There are always used planers for sale, but the number today is not excessive.

In the drilling machine field, the greatest supply is in the multiple-spindle type. There is a fair number of radials offered, but comparatively few single-spindle upright machines. The supply of shapers is small. In the grinding machine field, there is a scarcity of universal and surface grinders, with a fair quantity of plain grinding machines being offered.

The best makes of vertical boring mills are scarce—in fact, it would probably be impossible to obtain certain sizes of some specific makes. This is also true of horizontal boring machines—few machines of the well-known makes are available. The supply of gear-cutting machines is not above normal, and buyers have found it difficult to obtain specific makes in the local markets. Some machines may be available elsewhere, but it is not easy to bring the buyer and seller together.

In the press field, there is a large quantity of presses built especially for war work—for the drawing of cartridge cases, for example. But there is no surplus of small presses and comparatively few toggle presses are available.

Briefly summarized, there are few machines in the used machinery market of the best grade of small and medium sized types. Much of the machinery in the hands of the dealers is special, and some is obsolete; and sooner or later some of this will be scrapped as there is no market for it.

Opinions of Dealers in the Used Machinery Field

The opinions of a number of the leading dealers in the used machinery field will prove of interest. A well-known dealer in the Middle West makes the following statement: "We find a scarcity of good tools that can be purchased at reasonable prices and feel certain that some of our competitors who are sacrificing their stock to do business will find it very difficult to replace it later on. The average buyer today desires to purchase machine tools and other equipment at a lower price than the average dealer can buy them for, and the owners of good tools that are for sale are holding them at higher prices than the dealer is willing to pay. This condition will lead to a scarcity of good tools in the hands of the dealers and means higher prices later on."

Another dealer in the same territory says: "We have looked at a great deal of machinery that is for sale around the country, but naturally are buying only the desirable machines and only those that we can buy at a price which will enable us to carry such machines for from three to five years and face a further decline in machine tool prices."

It is only from the cities that were exceptionally active in war work that we hear of more than normal quantities of machine tools being available in the used machinery market. A dealer in one of the New England cities, well known for its war activities, says: "The opportunities for securing used machinery are greater than they have been for a number of years, and in our opinion there is more used machinery on the market today than at any time since 1914." This view is the exception, and is explained by local conditions. A similar opinion is given by a dealer in one of the large Middle-Western tool and contract shop centers where many of the tool shops have gone out of business.

A New England dealer believes that there is going to be a fine market in 1922 for good up-to-date, overhauled second-hand machine tools; but he states that at the present time "there are very few good second-hand machines on the market for resale at the proper prices."

In Philadelphia it is found that sales of both new and used machinery are from 15 to 20 per cent better than for last October, and the present outlook is better than it was during the past year.

In Pittsburg the stock of used machinery is no larger, comparatively, than would be considered normal in pre-war years—that is, speaking of volume alone—and the stocks in general are smaller than those of a year ago.

INDUSTRIAL CONDITIONS IN FRANCE

Business conditions in France are not quite so good at present as they have been during the last two or three months, due in part to the recent political changes. Our correspondent writes, however, that the outlook is encouraging, especially in financial circles. One indication of this is the confidence shown on the stock exchanges. If the financial condition improves, there is no doubt that general business conditions will also be favorably affected. It was generally thought that the industrial situation would be greatly affected by troubles due to proposed reductions in wages of miners in the northern part of France, but after several conferences, a satisfactory agreement was reached between the workmen and their employers with the result that the danger is past.

An order for 800 freight cars has recently been placed by the Nord Railroad Co. In addition, the same company has asked for quotations on from 2000 to 2500 passenger cars. An order has also been obtained from Roumania for 50 trolley cars and 50 trailers. Several orders have been placed with manufacturers of nuts and bolts. One order for expansion bolts was accepted at 110 francs per 100 kilograms (about $4.40 per 100 pounds, present exchange). Another order for bolts weighing 85 kilograms (about 190 pounds) per 100, was accepted by a factory in the Ardenne district at 77 francs per 100 kilograms (about $3.10 per 100 pounds). These prices include delivery to a railroad station in the vicinity of Paris. An order for galvanized-steel coopers' tools has been accepted by a company in the Lorraine district at 94 francs per 100 kilograms (about $3.75 per 100 pounds).

Conditions in the bicycle industry continue to be very good, French dealers now being able to compete successfully in France with British manufacturers. However, they are unable to market their product abroad because of the German competition made possible by the low rate of exchange. The competition among foundries is very keen. Simple steel castings averaging 30 kilograms (about 65 pounds) are quoted at 130 francs per 100 kilograms (about $5.20 per 100 pounds).

* * *

SAFETY CENSUS

The National Safety Council is taking a census of the men and women engaged professionally in safety and industrial health activities in all the industries of the United States as well as in public safety work. The council frequently receives requests from firms, municipalities, colleges, and other organizations for help in finding speakers or writers on safety subjects, and the census records will greatly increase the facilities of the council for filling such requests. To assist in obtaining the names of persons engaged in preventing accidents and promoting good health in the machine-building industry, readers of MACHINERY employed in this class of work are requested to communicate with the National Safety Council, 168 N. Michigan Ave., Chicago, Ill., who will supply them with forms to fill out, giving the necessary data.

* * *

The general depression in Scandinavian financial and industrial life still prevails, and financial experts say that the crisis will be of long duration, according to a communication from Commercial Attaché W. L. Anderson at Copenhagen, Denmark. Scandinavian industries continue to struggle with high production costs, and are operating at a minimum profit. Employers claim that wages must be reduced further before the industries can be put on a competitive basis. Unemployment continues to be a serious problem, and the number of unemployed has increased slightly of late. The Swedish iron and steel production has been reduced to a minimum, the high costs of production resulting in inability to compete with foreign iron and steel products.

USE OF PREHEATING TORCH FOR REPAIR WORK

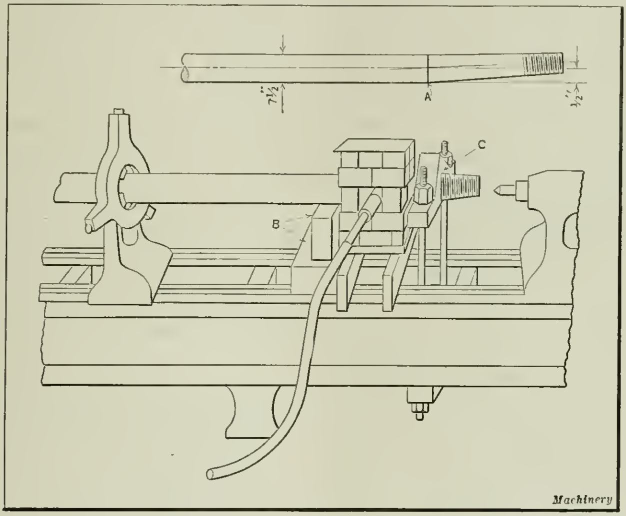
By J. HARRY CLEMMENCY, Superintendent Repair Shops, Bureau of Water, Philadelphia, Pa.

A great deal has been written on the subject of thermit welding and its usefulness in repair work. Little attention, however, has been given to the use of the preheating torch of the thermit welding outfit as a means of facilitating repair shop work. While the preheating torch is considered as auxiliary equipment, designed primarily to produce conditions favorable to a perfect thermit weld, it has nevertheless proved well adapted for a great variety of work encountered in the repair shops of the Philadelphia Bureau of Water. The following examples of work done in these shops with the aid of the preheating torch will suggest ways in which it can be employed in the average machine shop.

The preheater itself is so simple in construction and so compact that it may readily be moved about to any place where heat is to be applied. In machine shops, especially those engaged in miscellaneous repair work, it is frequently necessary to provide means of applying intense heat to definite points, and the preheater will be found admirably adapted for work of this nature.

Straightening Piston-rod

An unusual task that illustrates the usefulness of the preheater was the straightening of a 7½-inch steel piston-rod that had received a short bend as a result of meeting with an obstruction in the cylinder of a pumping engine. The bend was at the shoulder point of the tapered end as shown at *A* in the accompanying illustration. The end of the rod was thrown out about ½ inch from the center line as indicated by the somewhat exaggerated view. A careful examination at the point of the bend revealed no trace of a crack or flaw. It was therefore decided to straighten the rod and put it back in service.



Straightening Bent Piston-rod with the Aid of a Preheating Torch

Ordinarily there is nothing difficult about straightening a bar of steel 7 or 8 inches in diameter, but when the operation is complicated by the fact that the rod to be straightened is finished and no hammer or sledge blows are permitted, and that it is required to be true when finished, it will be readily apparent that the work presents some difficulties. The success with which the straightening was accomplished was in a large measure due to the use of the preheating torch of the thermit welding outfit. In performing the straightening operation, the rod was held in a heavy 36-inch lathe. One end was placed in the chuck and the other end supported firmly on steel blocks *B* built up from the ways of the lathe at a point just back of the bend. The lathe steadyrest was used to centralize and steady the rod, being placed a foot or two back of the blocking as shown.

A piece of sheet iron was placed under the point of the bend, and upon this was built an improvised furnace of old discarded firebricks. The top of the furnace was covered with a piece of sheet iron. An opening was left in the front of the furnace just below the center of the rod into which the burner of the preheater was introduced. The heavy V-shaped clamp *C* was placed over the end of the rod, and two stud bolts passed through the ends of the clamp and down between the shears of the lathe through a heavy cross-clamp placed under the lathe bed. When the torch was lit, the flame, being confined by the firebricks, swept around the rod at the proper point and thus speedily heated it to the required temperature. Wrenches were applied simultaneously to the two nuts on the clamp stud bolts. The bent end was thus gradually pulled back to its original position, the center of the tailstock serving as a guide to determine when the work was properly centralized. When the blocking and clamps were removed, it was only necessary to take a very light cut over the tapered portion of the rod in order to insure a perfect fit and alignment. The ease with which this piece of work was handled was due to the fact that the flame of the preheating torch was confined to the right portions of the work.

Use of Preheater in Assembly Room

It would be difficult to describe all the uses to which the preheating torch may be adapted in the assembly department. The possibilities are practically unlimited, and each shop can develop its service in line with its own particular requirements. In the general work of assembling miscellaneous machine parts, the application of heat is often desirable and sometimes necessary. For work of this kind where tight and shrink fits are required the hot clean flame of the preheater will be appreciated when its advantages are fully realized. The flame of the preheater can also be used to advantage as a means of loosening parts that have become cemented together by corrosion. In dismantling old machinery, many cases of this kind are encountered.

Melting Babbitt and Heating Rivets

The preheater is also useful in babbitting work. It has been found that babbitt can be removed from old bearings more rapidly and conveniently with the preheating torch than by any of the methods usually employed. A number of bearing shells are placed in a line over a metal receiver and the flame of the preheater passed from one to the other, thus melting the babbitt linings in a few minutes. When cracks develop in cast-iron cylinders that are to be welded with the acetylene torch, the preheating essential to a good weld can be conveniently done with the preheater.

In one instance where a large number of rivets were to be driven at a considerable distance from a forge, the work was facilitated by arranging a few firebricks on a piece of sheet iron which served as an oil-burning furnace to heat the rivets. By introducing the flame of the preheater into the open side of this furnace sufficient heat was quickly generated to bring the rivets to the required temperature for driving. Kerosene is used for all heating operations done with the preheater, except preheating for thermit welds, in which case gasoline is invariably employed.

Duralumin and Its Use as a Gear Material*

By ROBERT W. DANIELS, Baush Machine Tool Co., Springfield, Mass.

DURALUMIN is an aluminum alloy produced after years of search for a metal combining the lightness of aluminum with the strength and toughness associated with ferrous metals. This condition has been met to a remarkable degree, and the resulting physical characteristics make duralumin a most desirable material for certain kinds of gearing. The commercial manufacture of the metal in this country dates back little more than two years, although it was first made in Germany and developed by A. Wilm and associates, during the years intervening between 1903-1914.

The principal and unusual feature of duralumin is that after it has been hot-, or hot- and cold-worked, it may be further strengthened and toughened from 40 to 50 per cent by heat-treatment. This heat-treatment is somewhat analogous to the heat-treating of alloy steels and consists of quenching at temperatures below the melting point, followed by an aging process. The increased physical properties are not all produced immediately on quenching, but increase during the subsequent aging. In addition to being made in Germany, the manufacture of duralumin was taken up in England by Vickers, Ltd., prior to the war. Its use for structural purposes in connection with aviation brought the material to the attention of the engineering world, and today duralumin is recognized as occupying the same relative position to ordinary aluminum sheets or bars that heat-treated alloy steel does to ordinary carbon steel.

Physical Properties of Duralumin

The strength and toughness of duralumin are comparable with mild steel, and are obtained with a specific gravity of 2.81 as against 7.8 for steel. The melting point is approximately 1210 degrees F., the recalescence point, 970 degrees F., the annealing temperature approximately 680 degrees F., and the coefficient of expansion 0.00001798 per F. degree of temperature. The chemical composition of the alloy varies within the following limits, copper 3 to 5 per cent, magnesium 0.3 to 0.6 per cent, manganese 0.4 to 1 per cent, the remainder being aluminum plus impurities. Small quantities of other metals are sometimes added for certain reasons; for instance, chromium may be added to increase the burnishing qualities of the metal.

In the annealed form duralumin can be drawn, spun, stamped, and formed into a great variety of shapes, similar to brass and mild steel. The physical properties in this state average: Ultimate tensile strength, 25,000 to 35,000 pounds per square inch; yield point, 22,000 to 24,000 pounds per square inch; elongation in 2 inches, 12 to 15 per cent; Brinell hardness, 57; and scleroscope hardness, 11.

Duralumin in its heat-treated form may be slightly shaped or formed and may be bent cold to 180 degrees over a mandrel having a diameter of four times the thickness of the sheet. Its remarkable tensile strength is here combined with its maximum elongation as follows: Ultimate tensile strength, 55,000 to 62,000 pounds per square inch; yield pound, 30,000 to 36,000 pounds per square inch; elongation in 2 inches, 18 to 25 per cent; Brinell hardness, 93 to 100; and scleroscope hardness, 23 to 27. Heat-treated duralumin forgings have similar physical properties. When the sections of forgings are heavy, it is advisable to lower the minimum tensile requirements to 50,000 pounds per square inch. This will cause a proportional increase in elongation.

*Abstract of a paper read before the American Gear Manufacturers Association

Heat-treated and hard-rolled duralumin is used where no bending or forming is required. It is a hard, strong, springy metal in this state, and machines and polishes well. Its physical properties in this form average: Ultimate tensile strength, 67,000 to 72,000 pounds per square inch; yield point, 58,000 to 65,000 pounds per square inch; elongation in 2 inches, 3 to 8 per cent; Brinell hardness, 130 to 140; and scleroscope hardness, 39 to 42.

General Characteristics

Duralumin is unaffected by mercury, is non-magnetic, withstands atmospheric influences, and offers unusual resistance to sea and fresh waters. It is only slightly affected by numerous chemicals which readily corrode other metals and alloys and does not tarnish in the presence of sulphurated hydrogen. It takes a polish equal to that of nickel-plated articles and remains bright without cleaning longer than plated or silvered articles. It is an ideal substitute for aluminum, German silver, brass, copper, and steel when lightness combined with strength is required. Although duralumin is only one-third the weight of steel, heat-treated duralumin forgings approximate mild steel forgings in strength, so that wherever weight is a deciding factor, duralumin is satisfactory for most shapes made by hot-working or forging. Duralumin forgings are especially desirable for reciprocating or moving parts where the inertia due to their own weight, forms a large part of the total stress. Duralumin machines easily and, as it does not corrode, is suitable for use in many places where weight is not the prime essential.

Process of Manufacture

The manufacture of duralumin is somewhat analogous to that of steel and is carried on in the following sequence:

1. Manufacture of the alloy from its aluminum base.
2. Casting the ingot.
3. Hot-rolling or cogging in blooms, billets, or slabs.
4. Hot- or cold-working to the final shape.
5. Heat-treating.

The ingots are poured at as low a temperature as practicable, that is, just enough above the melting point to fill the mold and prevent cold shuts. They are then either hot-rolled or cogged into slabs, blooms or billets, similar to the manner of working steel. This hot working is done at a temperature of from 840 to 900 degrees F. Such low temperatures cannot be judged by color, and it is therefore necessary to use pyrometers in heating the metal previous to working it.

The final rolling or forging may be done hot or cold according to the character of the work being handled or the shape it is desired to produce. The hot- or cold-worked metal in its final shape shows greatly improved physical properties over the cast ingot, but the full development of its qualities is obtained only by a specific heat-treatment. To obtain this heat-treatment, the metal is heated to a temperature of from 930 to 970 degrees F. for a period of time depending upon the section of the piece, and then immediately quenched. The heating and quenching improve the physical qualities of the metal, but the maximum results are obtained only by a subsequent aging. During the aging period, which takes from one to five days, the tensile strength, hardness, and elongation of the alloy increase markedly. Aging is sometimes accelerated by placing the metal in a hot water bath of a temperature up to 212 degrees F. or in a hot room. The heat-treatment develops properties which have not been obtained in a like degree in any other aluminum alloy. The cast ingot has a tensile strength of from 28,000 to 32,000 pounds per square inch, and an elongation of from 1 to 3 per cent.

When it is required to put a considerable amount of work upon duralumin in its finished state, it is often found necessary to anneal the sheets between operations in precisely the same manner as with other metals. This annealing should be done at about 660 degrees F. If several drawing operations are to be performed, it may be necessary to anneal the metal between such operations. Annealed duralumin can be heat-treated and the maximum physical properties obtained, no matter what shape or form the metal may be reduced to. Conversely, heat-treated duralumin may be annealed. Duralumin may be cold-worked after heat-treatment and aging. This operation produces a hard smooth finish, and materially increases the tensile strength of the metal at the expense of elongation.

Use as a Gear Material

For a given section, the weight of duralumin is about one-third that of bronze, and for parts produced in large quantities, duralumin is the cheaper of the two metals. Therefore duralumin is an ideal material for worm-wheels, and especially those used in automobile constructions, provided the wearing qualities are satisfactory. The tensile strength and relatively high elastic limit insure a superior tooth strength, while the homogeneous structure and uniform hardness of heat-treated duralumin forgings insure entire freedom from hard spots, porosity and spongy areas so common in bronze castings, which entail not only a machine loss but uneven tooth wear in service. The data from various laboratory tests on bronze and duralumin worm-wheels may be summarized by saying that tests destructive to duralumin worm-wheels were also destructive to those made of bronze.

When duralumin and hardened steel are run together the results are always good. An example of this application was shown by having duralumin connecting-rods running direct on the wrist-pins. A better life was obtained at this point than with conventional bronze-bushed rods of equal bearing area. Comparative tests of bearings made from duralumin and bearings made from babbitt show that for shaft speeds exceeding 700 revolutions per minute and loads over 200 pounds per square inch, duralumin bearings developed less friction, remained cooler and showed practically no loss in weight under most severe conditions. For lower bearing pressure and slower speeds, babbitt metal was superior.

An important condition was revealed in tests with worm-wheels made of duralumin, by examining the lubricant used. After long tests with bronze wheels where the oil has not been changed, the oil is found to contain particles of bronze in suspension. This condition is sometimes very marked and is of importance not only as indicating tooth wear but as showing the deterioration of the lubricating value of the oil. Oil heavily charged with metallic particles acts more like an abrasive and less like a lubricant, and therefore is an important factor in the wear of automobile gearing, where the oil is infrequently renewed. When duralumin wheels were used, the charging of the oil with metallic particles was practically negligible.

The different tests point to excellent life for duralumin worm-wheels, unless the wheels are roughened by lack of lubrication or too high a tooth pressure which will injure or destroy any worm-gearing.

The same qualities that make duralumin a desirable material for worm-wheels also make this material valuable for other types of gears. It is suitable for this class of work when the pressures are sufficiently within its elastic limit of 30,000 pounds. Where this condition is met, and weight and quietness are desirable, duralumin will satisfactorily replace iron, steel, brass, fiber, fabrics, etc. Where duralumin can be run with steel rather than against itself the best results are obtained. An example of this application is found in the timing gear trains of automobile motors where both long life and quietness are essential. Helical duralumin gears alternated with steel gears have been very successful in service. That duralumin gears when meshed with steel gears are quiet may seem somewhat paradoxical since, when struck, all duralumin forgings are resonant. However, this condition obtains and is undoubtedly due to the difference in pitch of the sound vibrations of steel and duralumin.

PRICES OF MACHINE TOOLS

It is apparent that there has been some hesitancy in the buying of machine tools due to lack of confidence in the stability of machine tool prices. While it is true that a large number of shops are not in operation to a sufficient degree to require new machinery, there are many that should buy to replace inefficient equipment and reduce their production costs so that they can successfully enter into competition with other plants having more modern machine tool equipment especially suited to their needs.

One of the well-known firms in the turret lathe field has carefully analyzed future labor and raw material costs, and has announced that its prices have been brought down to such a basis that there can be no further reductions. In order to indicate the reductions that have taken place, this company has published in its advertising the peak prices and the present-day prices for its turret lathes. This comparison indicates that machines costing, at peak prices, $3900 have been reduced to $2450; those costing $2690, to $1695; and the smallest size, costing $590, are now being priced at $370. The reductions on other machines in the line are in similar proportions, and it is not necessary to quote them all in detail.

The machine tool builders at present are divided into two groups—often through force of circumstance. One group comprises those who are liquidating their inventories at prices either yielding no profit at all or a loss, and who are taking orders for equipment at less than either present or expected future costs would justify. The other group includes those who are anticipating future costs in such a manner as to reduce their prices immediately to a final level to which they will adhere. The company whose announcement relating to final price reductions is appearing at present in the trade journals belongs in the latter class.

There is no reason why machine tool builders should sell their equipment below cost, virtually giving away part of it to the users. The user should be and is willing to pay for value received, provided he really needs the equipment and the industry as a whole maintains a consistent attitude of obtaining a reasonable price for its product. After all, the buyer of equipment is not pursuing the wisest course if he buys machinery merely because it is cheap. His main purpose should be to obtain productive efficiency. Taking the machine tool industry as a whole, there are no additional sales made because prices are at or below cost. Some one concern may obtain an order in preference to another company because it is selling at a very low figure, but the industry as a whole suffers if it does not receive a fair return for its products. And ultimately the machine tool buyer suffers also, because there will be less advance in the development of production machinery.

The machine tool builders should do all in their power to increase the confidence of the buyer in their product, both as to its quality, its capacity for production work, and the stability of its price. The best service that could be rendered the entire industry would be for machine tool builders in general to analyze their costs in the manner indicated, and definitely announce that they are quoting bed-rock prices. A stable market is always the best market, not only for the buyer but also for the seller.

The British Machine Tool Industry

From MACHINERY'S Special Correspondent

London, February 11

CONDITIONS in all branches of trade show a slight improvement, with the possible exception of the shipbuilding industry. In the latter case the idle time is being utilized in investigating the merits of new engine design and the suitability of the application for marine propulsion purposes, especially in connection with internal combustion engines of the Diesel type.

Conditions in the Automobile Industry

Under present conditions the most hopeful field for the machine tool maker is the automobile industry, particularly that branch which is engaged in the manufacture of light cars, and some new equipment is being bought by manufacturers in this line. It will be interesting to note the effect on the automobile industry of the increased value of the pound sterling in the United States, as at present American automobiles are being imported into this country on a smaller scale than for many years. Already certain American cars are being offered at very low prices, and any continued appreciation in the pound value will tend to reduce these prices still further. British makers can hope to improve the home and overseas trade only by building more of the most popular types of cars.

The demand for tractors also appears to be improving, which should, in turn, stimulate the market for machine tools and the necessary manufacturing equipment. The Ford Co. in Cork is reported to have been in the market for such equipment, and since it is located in that part of Ireland where tractors should find a big opening, business prospects are likely to be good as soon as conditions in Ireland become settled. Meantime, a gratifying increase in orders is reported among steel firms who supply the automobile trade.

General Industrial Conditions

In industry generally, buying is still confined to straggling orders sufficient only to meet the needs of the moment. Foundries are becoming busier, but here again the automobile trade is the main cause. One foundry firm has secured an order for 5000 engine crankshafts, and this represents, perhaps, the largest order of this kind that has been placed in this country. There is some improvement in the engineering trades in the Birmingham district, where government orders for bicycles and important inquiries from France for motorcycles are outstanding developments.

Much greater attention is being paid to special tooling equipment, and although this is most noticeable in the automobile industry, other branches of engineering are becoming more alive to the advantages of well planned manufacturing equipment. There are now several firms in the Midlands who specialize on tool production, and these, almost without exception, have orders in hand for complete tool, jig, and fixture equipment. and are running double shifts. In small tools a fair trade is being maintained, but this is understandable, as even with a small proportion of the total capacity of shops occupied, there is a continuous, though meager, consumption of small tools.

In Sheffield, much satisfaction is felt as prominent firms have secured a large amount of work in connection with the electrification of South African Railways for which the Metropolitan-Vickers Co., Manchester, has secured contracts for seventy electric locomotives to the value of £1,000,000. Considerable developments in connection with the electrification of many of the local systems of British Railways are being considered, and the Great Eastern Railway is having an electric locomotive built for passenger service and designed to draw a 450-ton train at 65 miles per hour. It is also capable of attaining a maximum safety speed of ninety miles per hour.

Apart, however, from the few instances noted there is little cause for optimism, and the hopes for a steady increase in business in the new year have proved unfounded. Very little new business is being done. That there exists, however, a big potential demand is shown in the case of a well-known machine tool concern in Yorkshire which, while working short time with a minimum force, finds it necessary to work over-time in the estimating department.

Overseas Trade

During the whole of last year the exports of machine tools showed a fairly steady decline from month to month. As against 2800 tons having a value of £400,000 exported in January 1921, only 760 tons having a value of £112,000 were exported in December. After a rapid fall to a little over 200 tons in March, the imports of machine tools remained somewhere around this figure for the rest of the year. During December the value per ton of imports fell below that of exports, the figures being £125 and £148, respectively. This very unusual condition was, to some extent, due to the increased value of the pound sterling in America. In passing, it is interesting to note that the total exports for the United Kingdom, based on 1913 prices, were in 1920 about one-third less than those of 1913, whereas in 1921 the exports amounted to less than half those of 1913.

Materials and Prices

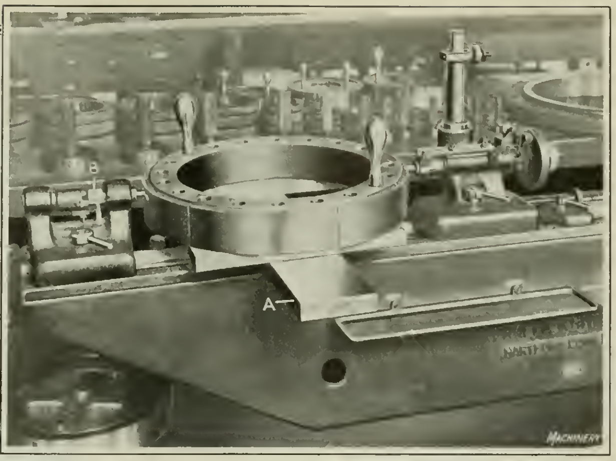
British makers in the iron and steel industry are beginning the year in an extremely favorable position as compared with a year ago, and although at present they are working in many cases below cost in order to provide employment, the outlook is regarded as more promising than for the last two years. Costs are being stabilized and there is some evidence that new orders are to be placed. The industry appears to be passing to a more active condition.

Any increased business seems to be generally at the expense of Continental and American makers. Because of the pig iron, freight and railway charges Continental firms find it almost impossible to compete with British manufacturers in the home market. The price of pig iron has fallen between 5s and 10s per ton during January, and now stands at £4 to £4 10s, according to the grade. Finished steels remain constant at a price between £9 and £11 15s for bars and plates.

As regards the prices of machine tools, there has been a movement in favor of drastic reduction, as a means of stimulating trade, but the majority of makers are convinced that no concession which it would be possible for them to make would have any material effect. Generally speaking, in the Midlands machine tool prices are about 20 per cent below those prevailing at the end of 1920. Although the price of raw materials and wages has dropped in some cases by considerably more than this amount, very few works are running at full capacity, and the heavy overhead in relation to the reduced output has materially increased the cost. The only way out appears to be by the usual route of increased demand, and until that arises prices cannot reach a stable level.

Measuring Thread Plug Gages

By J. M. HENRY
Pratt & Whitney Co., Hartford, Conn.



ACCURATE and convenient measurements of thread plug gages are made in the mechanical laboratories of the Pratt & Whitney Co., Hartford, Conn., through the use of the measuring machine manufactured by this concern. In the heading illustration is shown the usual method of mounting large casing gages for checking their taper threads by the three-wire system of measurement. Block *A* is mounted directly on the vee and flat way of the machine and held in place by means of a bolt and nut engaging the T-slot of the bed. The top surface of block *A* is machined at an angle relative to the bottom surface, this angle corresponding to the taper per foot of the gage thread to be measured. In the case illustrated, the taper is 3/8 inch per foot and the gage is about 15 1/2 inches outside diameter.

Block *A* is placed on the bed in such a manner that when the gage is mounted on parallels to bring it to the required height relative to the measuring anvils, the side toward the dividing head of the machine is at right angles to the anvil face of the dividing head. The opposite side is at an angle with the tailstock anvil corresponding to twice the taper per foot of the gage threads. The reading is obtained over the three wires by using the machine in the regular manner. At the time the photograph was taken the measuring point had been reached, as is indicated by the drop plug *B*, the handle of which has dropped from a horizontal to a vertical position. The exact pitch diameter of the gage is accurately computed from the reading obtained, by allowing for the angle of the side with the tailstock anvil.

Small plug gages are set up in a somewhat similar manner to that described, although the apparatus used is smaller. As shown in Fig. 1, a cast-iron block *A* is usually mounted over the ways. This block resembles those used for supporting end measures, but it is machined flat on the top instead of having a vee extension. Parallels are placed on top of block *A* to bring the portion of the thread to be gaged between the measuring anvils. The ideal condition is reached when the two wires on the tailstock side are equidistant from the center of the anvil, although measurements can be taken so long as both wires bear against any point on the anvil face. Taper blocks are used for small taper gages in the manner previously described for the large casing gage.

A device for measuring thread plug gages when held between centers is illustrated in Fig. 2. A baseplate *A* is secured to the ways of the machine, and on top of this plate is carried a second plate *B*, which has a T-slot at each end for securing the stationary center *C* and the movable center *D* to it. Plate *B* is mounted on three balls to allow freedom of movement when taking a measurement. At the back end of the lower plate *A*, a ball rests in a V-groove, and directly above it, there is a hardened steel button in the top plate,

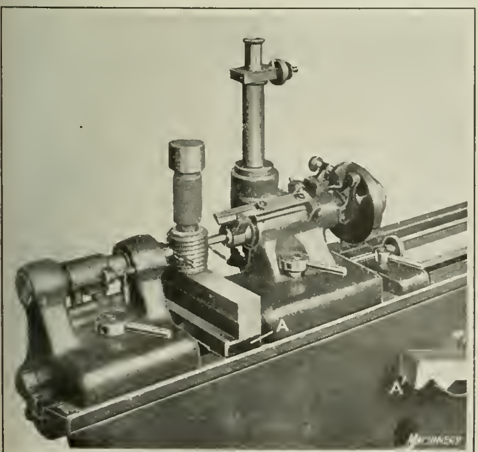


Fig. 1. Method of mounting Small Thread Plug Gage for measuring by the Three-wire System

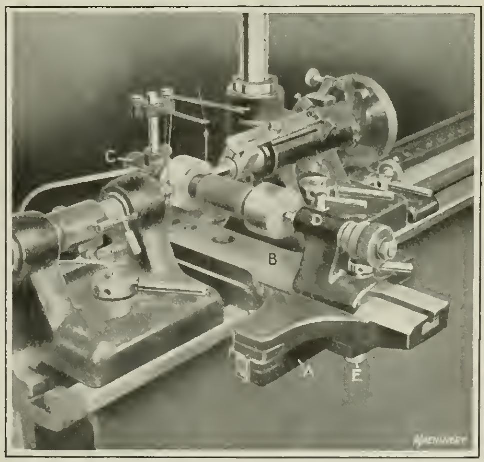

Fig. 2. Attachment developed to facilitate the measuring of Thread Plug Gages held between Centers

which rests on the ball. At the front end of the attachment two balls are used to provide ample support, one being placed at each end of the extensions of the plates. These balls are held between V-grooves in the upper and lower plates, and stops prevent them from falling out.

By this method of mounting, a gage may be brought between the anvil faces without the difficulties experienced with a solid mounting, because the floating movement of the upper plate, which rolls on an axis parallel to that of the anvils, insures that the measuring pressure of the anvils will not be affected. To prevent the plate from rolling too easily and endangering the anvil setting by causing the drop plug to fall out, a spring friction device fastened to the lower plate bears against the upper one. The friction is applied by operating knob *E*. The stationary center *C* is provided with an adjustable rod carrying a bracket from which fingers extend to permit the suspension of the three measuring wires over the gage. The movable center is adjusted by a knurled screw-knob. Both centers can be clamped and adjusted to suit the length of the plug gages.

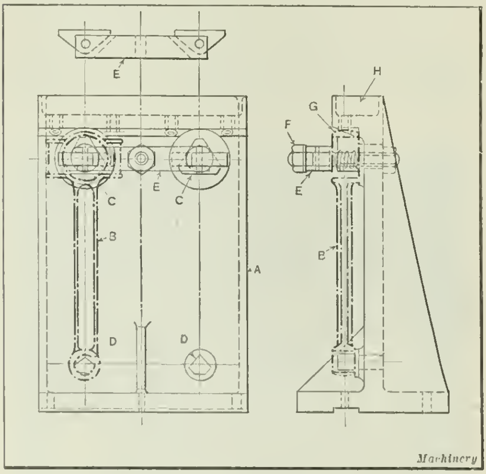
JIG FOR DRILLING CONNECTING-RODS

By WILLIAM OWEN

The jig illustrated was designed for use on a Moline "Hole Hog," and is so proportioned that two or three jigs can be lined up and bolted to the machine table if desired. The body *A* is of cast iron and is well ribbed. It is slotted on the bottom to provide a means of accurately locating the base on the machine table. One connecting-rod is shown in place by dot-and-dash lines at *B*. The connecting-rod is located at the top by the plug *C* and at the bottom by the plug *D*. These plugs have three bearing surfaces, a feature which eliminates much of the annoyance that would otherwise result from chips clinging to the plugs, and it also allows the rod to be slipped on easily.

The rods are held in place by an equalizing clamp *E*, actuated by the stud and nut *F*. One turn of the nut permits the clamp to be turned to a perpendicular position and the connecting-rods to be taken off or put on. This clamp will not twist the connecting-rod no matter how tight it is.

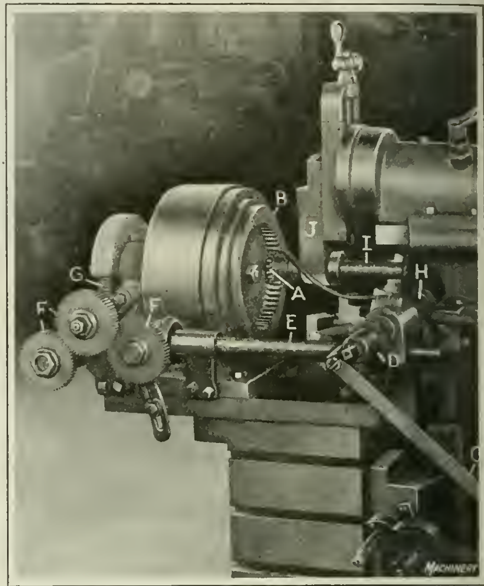


Drill Jig used in drilling Bolt Holes in Connecting-rods

The front edge of the arm in which the bushings are mounted is cut back at *G* so that the chips can work out, thus preventing drill breakage from this source. The cutting compound is fed to the drills by means of the trough *H*. This jig has proved accurate, is self-cleaning, and is adapted to high production rates.

CUTTING TEETH OF INTERNAL GEARS ON A SHAPER

The accompanying illustration shows a 14-inch crank shaper equipped with an auxiliary mechanism for cutting the teeth of an internal gear. Three functions are required of this mechanism, namely, the rotation and reciprocation of a formed gear-tooth shaping tool *A* over the face of the work *B*, and the indexing of the work, it being obvious that



Shaper equipped with a Special Attachment for cutting the Teeth of an Internal Gear

these movements must be synchronous. The way in which the desired movements are produced is described in the following paragraphs:

The link *C* extending up from the feed works actuates a pawl engaging the teeth of ratchet wheel *D*, it being possible to adjust the mechanism so that various numbers of ratchet teeth may be skipped by the pawl at each stroke to obtain the desired operating conditions. From the ratchet wheel, power is transmitted through a pair of spiral gears and a horizontal shaft *E* to a set of change-gears *F*, and by substituting different wheels provision may be made for obtaining the correct timing for cutting the teeth of gears with various numbers of teeth. The work-spindle is driven from gears *F* through the medium of a worm and worm-wheel as shown at *G*.

A horizontal shaft *H* transmits power through a pair of spiral gears to a spindle *I*, at the forward end of which the gear-shaping tool *A* is carried. Spindle *I* is splined into its driving gear and held by a special block *J* on the tool-head of the shaper, so that the spindle is free to rotate in this block but cannot move transversely through it. As a result of this connection of the spindle to both the reciprocating shaper ram and the rotating mechanism deriving power from ratchet wheel *D*, a combined rotary and reciprocating movement is imparted to the gear-shaping tool *A*. The stroke of the shaper is adjusted so that the tool just passes over the face of the gear blank in which the teeth are to be cut, and reverses in a clearance space provided at the back of the teeth for that purpose. On the job shown the gear to be cut has fifty-five teeth of 7 pitch, with a face width of 1 7/32 inches, and the time required for taking the roughing and finishing cuts in a gear of this size made of drop-forged steel is 1½ hours.

Cards and Records Used in Planning and Dispatching Work

By GEORGE H. SHEPARD, Professor of Industrial Engineering and Management, Purdue University

THE duties of the various units and members of a planning organization in a large contract or jobbing plant were discussed in December MACHINERY. The present article illustrates the different forms used in the functioning of a planning department of a large machine shop and describes their purpose. There are sixteen of these forms as follows: Job and shop order slip; shop memorandum slip; foundry credit memorandum; incoming plant delivery tag stub; outgoing plant delivery tag; material list; shop store stub; stub requisition; inter-shop order; progress card; instruction card; route tag; inspection tags; damage report; sample tag; and drawing index card.

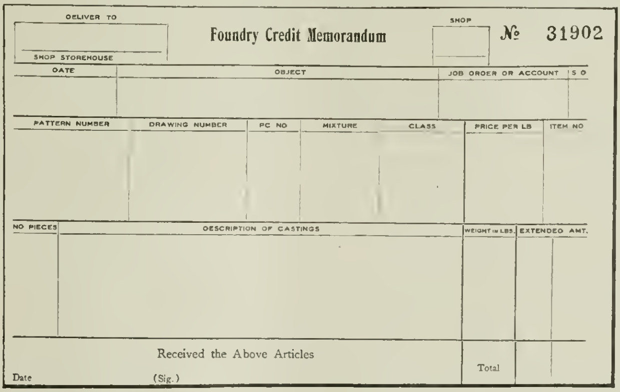
Files in Planning Office

Five files are used in keeping the records of the planning office. In one file are kept the progress cards, which are divided into two sections—active and inactive. The cards filed in the active section are those for orders that have been started in the shop, while the cards placed in the inactive section are for orders not yet given to the shop. On each card is indicated the actual progress of work in the shop for the corresponding order. In another file are kept jackets or containers for various data pertaining to a job, these jackets being filed under the name of the customer in the correct sequence of job order numbers.

A file for instruction cards is placed at the desks of the shop foremen, and this file is divided into pending and available sections. In the pending section are filed instruction cards covering work for which the material has not been delivered to the section or for which something requisite to the performance of the operation is lacking. In the available section are kept the instruction cards of the work for which the material has been delivered and which is ready to be performed. The fourth file consists of a perpetual inventory of shop stores. The latter consists of the bulk of the material frequently called for, and the inventory is kept in the customary manner. The fifth file is an ordinary tickler file for following up the delivery to the machine shop of material from other shops.

Job and Shop Order, Foundry Memorandum, and Delivery Tags

The job or shop order slip is issued by the central planning office and, as its name indicates, contains the job and shop order for work to be performed. The slip is sent from the central planning office to the departmental chief planner for his observation. It is next sent to the method man to be noted by him, and then to a clerk who fills in the data on a progress card as shown in Fig. 8, and on the jacket. The slip, together with the progress card and jacket is next sent to the inter-shop man who studies the shops that will handle the work and records this information in the proper place on the progress card. He then places the progress card in the inactive section of the file previously mentioned, and sends the job order slip and the jacket to the schedule man. The latter notes the job order, where blueprints will be needed, advises the blueprint man to secure the necessary prints of the parts, and then sends the order slip with the jacket to the jacket file. The job order is now represented



DELIVER TO | SHOP STOREHOUSE | Foundry Credit Memorandum | SHOP | № 31902

Date (Sig.)

Fig. 1. Memorandum Slip on which is placed Information Relative to Castings delivered by the Foundry to the Receiving Clerk of the Machine Shop

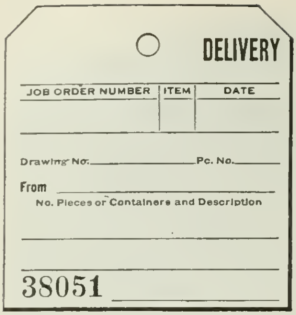

Fig. 2. Incoming Plant Delivery Tag Stub

by the progress card in the inactive section of the progress card file, which is continually reviewed by the schedule man.

Information and instructions from other shops regarding the job are written on a memorandum slip and never are accepted orally. This memorandum slip is received from outside shops by the receiving clerk and sent to the progress section which indicates the urgent items, from which it is sent to the chief planner for observation, after which it goes to the method man to be noted and assigned to a planner who plans the progress of the job through the shop. It finally goes to the jacket file.

Information relative to castings delivered by the foundry to the machine shop is given on the memorandum slip illustrated in Fig. 1, which is filled out by a clerk in the foundry office and delivered with the castings to the receiving clerk of the machine shop. The latter sends the memorandum to the progress section, where urgent items are suitably marked, after which the slip is sent to the chief planner to be noted by him. The chief planner next sends the memorandum to the method man who assigns it to a planner. The latter makes out the instruction card shown in Fig. 9 and the route tag shown in Fig. 11. The memorandum is then returned to the receiving clerk with a route tag; he places the route tag on the work and returns the memorandum to the progress section. The progress clerk notes on the progress card the receipt of the castings and sends the memorandum to the foundry. The foundry progress clerk notes receipt by the machine shop on his progress card and files the memorandum in his jacket file.

The incoming plant delivery tag stub shown in Fig. 2 is attached to material delivered to the receiving clerk of the machine shop, who tears off all but the narrow strip above the words "Job Order Number" etc., on which he marks for identification, the serial number of the stub, which in this case is 38051. The receiving clerk sends this stub to the progress section to have urgent items marked, and it is then sent to the chief planner to be noted. As in the case of the foundry memorandum, a planner also fills out an instruction card and a route tag and sends the stub with the route tag to the receiving clerk. The latter returns the stub to the progress section for noting on the progress card, it being later sent to the shipping clerk.

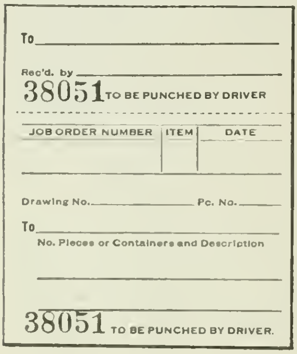

Fig. 3. Outgoing Plant Delivery Tag

The plant delivery tag for outgoing material illustrated in Fig. 3 is torn from the tag in Fig. 2, which originally has three sections, each of which is filled out by the shipping clerk. Of the three sections, the first (Fig. 2) goes with the material to its destination, the second (Fig. 3) goes to the files of the transportation department, and the third (Fig. 3) is stamped with the date and sent to the progress section of the shop that makes the shipment, to be recorded on the progress card. This portion of the tag is then placed in the jacket file.

Material List, Shop Store Stub, Stub Requisition and Inter-shop Order

The material list shown in Fig. 4 is made out in duplicate by the planner for each job, care being taken to give the number of pieces and the size to which stock is to be cut. The route tag number is also given for identification purposes. The planner sends the duplicate copy to the progress section so that it can be recorded on the progress card, after which it is sent to the jacket file. The original copy is sent with the route tag to the material man who fills out the shop store stub, Fig. 5, and the stub requisition, Fig. 6.

The shop store stub is a requisition on stores already issued to and kept in the shop. Each item on the stub must have the route tag number or numbers for the items on the job order for which the material is intended. The material section makes three copies of the shop store stub, one of which is clipped to the material list and sent to the jacket file. The other two copies and the route tag are given to the move man, who gives one of the stubs to the shop storekeeper to keep as a record. The route tag is attached to the work, which is then trucked to the desired section of the shop. The second copy of the shop store stub given to the move man is then signed by the supervisor receiving the material, and sent to the progress section, after which it is placed in the jacket file. The copy of the stub attached to the original material list and this list are then destroyed.

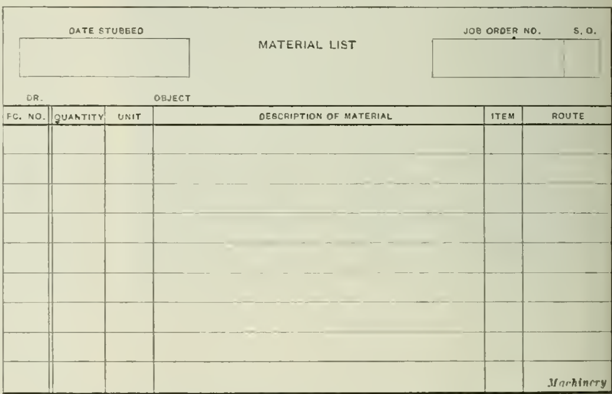

Fig. 4. Material List which gives the Number of Pieces and Sizes to which Stock is to be cut

The stub requisition, Fig. 6, is a demand made directly on the general storekeeper of the plant for material. Each item on this requisition must show the route tag number or numbers for the items on the job order for which the material is intended. As previously stated, the stub requisition is filled out in the material section from the material list and route tag received from the planner, four copies being made. One copy is clipped to the route tag and material list, and retained by the material man as a tickler. The other three copies are sent by mail or by an emergency trucker to the storehouse, from which the material and two copies of the requisition are taken by the transportation department to the shop store-room. Here one copy is signed by the shop storekeeper and sent back to the storehouse, while the other (the third) copy is sent to the material man. The latter copy with the route tag is then given to the move man and the other copy held by the material man is placed in the jacket file. After the move man delivers the material to the proper section of the shop, the third copy is signed by the supervisor receiving the material and sent to the progress section to be noted on the progress card; it is then sent to the jacket file, after which the copy previously placed in the jacket file is destroyed.

The inter-shop order is illustrated in Fig. 7; this is made out in triplicate by the planner. On orders of this kind for the foundry, the route tag number of the item is included so that the foundry clerk may write this number on the foundry slip for future identification of the items. After an inter-shop order has been filled out, the planner sends one copy to the method man for approval, who forwards it to the chief planner of the central planning office for his information and approval; if he disapproves of it he vetoes it. The other two copies are sent to the progress section to be noted on the progress card, after which one of these copies is sent to the shop where the work is to be done, and the duplicate is placed in the jacket file. The inter-shop order is a means of securing the flexibility and promptness of procedure necessary in a contract or jobbing shop. By using it as directed, the planning office of any shop can order necessary work directly from another shop without the intervention of the central planning office unless the chief planner of the latter sees fit to exercise his veto power.

The Progress Card

The progress card which has been referred to a number of times in the foregoing is illustrated in Fig. 8 partially filled out. On this card the different symbols represent the following machines and departments: B1, milling machines, shapers, and gear-cutters; C, engine lathes up to 36-inch swing; S, machined parts store-room; YC, assembly section; and YCA, disassembly space. The numbers in the column headed "Source and Receipt" represent other shops.

In making out the progress card, a typist fills in the job order number, object, any essential information as a "brief" of the job, the issue date of the order, and the number of the shop receiving the original order. The card is then sent to the inter-shop man, who, if the job order has a completion date, determines the dates on which all items and the order as a whole should be completed in the machine shop. Information or instructions necessary for other shops, and the delivery that other shops must make to the machine shop, are also indicated on the progress card by the inter-shop man.

The progress card is then sent to the planner who fills out each item, giving a description of the item, the number of pieces desired, the kind of material, the pattern number, his signature, and drawing, piece, and route tag numbers. When the material list is issued, the planner puts a diagonal line in the "Material Ordered" column, and when the inter-shop order is issued he puts the date under the diagonal line. When instruction cards are sent to the method man, the planner inserts a date in the "Instruction Cards Issued" column. He also places a date under "Material" in the "Source and Receipt" column, upon the receipt of a foundry slip or incoming plant delivery tag stub, showing that the material has been received in the machine shop.

The progress card is then sent to the progress clerk, who checks entries made by the planner upon receipt of the material list, the inter-shop order, the triplicate instruction cards, the foundry memorandum slip, and the incoming plant delivery tag stub; inserts a date in the "Material Ordered" column, over the diagonal line placed by the planner, upon the receipt of the requisition for the material on its way to the stores; places a diagonal line under the letter in the "Routing" column for the section from which a white inspection tag of the type shown in Fig. 12 is received; inserts the date of receiving an instruction card marked complete, under the letter in the "Routing" column for the section

Fig. 8. Progress Card upon which a Record is kept of the Progress of Work through the Shop

from which the card was received; inserts the date of receiving a plant delivery tag stub showing the shipment of material, under the number of the shop to which the material should be sent as shown by the routing schedule; and inserts the date of receiving the signed requisition triplicate under "Material" in the "Source and Receipt" column.

Instruction Card and Route and Inspection Tags

The instruction card, Fig. 9, forms a basis for the progress records and should be filled out accurately. In the "Item" space is given a description of the job and the kind of material to be used. In the "Description" column, instructions are given to the shop concerning the method in which the job is to be performed. Such a clear and detailed description of work to be done should be given that the man who is to do the work will readily understand what is wanted. Free-hand sketches are of practical value in this respect. The instruction card is furnished in four colors—white, yellow, blue, and pink. The white card is for customers' orders and tool orders; the yellow card for special manufacturing orders; the blue card for stock orders; and the pink card for rush jobs.

The planner makes three copies of the instruction card, one copy being sent to the progress section so that the necessary entries may be made on the progress card, and then to the jacket file. The other two copies are sent to the method man for approval and then to the foreman of the shop concerned. Upon the completion of the work, the foreman retains one copy for his private file and forwards the other to the progress section to be noted on the progress file, after which it is placed in the jacket file. The instruction cards filed in the jackets are the basic records from which can be summarized, as desired, the quantities of various parts made and of the materials used. All carrying of stock and determining of maximum and minimum limits should be based on these records. They also are valuable in deciding whether it will pay to specialize or standardize the making of any product, that is, to change its production from a jobbing to a manufacturing basis.

The route tag issued by a planner for a job is shown in Fig. 11. On the back of this tag is a list of the shops and departments through which the work must pass, the shops and departments being numbered serially to indicate the intended route. Group and master tags are made out in red ink, while tags for individual items are made out in black. The planning office uses a white tag for partial deliveries of work, while shop supervisors use a green one, thus denoting the partial lots originating in the shop. If a planner

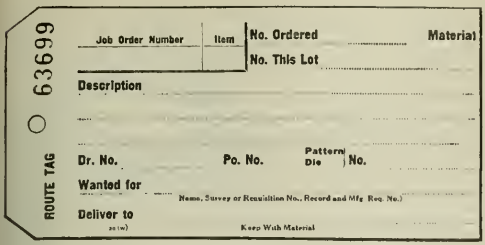

Fig. 11. Route Tag, which gives a List of the Successive Shops and Departments through which the Work must pass

attaches the route tag to a material list, both are sent to the material man, and if the tag is attached to a foundry slip, it is sent with the latter memorandum to the receiving clerk. When material on hand is to be used, the route tag is attached to the original instruction card and follows the same route as this card. The route card remains with the work until the latter is completed, and is then destroyed by the shipping clerk.

The inspection tags used on a job are shown in Fig. 12, the "Passed" tag being white in color, and the "Rejected" tag, red. Both of these tags are made out by the inspector. The "passed" tag is attached to the work and goes with it to the next section, where it is signed by the assistant foreman of the section. It is then sent to the progress section to be noted on the progress card, and finally placed in the jacket file. The "Rejected" tag is sent to the shipping clerk with defective material, and then to the progress section to have the proper notations made on the progress card, after which it is also placed in the jacket file. When an article is repaired, or errors are otherwise corrected, the shipping clerk destroys the red tag.

Damage Report and Sample Tag

When work is damaged in a shop, a report is made out by the foreman of the department on the form shown in Fig. 10. This report is then sent with the defective material to the shipping clerk, who forwards it to the progress section to be noted, on the progress card. It is then sent to the departmental chief planner for his observation, after which it goes to the material man. The latter makes out a credit and debit transfer stub in five copies—two pink, two green, and one white. The damage report and transfer stub

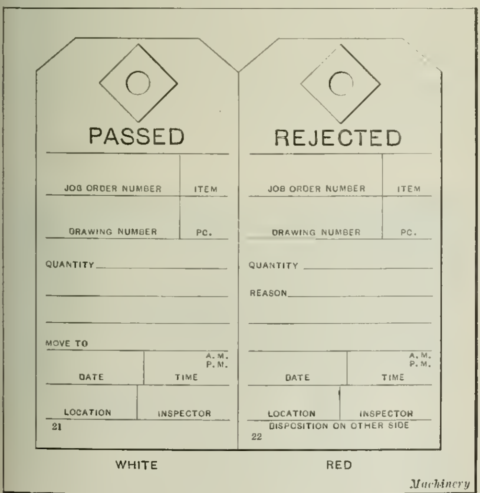

Fig. 12. White and Red Inspection Tags used for passing or rejecting Work

are then sent to the departmental chief planner for his approval and signature, after which the damage report is sent to the general foreman for action. The transfer stub is sent to the progress section to be noted on the progress card, after which the white copy is placed in the jacket file. One pink and one green copy of the transfer stub are sent to the shipping clerk, and the other pink and green copies are sent with the material to its destination.

The sample tag shown in Fig. 13 is attached to a sample which is to be sent to another shop. This tag is filled out by a planner who tears off the stub and sends it to the progress section to be noted on the progress card. The planner attaches the body of the tag to the sample and sends both to the receiving clerk, who forwards them to the shop designated by the tag. This shop later returns the sample and tag to the receiving clerk, who sends them to the section of the shop that is designated by the route tag. At the time the sample is returned with material to the shipping clerk, the sample tag is destroyed. When a request is made to a customer for a sample, the same tag is used, the stub being detached and sent to the jacket file. The body of the tag is sent with the request to the customer, the latter being asked to attach the tag to the sample when forwarding it.

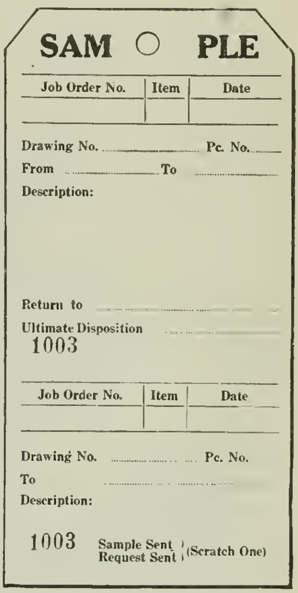

Fig. 13. Tag attached to Samples of Work sent to Other Shops or received from a Customer

The drawing index card is a record of the blueprints in the possession of the shop. These cards show the supply of every print on hand and to whom prints have been issued. They are kept by a clerk located in the shop planning office, and are filed in card index form by the symbol designation of the prints.

PLANING METHODS

By H. K. GRIGGS

Referring to the article "Planing Stock Reel Supports for Automatic Screw Machines" on page 205 of November, 1921, MACHINERY, the writer wishes to call attention to a mistake that is commonly made in setting up planer work, namely that of placing the angle-plate wrong side out. This mistake is particularly noticeable in planing such work as the flange faces of large pipe elbows. When the angle-plate is used as shown in the illustrations of the article referred to, there is a tendency for the pressure of the cut to lift the angle-plate from the planer bed, thus causing the tool to dig into the work. The lifting force is sometimes great enough to raise the table sufficiently to bring the pinion out of mesh with the rack and thus cause serious damage to the machine. By turning the angle-plate around, the pressure of the cut will spring the work downward and thus eliminate danger of the tool digging in. In the case of the work referred to, it is the writer's opinion that the castings could be more easily put on the planer if the angle-plate were turned around, and heavier cuts could be taken without causing chatter.

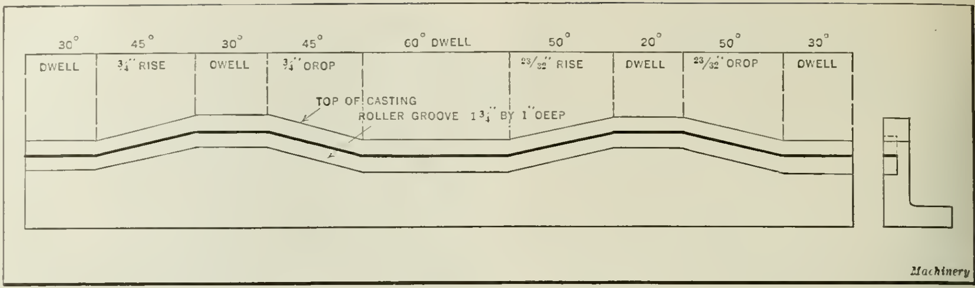

Fig. 1. Lay-out for Large Cam, which was cut on a 48-inch Boring Mill

SPRING MEETING OF THE A. S. M. E.

The tentative program of the spring meeting of the American Society of Mechanical Engineers, to be held in Atlanta, Ga., May 8 to 11, includes a strong technical program, covering machine shop and textile sessions, and papers relating to management, power, fuels, and the handling of materials. The power division's program will relate specifically to hydro-electro power developments in the Southeast. A paper giving the results of recent tests on a 60,000 kilowatt turbine at the Interborough Rapid Transit Co. of New York will also be presented. "Material Handling Equipment in the Steel Industry" will be the subject of one of the papers read; this paper will treat of the entire industry in a comprehensive manner, and will show how the handling of materials hinges on the adequate design of mechanical handling equipment. In connection with the meeting an excursion will be made to Birmingham, Ala., to inspect plants engaged in the manufacture of iron and steel. The programs of the management, textile, and machine shop divisions will all be devoted to problems arising in the textile industry, the machine shop division dealing particularly with textile machinery maintenance. After the sessions in Atlanta, those interested in seeing textile plants in operation will visit Greenville, S. C.

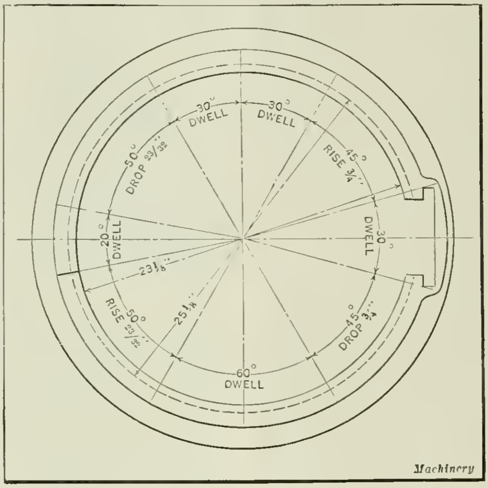

Fig. 2. Plan View of Finished Cam

CAM CUTTING ON A BORING MILL

By ARTHUR MUMPER

Having a cam to cut which was too large to be handled on any of the machines ordinarily used for cam cutting, the writer suggested doing the work on a Cincinnati 48-inch vertical boring mill as described in the following. The cam, which is shown in Fig. 4, was to be used in the construction of a special machine, and was required to be cut accurately. The lay-out for the job is shown diagrammatically in Fig. 1 and a plan view of the finished cam may be seen in Fig. 2.

The first thing to do was to get the ram of the machine to slide up and down with the least possible friction. An attempt was made to remove the pinion from the short feed-shaft which runs from the front to the rear of the ram on the boring mill. This proved impossible without removing the saddle from the cross-rail, and as time was an important consideration in this case, it was decided simply to remove the rack from the ram and fasten a bar of cold-rolled steel in its place, making this bar just enough smaller to allow the front pinion to clear it. This served the purpose, but it was found necessary to fasten a heavy counterweight on the ram, in order to make the tool follow the drop of the master cam, and reproduce the correct shape on the work.

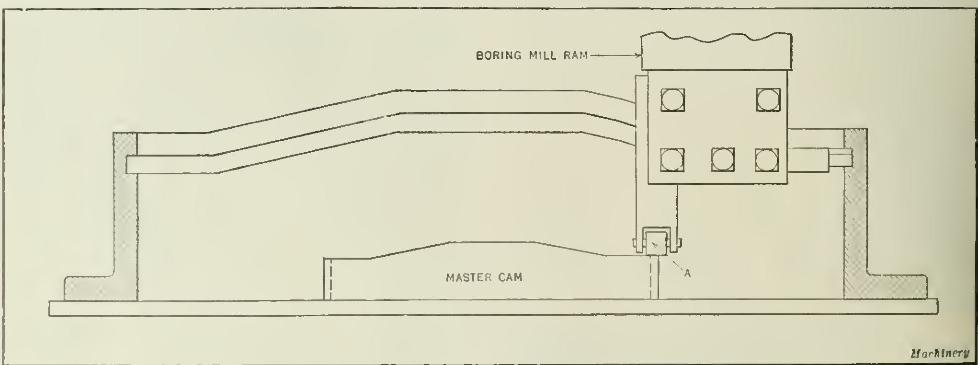

Fig. 3. Boring Mill Set-up for cutting Groove in Cam shown in Fig. 2

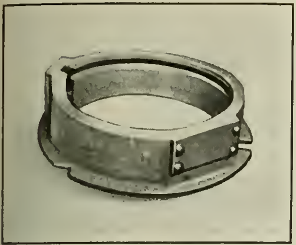

Fig. 4. Finished Cam

From the illustrations it will be apparent that the casting was so designed that it could be easily bolted to a bedplate. Hence a bedplate was cast for this purpose which was held in the chuck of the machine. The master cam was laid out on a bar of cold-rolled steel. ½ by 1¾ inches in size, which was then bent around a shaft 12 inches in diameter, the ends being clamped together. The master cam was 12 inches in diameter, while the diameter of the inside of the cam to be cut was 23⅛ inches. The master cam was clamped on the bedplate and in the true center of the job. Next a roller *A*, Fig. 3, was made and clamped to the inner side of the box-tool holder of the machine. This roller carried the weight of the ram, and as it rode on the master cam it imparted vertical movements to the box-tool holder, which resulted in cutting the cam groove to the required contour. The tool used in cutting the groove was a common straight parting tool about ⅝ inch wide on the cutting edge. As specified in the layout. Fig. 1, the cam groove was cut 1 inch deep by 1¾ inches wide. In Fig. 5 the cam is shown clamped to the boring machine table in position to be bored, previous to cutting the cam groove.

SCREW THREAD PRACTICE IN EUROPE

The U. S. standard screw thread appears to be little used in Europe. The form in most general use is the Whitworth thread, and consequently the metric countries, particularly Austria, Germany, Holland, Sweden, and Switzerland, are anxious to agree on tolerances for this form of thread. They believe that the Anglo-Saxon countries should take the lead in this work, but are anxious to have an agreement reached as soon as possible. It is reported that Austria, France, Germany, Holland, Italy, Sweden, and Switzerland either have adopted or will adopt three systems of screw threads, namely, the International System (metric), the Metric Fine Thread, and the Whitworth Thread.

The Germans have decided to discard several less used metric systems so as to have not over three in use. They are much interested in the number of threads per inch for the very large Whitworth screws. The German shipbuilding industry wants to continue the use of pitches coarser than four threads per inch on account of their use on British ships, but the other German industries want to limit the number of threads per inch to four, as recommended by the National Screw Thread Commission of the United States.

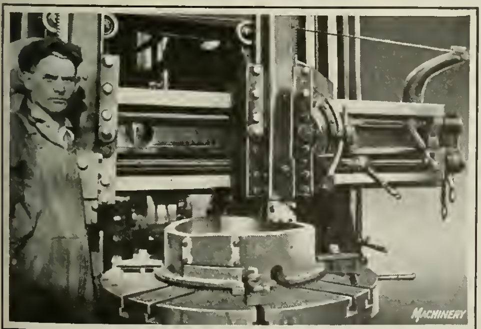

Fig. 5. Boring Operation on Cam

Germany, Holland, Sweden, and Switzerland take the nut as the fundamental basis, according to Secretary Agnew of the American Engineering Standards Committee. The Swiss have done extensive work in establishing screw thread tolerances for metric and Whitworth threads, but the results have not been published. The Dutch standards for bolts are now being revised. The British have organized an association of Bright Nut and Bolt Manufacturers, and this has greatly stimulated work on the general question of screw threads and on the details of nuts and bolts. It is believed that the Society of Automotive Engineers' thread is being extensively used in England, and the British association is undertaking to determine the extent of its use.

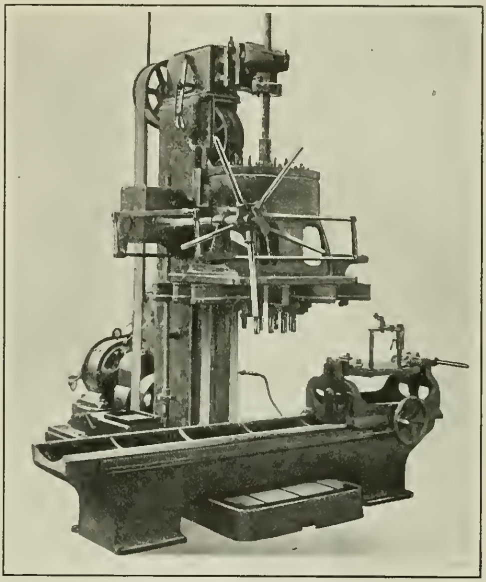
UNIQUE SLIDE FOR TRUNNION JIG

The accompanying illustration shows a unique means of traversing a trunnion jig beneath the spindle head of a No. 14 "Natco" multiple-spindle drilling machine. The photograph was taken in a machine shop in France. It will be seen that the bed of a dismantled lathe has been placed on the floor with the gap between the legs extending over the base of the drilling machine, the ways of the lathe bed being utilized as sliding surfaces for the jig. The latter is fed across the bed by revolving a handwheel on the jig, which rotates a pinion engaging the teeth of the rack on the front of the bed. The bed belongs to a worn-out lathe, and if an enterprising mechanic had not thought of its present application it would no doubt have been scrapped.



Old Lathe Bed utilized as a Slide for traversing a Jig under a "Natco" Multiple-spindle Drilling Machine

* * *

The waste from accidents is one that should be given greater attention than any other industrial waste. In a paper presented before the Industrial Waste Session at the Pennsylvania Industrial Relations Conference, it was pointed out that the rate of accidental death in the United States for each million of population is 860, as compared with 452 in England and 477 in France. Statistics were also presented giving the direct and indirect cost of fatal and non-fatal accidents as $1,500,000,000 annually. This is only the dollars and cents waste. Other elements of loss are not reducible to such a basis and are not replaceable.

Graphic Representation of Absorption of Impact by Springs

By LESLIE H. MANN, Engineer with Perin & Marshall, Consulting Engineers, New York City

THE determination of the energy absorbed by a spring under load as treated herein is based upon the assumption that the body producing the deflection of the spring is moving with its center of gravity in line with the axis of the spring, or in line with the point that will cause the spring to act most efficiently. It is further assumed that the deflection of the spring is proportional to the applied load, and the inertia of the spring is considered to be a negligible factor.

In the formulas,

W = weight of moving body;

V = velocity of moving body in feet per second at instant of striking the spring;

g = acceleration due to gravity (32.16 feet per second);

P = maximum applied force in pounds, or slowly applied load which would deflect the spring as much as will the moving body;

F = deflection of spring in feet;

E = energy in foot-pounds absorbed by the spring during deflection.

From the hypothesis and the laws of mechanics,

$$\frac{PF}{2} = E, \qquad \text{or} \qquad P = \frac{2E}{F}$$

$$\frac{WV^2}{2g} = \text{energy of body at instant of striking spring}$$

If the load deflects the spring vertically downward, additional energy WF is developed so that

$$E = \frac{WV^2}{2g} + WF \qquad (1)$$

If the load is directed toward the spring obliquely downward at an angle Z with the vertical, additional energy, $WF \cos Z$, is developed, or

$$E = \frac{WV^2}{2g} + WF \cos Z \qquad (2)$$

The general formula for the energy absorbed by a spring during deflection may be written:

$$E = \frac{WV^2}{2g} \pm WF \cos Z \qquad (3)$$

The last term in this formula takes the *positive* sign when the motion toward the spring is *downward*, and the *negative* sign when the motion toward the spring is *upward*. When the motion is *horizontal*, angle Z will, of course, be 90 degrees, and since the cosine of 90 degrees is zero, the last term will in this case disappear entirely and the formula becomes

$$E = \frac{WV^2}{2g} \qquad (4)$$

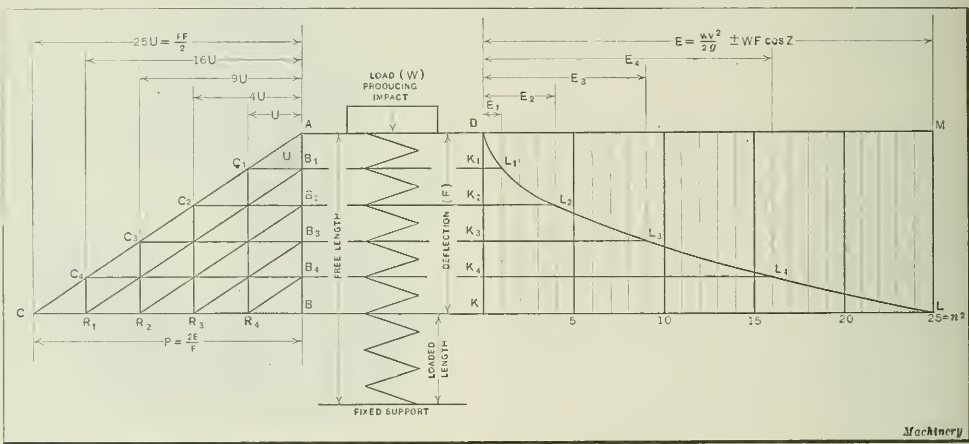


Fig. 1. Diagram for analyzing the Formulas for Absorption of Energy by Springs under Deflection

The formulas given in the preceding are placed in tabular form for convenience as follows:

Direction of Motion	Formula
Vertically downward	$E = \frac{WV^2}{2g} + WF$
Obliquely downward	$E = \frac{WV^2}{2g} + WF \cos Z$
Horizontal	$E = \frac{WV^2}{2g}$
Obliquely upward	$E = \frac{WV^2}{2g} - WF \cos Z$
Vertically upward	$E = \frac{WV^2}{2g} - WF$

The diagram Fig. 1 represents a load W striking against a helical spring which has a fixed support. The graphic depicting of the formulas is applicable to springs made from wire of any sectional shape, and, in general, to springs of any type. Draw two parallel lines AM and CL, the perpendicular distance between them representing the deflection F.

Draw AB and DK perpendicular to the horizontal lines and parallel to the line of deflection F, and divide these two lines into any desired number of equal parts n, as, for example, five. These divisions are represented by spaces AB_1, B_1B_2, DK_1, etc. Through corresponding division points on AB and DK draw the horizontal lines C_1K_1, C_2K_2, etc. By selecting the proper formula from the above tabulation, which will agree with the condition under which the spring is located, the computation for E may be made, and this value may then be graphically represented by making DM equal to E, using any convenient scale.

After calculating the value of P from the formula $P = \frac{2E}{F}$, lay off BC equal to this value, using any other convenient scale. Divide BC into the same number of equal parts as AB was divided into (in this case five), and designate the division points as shown. Complete the triangle by connecting points A and C and then draw similar inclined lines through the remaining division points; also draw the vertical lines C_4R_1, C_3R_2, etc.

The formula for energy absorbed by the spring has been shown to be $E = \frac{PF}{2}$, and since the sides AB and BC of the triangle equal, respectively, F and P, it follows that the area of triangle ABC which is $\frac{PF}{2}$, represents graphically the amount of energy E absorbed by the spring in its deflection from A to B. Likewise, the area of the small triangle AB_1C_1 represents the amount of energy absorbed by the spring during its deflection from A to B_1; also the area of the triangle AB_2C_2 represents the amount of energy absorbed through the deflection from A to B_2; and further, the area of each triangle shows graphically the energy absorbed in deflecting the spring a distance equal to the altitude of that triangle. It is evident that the area of the large triangle ABC is equivalent to twenty-five small triangles AB_1C_1, this unit area being designated on the diagram by letter U. Next, divide DM into the same number of parts as there are small triangles in the large one, that is, twenty-five, and from the division points on DK draw K_1L_1, K_2L_2, etc., equal to the same number of these subdivisions as there are units U in the corresponding triangles AB_1C_1, AB_2C_2, etc. A curve, which is parabolic, is then drawn through the termination of these horizontal lines, as shown in the diagram.

ABSORPTION OF IMPACT BY SPRINGS

Deflection	Area Representing Impact	Number of Units U or Parts of DM	Energy Absorbed
D to K_1	AB_1C_1	$1 = 1^2$	$K_1L_1 = E_1 = \frac{E}{25}$
D to K_2	AB_2C_2	$4 = 2^2$	$K_2L_2 = E_2 = \frac{4E}{25}$
D to K_3	AB_3C_3	$9 = 3^2$	$K_3L_2 = E_3 = \frac{9E}{25}$
D to K_4	AB_4C_4	$16 = 4^2$	$K_4L_4 = E_4 = \frac{16E}{25}$
D to K	ABC	$25 = 5^2 = n^2$	$KL = E = \frac{25E}{25}$
K_1 to K_2	$B_1B_2C_2C_1$	$3 = 4 - 1$	$E_2 - E_1 = \frac{3E}{25}$
K_2 to K_3	$B_2B_3C_3C_2$	$5 = 9 - 4$	$E_3 - E_2 = \frac{5E}{25}$
K_3 to K_4	$B_3B_4C_4C_3$	$7 = 16 - 9$	$E_4 - E_3 = \frac{7E}{25}$
K_4 to K	B_4BCC_4	$9 = 25 - 16$	$E - E_4 = \frac{9E}{25}$

Machinery

In the accompanying table, the data contained is deduced from the diagram, and shows the amount of energy absorbed during deflection of the spring from its free length to any point of equal division of F, and also the amount of energy absorbed during each successive portion of the deflection. It will be noted that the energy absorbed during the last part K_4K of the deflection is nine times that absorbed through the first part DK_1 of the deflection.

A diagram which may be used to determine graphically the energy and the load values for a given deflection is shown in Fig. 2. The rectangle $ABCD$ has its parallel sides divided into ten spaces each. Draw the diagonal AC and the parabola AKC. Prolong CD through E and F and prolong CB to G. From B lay off the oblique line BM, terminating in the line EF, which will show to any convenient scale the total energy absorbed. In a similar manner, from A lay off AL terminating in line EF, and line AT terminating in line CG, to represent the maximum load in pounds and the deflection in feet, respectively.

From any point of deflection, as T_1, draw T_1C_1 parallel to GC, intersecting the parabola at K and the diagonal at C_1. Drop a perpendicular KM_1 to BM. Where this perpendicular intersects BC, the fraction of the total energy is indicated. Erect a perpendicular from point C_1 intersecting AL; where this perpendicular intersects AD the fractional part of the maximum force or load is indicated. By properly graduating lines AT, BM, and AL, representing assigned total values, corresponding intermediate values of deflection, energy, and load may be quickly determined. It is evident that at 0.5 of the total deflection, the energy already absorbed is only 0.25 of the total energy E; also the corresponding force or load P on the spring is 0.5 of the maximum load. In the present case, where the deflection is 0.15 foot, the energy absorbed is 0.25 of the total energy or 525 foot-pounds; and the load on the spring is 0.5 of 14,000 pounds, or 7000 pounds.

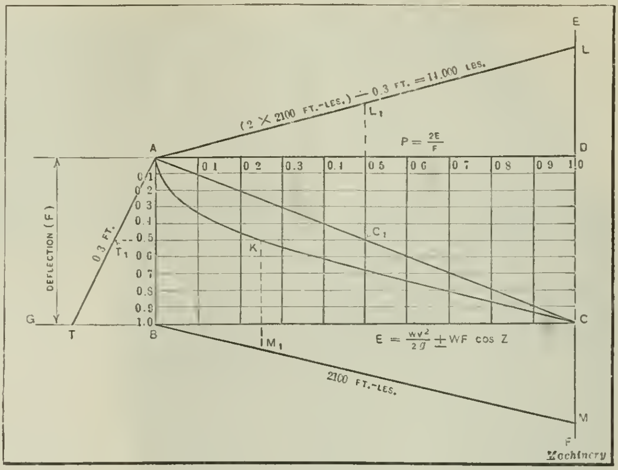

Fig. 2. Graphic Method of determining Values of Spring Deflection, Energy Absorption, and Load

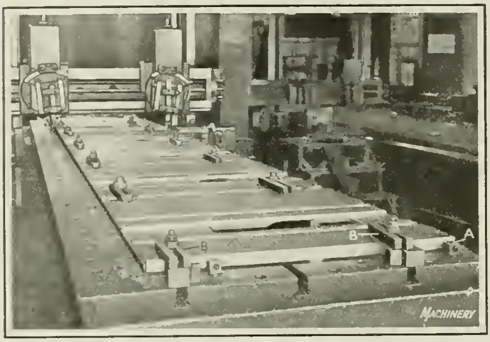
PLANING SAW BENCH TABLES

The accompanying illustration shows a Niles-Bement-Pond planer equipped for planing the ends of saw bench tables in the plant of the Pratt & Whitney Co., Hartford, Conn. Six castings are set up in a string, so that they can be operated upon at one continuous cut. The work is rather unusual because of its great length and width, as compared with the



Planing the Ends of Wood-cutting Saw Bench Tables

thickness. Two end-stops *A* receive the thrust of the cutting tools and also locate the finished edges of the work at right angles to the line of travel of the planer table. The work is held down by two straps *B* located between each pair of castings. The two cutting tools are of simple design, one operating on each end of the castings. The material is cast iron, and the depth of cut on this job is ½ inch, the feed ⅛ inch per table stroke, and the cutting speed 30 feet per minute. The top surface of these castings was planed at a previous setting on the same machine, and this job is of interest because of the large area that is finished. On this operation the depth of cut was 1/16 inch, and the tools were fed at a rate of ⅞ inch per table stroke, with a cutting speed of 30 feet per minute.

SNAP GAGE DESIGN

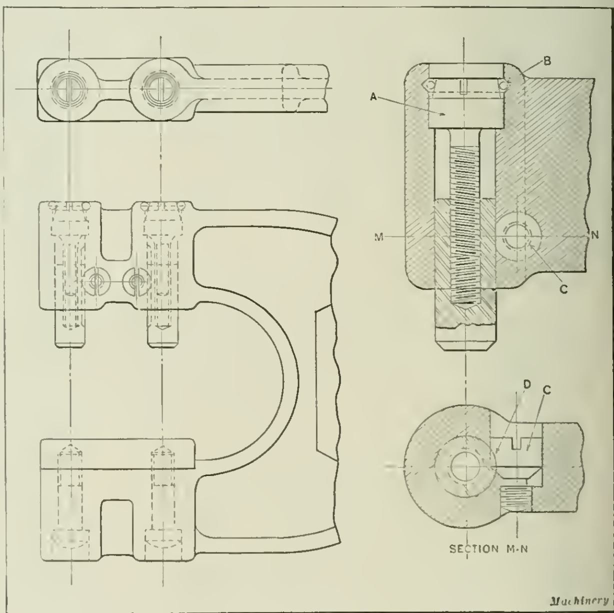
By J. B. CONWAY

A table prepared by the writer, which appeared in August, 1920, MACHINERY on page 1123, gave dimensions for snap gage frames in sizes ranging from ¼ to 17 inches. The adjusting and locking devices shown in the accompanying illustration were designed by the writer, and have been used successfully on frames of the type described in the article referred to, as well as on gage frames of similar design. In designing snap gages, there are several points that must be carefully considered if satisfactory results are to be obtained. A frame of substantial design, preferably of material that will break before distorting, is of first importance. An adjustable feature to provide for readily adjusting to different sizes, and to compensate for wear, and a locking device or mechanism which provides for independent adjustment of the different parts are practically indispensable.

The design of frames described in the article mentioned will be found rugged and durable. Selection of the material from which they are to be made, either cast iron or other material, is left to the judgment of the designer. Whether four anvils or blocks are employed is also a matter of opinion, and depends somewhat on the conditions under which they are to be used. Referring to the accompanying illustration, it will be seen that means of adjusting the gage plugs and of securing them in position after they are set to the desired points are incorporated in the design. Aside from the frame and anvil this design consists of an adjustable plug, an adjusting screw, a retaining ring, and a locking screw.

The plug is adjusted in or out by means of the adjusting screw *A*, which has a left-hand thread. When the adjusting screw is turned in a clockwise direction, the distance between the gaging points is decreased. To increase the size of the gage the screw is given a reverse movement. The adjusting screw is retained in position by ring *B* which fits in a V-shaped annular groove as shown. This ring is made of spring brass or steel, and is split to allow for closing it a sufficient amount when placing it in position. A groove cut in the plug at *D* is made to conform to the shape of the head of the locking screw *C*. The action of screw *C* when it is forced against the plug is to grip the side in contact with the head, and as further pressure is exerted it binds on the parallel side of the head. This affords a positive lock, and insures setting the plug in its original position with respect to its face whenever it is changed for adjustment or after relapping.

Besides the usual care required in maintaining accuracy in gages of this kind, attention must also be given to the accuracy of the seat on the head of the locking screw and to the angle of the groove in the plug. The proximity of the locking screw to the plug can be such that the distance will just permit the passage of the body of the screw without actual contact between the screw and the plug. This design of locking device can be employed on gages of other types such as large "sweep" or "windmill" gages, inside gages, and various types requiring adjustability of the gaging points or surfaces.



Snap Gage equipped with Adjusting and Locking Devices

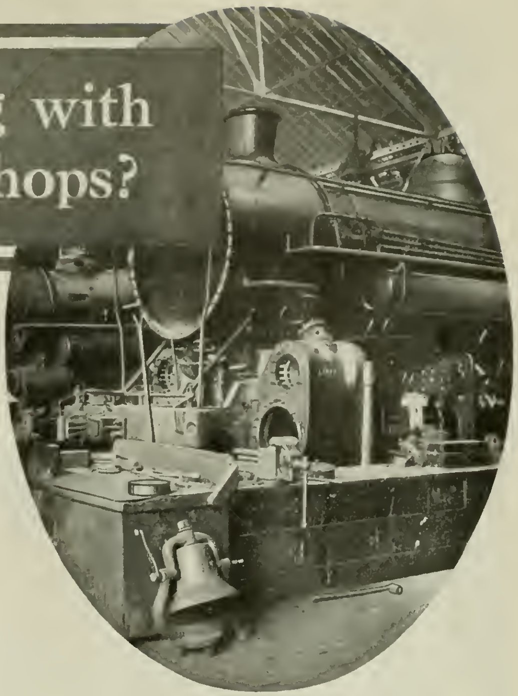
National standardization bodies now exist in fourteen countries as follows: Austria, Belgium, Canada, Czecho-Slovakia, France, Germany, Great Britain, Holland, Italy, Japan, Norway, Sweden, Switzerland, and the United States.

What is Wrong with the Railroad Shops?



An Investigation into the Relative Costs of Performing Machining Operations in Seven Representative Railroad Shops

By EDWARD K. HAMMOND

THOSE who are capable of passing reliable judgment are of the opinion that the average efficiency in American railroad shops is far beneath that of industrial plants engaged on similar lines of work. The trouble is largely due to unsuitable equipment and inefficiency of railroad shop labor. The methods employed are usually satisfactory, but there is room for improvement both as regards the mechanical equipment of the railroad shops and the efficiency of the men employed in them. The railroad's finances have often made shop superintendents hesitate to requisition mechanical equipment which their better judgment told them was imperative.

Labor has been the other drawback. Prior to the period of government control, many of the shops were operated under some piece-work or bonus system that created an incentive to do efficient work, but after the government took control, the so-called National Agreement on Working Conditions abolished all such systems of remuneration and put all the workers on an hourly or monthly pay basis. A falling off in efficiency was inevitable, and this was most pronounced in those shops where bonus or piece-work methods were formerly in use. These piece-work or bonus systems were not only a means of enabling the railroads to get out their work at what was more nearly a minimum production cost, but they also afforded all shop employes an opportunity for greater earnings.

Recently, the United States Railroad Labor Board handed down a decision providing for the re-establishing of various piece-work or bonus systems, and permitting the railroads to deal individually with their shop men; it is expected that if the necessary readjustments can be made in line with these rulings, a higher standard of efficiency will result.

Importance of Constant Supervision

It is undeniable that the efficiency of any productive organization deteriorates rapidly without constant supervision; but during the period in which the National Agreement was in full force, adequate supervision of labor was impossible. Today this obstacle has been largely removed, and in starting to increase railroad shop efficiency, one important step would be to send out men to make thorough studies of conditions in each of the shops, with a view to establishing the normal cost of every operation and ascertaining the cause of failure to attain this degree of efficiency. In most cases it would probably be found that both mechanical equipment and labor are partially responsible for low efficiency.

A man who has had an unusual opportunity to observe conditions in railroad shops suggests that better results can be obtained from shop workers by creating a financial incentive, such as a properly applied piece-work or bonus plan of payment, which would be of benefit to both the men and the management; and he believes this idea could be carried still further by placing the shop foremen on a bonus system as well as the men.

A Plan for Increasing the Efficiency of Labor

In working out such a plan for rewarding the efficiency of the foremen, it would be necessary to determine what working force would normally be required in each department for handling the average amount of work coming into the shop. Then if this normal force could be reduced by increasing the rate of output per man, the foreman would be paid a percentage of the saving in labor costs of his department. The foreman would urge the men to obtain the maximum production by pointing out the increase in their earnings made possible by the bonus system. Such a plan would be far-reaching in its effect, because it would overcome the jealousy that is sometimes felt by foremen because of the high earning capacity of men who are working on a piece-work basis.

Efficiency in the management of any manufacturing enterprise requires the successful adjustment of three fundamental factors—methods, mechanical equipment, and men. Conditions in a railroad shop are not radically different from those in industrial plants handling similar classes of work; in both cases, to make it possible to machine parts at a minimum cost, it is imperative (1) to develop methods for performing each operation rapidly; (2) to make sure that a machine of the proper type and one that is in good mechanical condition is available for handling every job; and (3) to have the machine operated by a mechanic with the necessary experience and ability, who makes an effort to produce the high rate of output possible with the machine and methods used. The present article is an investigation into the extent to which railroad shops meet these requirements of efficient management.

Machinery

To successfully apply such a system, the investigators who establish what constitutes a normal working force for each department must keep constantly in mind the fact that it is not the purpose to impose an unnecessary or unjustifiable amount of work upon any employe, but merely to have all the men in every department kept constantly employed during working hours. Frequently a machinist sets up a job and starts his machine on an operation which takes a considerable time to complete, and on which the machine works automatically until the job is finished. Under such conditions the mechanic is idle until it is time for him to remove a finished piece from the machine and set up another.

All such causes of lost efficiency should be overcome by providing other work for the man to do, such as operating a second machine engaged on the same work, or performing some other operation on the pieces that he is machining. This would afford an opportunity for the workman to earn more money, it would effect a saving for the railroad by reducing the number of men employed in the shop, and with a bonus system of the kind mentioned, it would allow the foreman of the department to earn a bonus.

Comparative Data on Railroad Shop Costs

With a view to emphasizing the importance of investigating the costs of handling railroad shop work and of correcting the causes of low efficiency, an investigation has been conducted by MACHINERY to ascertain the time required for performing a number of machining operations regularly handled in practically all such shops throughout the country. As might have been expected, these figures show a wide divergence, and their lack of uniformity shows that many of the shops are paying out large sums of money for labor, which could be saved if better mechanical equipment were used and the efficiency of machinists were greater. Those railroad shop managers who are dissatisfied with the results they are securing would do well to investigate immediately all conditions that exist in their plants. This would probably uncover many unsuspected sources of loss in even the best managed shops; and even where substantial expenditures were required for the necessary equipment, the new machines would earn a satisfactory return, because of their greater output and the reduced amount of labor required.

A typical instance will prove this statement. In machining the edges of main driving-rod straps, one shop handles this job on a planer and takes eight hours to finish one piece, while another shop handles the job on a planer type milling machine and finishes a piece in 1.04 hours. This means a loss to the first shop of 6.96 hours per piece, and allowing 77 cents per hour for labor, the equivalent in money is $5.36 per piece. Any shop that has a large number of main driving-rod straps to mill would find an investment in a milling machine to be well worth while; such a machine could also be used for other operations besides the one mentioned.

In collecting the figures in the accompanying table, an effort was made to include shops where the conditions are regarded as good, fair, and poor. This gives a representative survey of the conditions existing in railroad shops. Six of the shops are located in the United States and one in Canada. These data were collected for MACHINERY through personal investigations in the various shops made by a man who was for a number of years the superintendent in charge of a well-known American railroad shop.

Causes of Failure to Obtain Normal Efficiency

In collecting these figures, an effort was made to ascertain the cause of trouble in cases where the time required to handle a job was much above what is believed to be a normal average. Although there were exceptions to the general rule, in the majority of cases it was found that the method of tooling up each machine for its work had been modernized as far as possible, so that the fault was usually either with the type or condition of the machine that was used or with the efficiency of the man assigned to the job. These two causes of inefficiency were about equally balanced.

Another interesting point developed during the course of this investigation was that in some shops where the average of conditions was very bad, certain operations were performed with an unusual degree of efficiency. A case in point is the machining of piston-heads where it is required to face the ends, turn the outside diameter, cut two ring grooves and bore the rod fit. In one shop where the general condition of the machinery is very poor and where the efficiency of the working force is equally unsatisfactory, this particular job is completed in a very reasonable time. This fact is the more noteworthy when it is borne in mind that the working force in this shop has been very hard to handle. The reason that the present job is so successful is not hard to find. A modern type of vertical turret lathe was bought for this machining operation, and it was carefully tooled up to enable the various steps in the complete operation to be handled in such a way that several tools are often working at the same time. The investment in this equipment is earning a very satisfactory return.

Wide Variations in Results Obtained by Different Shops

In looking over the comparative figures for various railroad shop operations, it will be seen that in many cases there is a wide variation in time, even though the type of machine on which the work is done is practically the same. In many such instances the explanation lies in the method of handling the work while setting up and removing it from the machine, or in some advantage secured through the provision of efficient auxiliary equipment. Another point which in some cases is responsible for the difference in results is that one shop adopts the modern manufacturing practice of setting up a number of pieces to be machined in a single operation, while another shop adheres to the old plan of handling one piece at a time. In order to bring its costs down to a normal average, the railroad shop must give the same care that the progressive industrial plant does to the perfection of every detail of manufacture.

Independent Contract Shops for Repair Work

In making repairs on locomotives and cars, each railroad shop bears somewhat the same relationship to the corporation which it serves that an entirely independent concern would, which had an absolute monopoly on the class of service the railroad desired to purchase. In other words, there is no competition, and consequently no stimulus toward higher efficiency and lower costs.

With a view to avoiding the limitations of efficiency set up by the terms of the National Agreement, eight railroads in the United States have, up to the present time, placed one or more of their car repair shops under the control of contractors who handle the work along strictly commercial lines. This plan has a number of advantages. In the first place, the contractor always realizes that his methods must be kept up to date and that he must take advantage of all possibilities of reducing production costs in order to hold the work against bids of competing organizations. Also, the independent contractor would not be hampered by many of the burdensome regulations that are still imposed by the United States Railroad Board.

In some quarters it is the belief that this constitutes the real solution of the railroad shop problem, and those who hold to this belief are inclined to advocate the idea of applying the same principle in handling locomotive repair work. The solution of the railroad shop problem is of the greatest importance, because the railroads exert a general and important effect upon the business and prosperity of the country.

There is no question about the urgent need of rehabilitating means for maintaining railroad equipment in an efficient operating condition. The problem is to decide which method is the more satisfactory—to continue operating the shops as a department of the railroads or to place them under independent control. If the former expedient is adopted, each railroad must conduct a thorough housecleaning; and if the shops are placed on an independent commercial basis, the same course of action would follow as a matter of course, because no experienced manufacturer would expect to be able to get results with the inefficient labor and obsolete equipment that are found in many railroad shops at the present time.

* * *

REDUCING THE COST OF JAPANNING

By HUGO A. BIESEN

In order to reduce production costs, the Cutler-Hammer Mfg. Co., Milwaukee, Wis., has adopted a new practice in connection with the japanning of machine parts. In the past this operation was performed after the castings had been machined. They were then sent to the japanning department where a hand painting or spraying operation was performed. This resulted in the japan partly covering the machined surfaces, and it was practically impossible to keep the japan from clogging tapped or reamed holes. When these castings arrived in the assembly departments it was invariably necessary to again tap and ream the holes clogged by japan. With the idea of eliminating this duplication of operations, the feasibility of performing the painting operation before machining was carefully considered. As a result a change in the sequence of operations was made, and at present all castings are sent to the japanning department before being machined.

This reversal of operations entirely eliminates the necessity of reaming or tapping holes twice, and leaves all machined surfaces clean and free from japan. The greater amount of care required in handling and machining castings already japanned does not offset the saving which results from elimination of the operations required to remove the japan from machined holes and surfaces.

The cost of japanning castings has also been reduced by an appreciable percentage in consequence of this change in procedure, since it is now possible to apply the japan by the dipping method, whereas it was formerly necessary to apply it by means of a hand brush or spray.

PROFILING FIXTURE

When profiling operations are of such a nature as to require more than one former for guiding the cutter, as when milling different curved surfaces at one setting of the work, several methods may be used in designing the profiling fixture to permit locating two or more former plates successively in the working position. One method is to use pivoted formers, which are swung around to the working position, one after the other, for controlling the path followed by the guide pin when taking separate cuts that cannot be controlled by one former. This plan has often been adopted when two former plates of different curvature are required, the second former being swung into the working position, as determined by a stop, after completing the cut controlled by the first former.

Another method is to use a single pivoted former which has two or more slots cut in it, or possibly plates attached to it, instead of using independent plates. The different slots or outlines formed on the single pivoted plate are successively brought to the working position opposite the guide pin as the former plate is indexed from one position to the next. With this arrangement a locating plunger or pawl may be used in conjunction with suitably located notches for governing the positions of the former plate.

The fixture shown by the assembly drawing Fig. 1, and on the profiler in Fig. 2, has an indexing former slide for locating the different formers in the working position, but in this design the slide has a lengthwise movement. The slide *A* is mounted in dovetailed ways extending across one side of the fixture. Beneath the slide there is a locating strip *B* containing as many notches *C* as there are former plates. These notches are engaged by plunger *D*, which is withdrawn for indexing the slide by means of handle *E*.

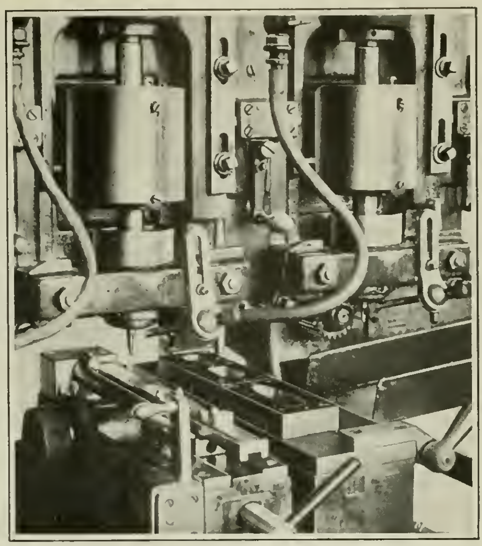

Fig. 2. Profiling Fixture equipped with Indexing Slide for locating Three Different Formers in the Operating Position

Handle *E* is connected to the end of shaft *F*, which has a groove extending throughout its length. This groove is engaged by a tooth on part *G*, which is connected with plunger *D*; hence slide *A* can be moved to any position and the locating plunger is always under the control of handle *E*. The groove in shaft *F* is formed by using a regular 6-pitch No. 8 gear-cutter, and the tooth on part *G* is milled by using a 6-pitch rack-cutter. Whatever former plates are required are attached to the top of the indexing slide, as shown in Fig. 2, which represents a profiling operation on the receiver of a rifle. The work-holding part of the fixture (see Fig. 1) consists of a quick-acting vise operated by a cam-lever *H*. The vise jaws are modified, of course, to suit the work. This design of fixture is frequently employed by the Pratt & Whitney Company whenever it is required to use more than one former.

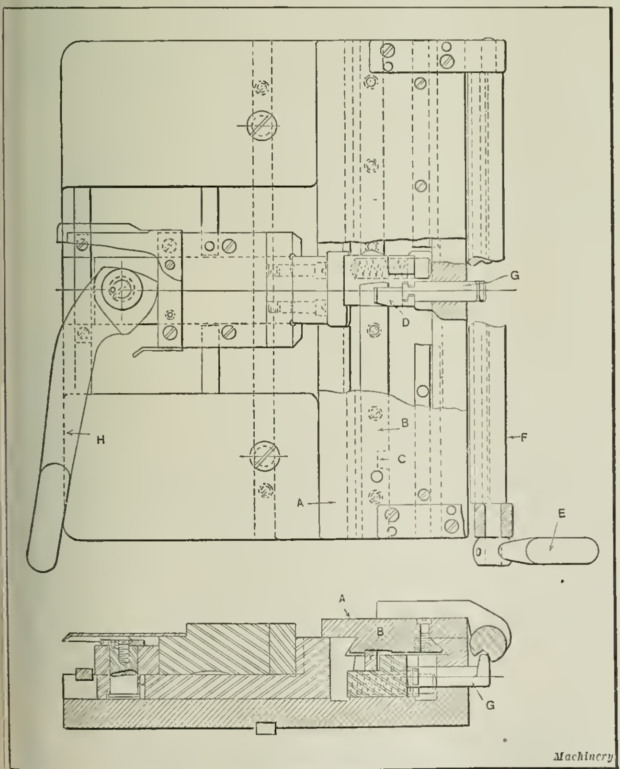

Fig. 1. Sectional and Plan Views of Profiling Fixture shown in Fig. 2

* * *

The advantages of standardization are summarized by the Chamber of Commerce of the United States as follows:

Easier financing and less capital tied up in raw, semi-finished, and finished materials, unnecessary equipment and extra storage floor space.

More economical manufacture on account of longer production runs with fewer changes; increased individual production; less idle equipment; reduced expenditure for clerical work and cost accounting.

More efficient labor, through greater stability and permanence of employment, because of the increase in skill due to repetitive processes in longer runs, and consequently increased earnings.

Better quality of product; prompter deliveries and increased efficiency in packing for shipment.

More efficient selling forces.

Increased rate of turnover.

Charts for Determining Belt Widths

By THOMAS J. COOK

MORE often than otherwise the success of an undertaking depends upon the careful study and working out of details which at first do not seem worthy of much consideration. This is especially true of belt transmission installations. Too often when installing a new belt, the width is selected without regard to the various factors that must be considered if the most efficient operating conditions are to be obtained. Sometimes a certain width is used simply because it can be carried on the face of the smaller pulley. A belt thus selected is frequently accepted as satisfactory simply on the grounds that it transmits the required horsepower.

For at least two reasons it is as great a disadvantage to employ a belt that is too wide or too thick as it is to employ one that lacks either width or thickness sufficient to supply the power demanded of it. If the size of the belt is in excess of what is actually required, the cost will be unnecessarily high. Another unnecessary expense of possibly more vital importance than the first is the extra driving power required. Although the extra power consumed in driving one belt may be very slight, it will perhaps, when multiplied by the number of belts installed in the plant, amount to an unnecessary overload for the power house that will be reflected in an equally unnecessary overhead expense.

Centrifugal force is a factor that must be taken into consideration in installing belting, especially in those cases in which the conditions demand a high speed. Up to a belt speed of 2000 feet per minute, this force need not be taken into consideration, but when the belt exceeds this speed it becomes a vital factor. If a belt is used that is either too wide or too thick, the centrifugal force becomes excessive, and the belt will have an increased tendency to continue in a straight line tangent to the face of the pulley instead of continuing in its true path about the circumference. As the centrifugal force increases the belt becomes looser on the pulley, which results in a marked decrease in the friction driving force. The lessening of the frictional driving force or the tendency of the belt to slip must therefore be overcome by increasing the tension of the belt. An increase in the tension is of course objectionable, as it materially reduces the life of the belt.

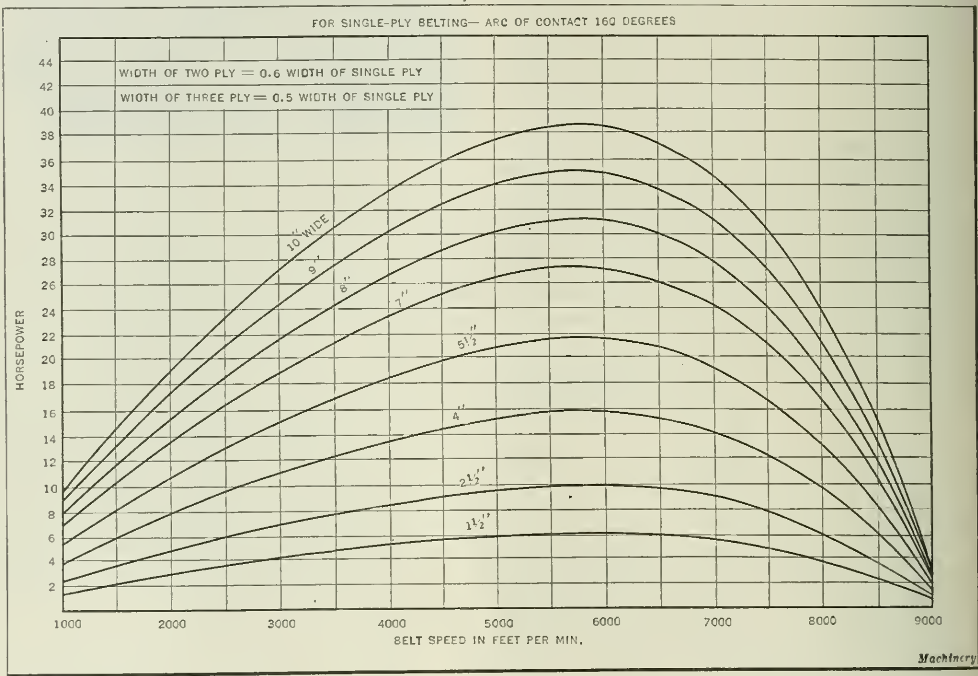

Fig. 1. Chart for determining Belt Widths when Pulleys are of Unequal Size

While there are many formulas that may be used to calculate the correct belt size for any condition, they all involve more or less tedious mathematical operations. Tables have been evolved which eliminate the necessity of making calculations to determine the proper size of belt to use under certain conditions, and many of these can be used with excellent results. To relieve those who are frequently called upon to determine the correct widths for belts, of the difficulties which may arise in making the required calculations, and to provide an even simpler medium than tables, the writer has devised the accompanying charts, which should enable anyone to ascertain at a glance the most efficient size of belt to be used for any condition which may arise.

The arc of contact of the belt on the smaller pulley must always be taken into consideration in determining the horsepower that a belt can transmit. The chart shown in Fig. 1

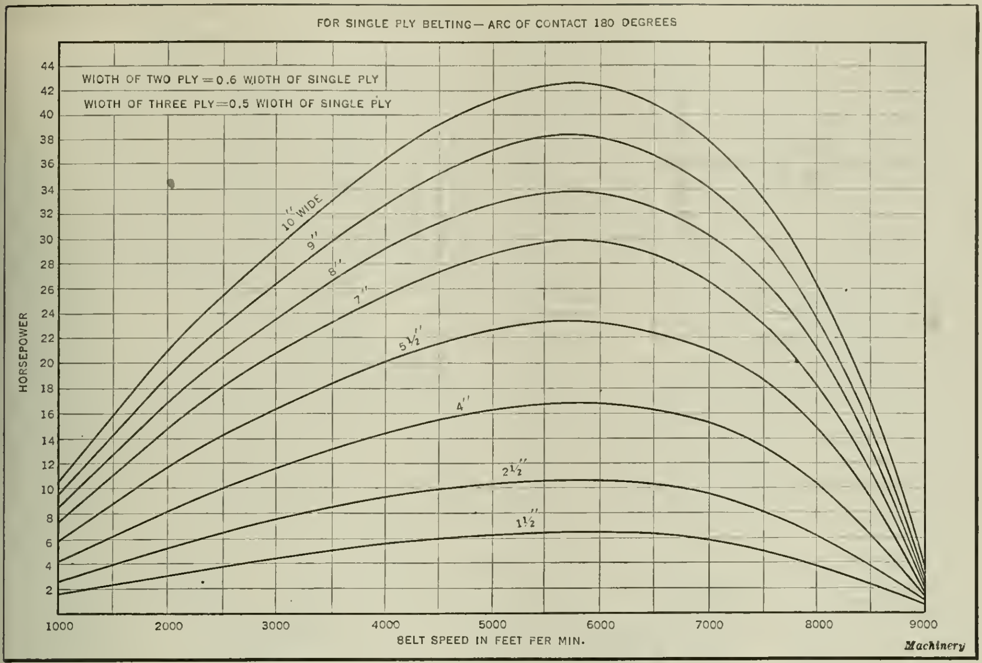

Fig. 2. Chart for determining Belt Widths when Pulleys are of Same Size

is for use when the arc of contact of the belt on the pulley is approximately 160 degrees. This chart is therefore suitable for use in the case of open belts where one pulley is smaller than the other. The chart shown in Fig. 2 is intended for use in the case of open belts where both pulleys are of the same size, that is, when the arc of contact is 180 degrees. The chart shown in Fig. 3 may be used in the case of cross belts, although such an installation is to be

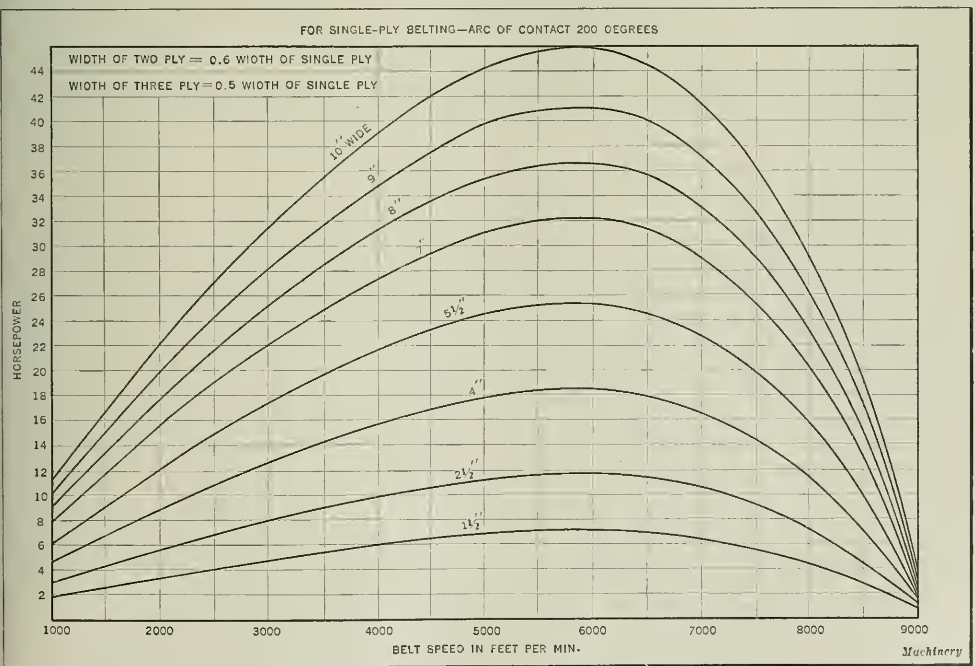

Fig. 3. Chart for determining Belt Widths when Cross Belts are used

avoided if possible on account of the increased wear, which shortens the life of the belt.

To illustrate the use of the charts, let it be required to find the size of a belt which is to transmit 42 horsepower running at a surface speed of 5500 feet per minute over pulleys of equal diameter having 8-inch faces. First locate on the 180-degree chart, Fig. 2, the point of intersection of the vertical line representing a surface speed of 5500 feet per minute, and the horizontal line representing a driving force of 42 horsepower. This point of intersection occurs about on the 10-inch curve or the curve representing a belt width of 10 inches. Thus, a 10-inch single-ply belt would transmit 42 horsepower. However, the pulleys have 8-inch faces so that a 10-inch belt could not be used. According to the note in the upper left-hand corner of the chart, the width of a two-ply belt of the same capacity as a single-ply belt is obtained by multiplying the width of the single-ply belt by 0.6. As 0.6 × 10 = 6, a 6-inch double-ply belt will therefore be the proper installation.

An 8-inch face pulley required to transmit 42 horsepower is an extreme case, but the example serves to show the application of the chart. The width of a belt can often be read direct from the curves. Every point on each curve shown on the chart was calculated separately, use being made of a well-known belting formula in which allowance is made for the effect of centrifugal force.

An inspection of the charts will disclose some interesting and important facts relative to the proper installation of belts. It will be noted that the curves continue in a straight line until they reach the vertical line representing a speed of 2000 feet per minute. This bears out the statement that centrifugal force does not have any noticeable effect until the belt runs in excess of 2000 feet per minute. At this point the curves begin to diverge from a straight line, gradually at first, and more rapidly as the speed increases, but always in an upward path, until the peak of the curves is reached between 5500 and 6000 feet per minute. This, therefore, may be said to be the efficient belt speed, but in actual practice a somewhat slower speed should be used.

Beyond a speed of 6000 feet per minute the centrifugal force becomes so great that the curves on the chart fall rapidly, indicating that the pulley is subject to more or less slippage with a consequent loss of power. This emphasizes the fact that no belt should be allowed to run over 6000 feet per minute. At the line representing a speed of 9000 revolutions per minute, the curves so nearly run out at the zero power line that it is evident that at this speed the belt will continually slip on the pulley and practically no power will be transmitted. Belt widths of 1½, 2½, 4, 5½, 7, 8, 9, and 10 inches have been selected in making up the charts, because by multiplying or factoring these widths it is possible to obtain a greater range of widths. For example, to find the horsepower that can be transmitted by a 3-inch single-ply belt running at 4000 feet per minute over pulleys of equal size, it is only necessary to use the 1½-inch curve of the chart shown in Fig. 2 and multiply the value given by 2. From this chart it will be found that a 1½-inch belt running under the given conditions will transmit 5.6 horsepower. Therefore a 3-inch belt will transmit 2 × 5.6 horsepower or 11.2 horsepower.

GENERAL-PURPOSE MILLING FIXTURES

By A. J. CAYOUETTE

Standardizing certain types of milling fixtures is a practical and economical practice, and has proved especially so in the manufacture of firearms. Milling fixtures of standard design are suitable for use in a wide variety of manufacturing. Designing milling fixtures which are simple in construction, strong, quick-acting, and which can be adapted for holding a large range of work will greatly reduce the costs and the time required for doing tool work. The designs of milling fixtures described in this article have been standardized to such an extent that many of the parts were made up and are kept in stock so that fixtures may be built up in a short time and at a lower cost than would be involved if a special holding fixture were required for each new piece of work.

The fixture shown in Fig. 1 has proved practical to standardize, and is an efficient tool for handling a variety of work. The range of the fixture can be extended by providing jaws to suit the contour of the part to be machined. The work is held between the stationary jaw *E* and the movable jaw *F*, the stationary jaw being fixed to the base of the fixture by dowel-pins and screws and located by a tongue and groove, while the movable jaw swivels on stud *G* which is carried in slide *D*. This slide is operated in a slot in the base of the fixture, as shown in the sectional view.

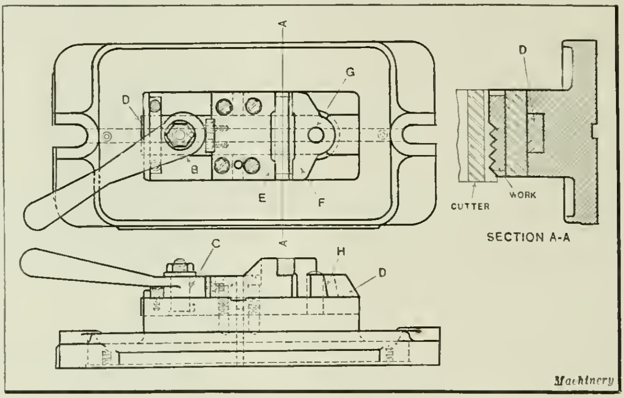

Fig. 1. Milling Fixture which will accommodate a Variety of Work

The work is securely clamped to the stationary jaw by operating the eccentric lever *B*, which is free to pivot about the fixed stud *C*, carried in the opposite end of slide *D*. Tool-steel plates, one attached to the base of the fixture and the other to the jaw *E*, provide bearing surfaces against which the eccentric lever operates, thus reducing wear and increasing the length of service of the fixture.

By making the movable jaw *F* so that it can swivel, the clamping pressure is equalized on the work. Surface *H* of this jaw is angular, and fits a corresponding surface at the rear of slide *D*, which prevents the jaw from lifting when the clamping pressure is exerted. The base of this fixture, as well as of the other fixtures illustrated in this article, is made of cast iron, and is molded to form a reservoir for lubricants and coolants employed in the milling operation. The reservoir is provided with a drain hole so that the liquid may flow back to the supply tank.

The fixture illustrated in Fig. 2 is designed to hold two pieces of work at a time, one set of jaws being stationary with regard to the plane in which they operate, while the other half of the fixture contains a clamping unit, the jaws of which may be raised or lowered to compensate for differences in the diameter of the two cutters that might result from wear. This fixture has all the advantages of that shown in Fig. 1 as regards rigidity and simplicity of operation, and the stationary half of the fixture is identical in construction with the one just described. The feature that permits vertical adjustment of the clamping jaws also enables this tool to be used (with the employment of properly designed jaws) on work which is slightly different in design but on which similar milling operations are to be performed.

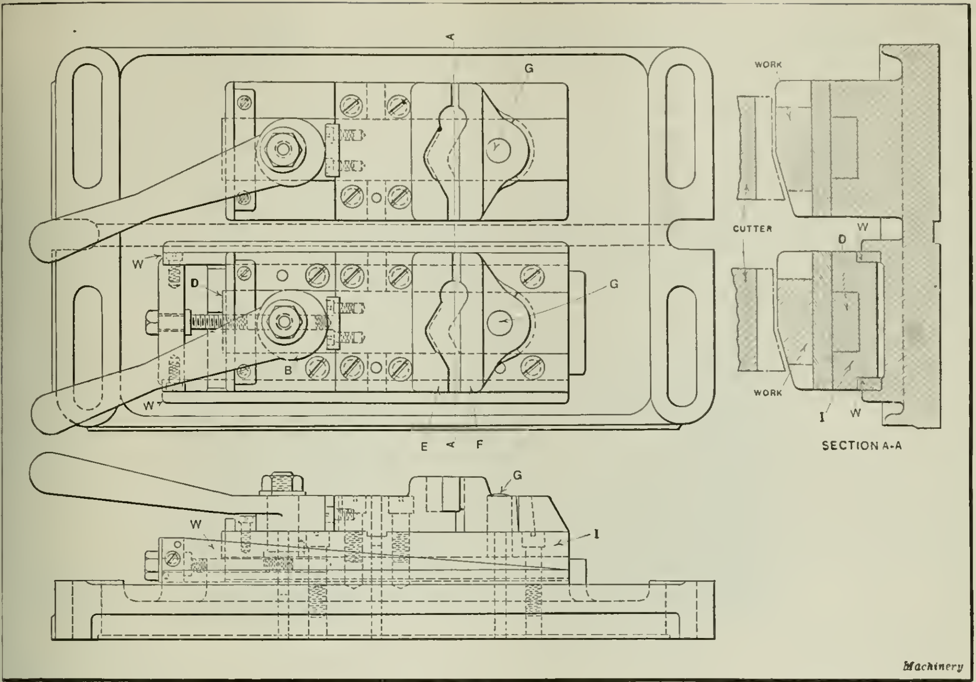

Fig. 2. Duplex Milling Fixture with Provision for adjusting the Vertical Position of One Holding Unit

The construction of the adjustable side of the fixture is, of necessity, a little different from the stationary side. The fixed jaw *E* is attached to a steel block *I* by a suitable tongue and by the use of dowel-pins and machine screws, after the general manner of attaching the fixed jaw to the base in Fig. 1. Slide *D*, therefore, operates in a suitable groove in this block, instead of in the base of the fixture itself. This steel block rides on two hardened steel wedges *W* which are fitted into the base on each side and provide the angular bearing surfaces by means of which the clamping part of the fixture is elevated.

After the proper vertical adjustment is obtained, the block *I* is fastened to the base of the fixture by screws and dowel-pins, as shown. The wedges extend beyond the travel of block *I*, and their ends are joined by a piece in which are carried the adjusting screw and lock-nut used in obtaining the adjustment. This raising or lowering of the block *I* carrying the clamping jaws can be readily effected by the

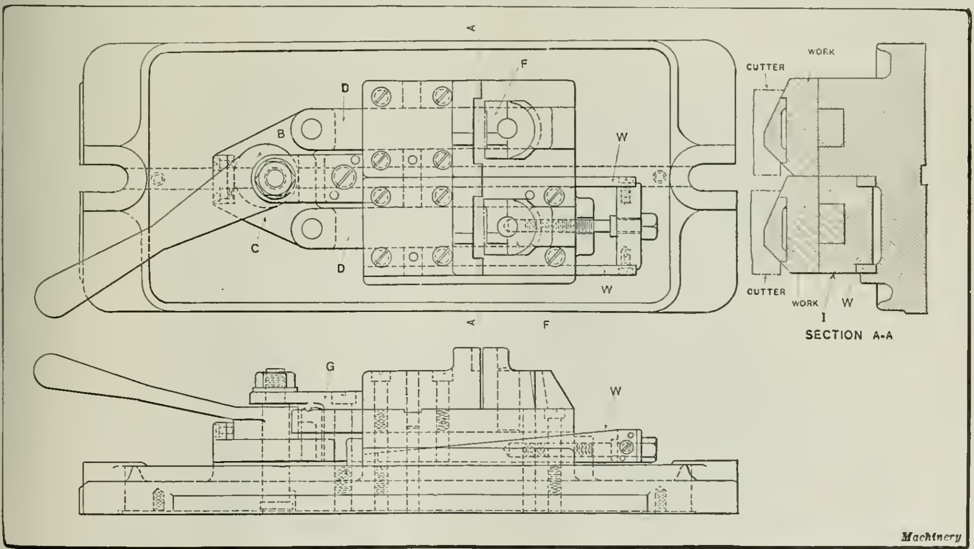

Fig. 3. Fixture Similar to that shown in Fig. 2, but with only One Cam for clamping the Work

simple means provided. The mounting of the jaw *F* is similar to that shown in Fig. 1, except that block *I*, instead of the base of the fixture, carries the stud *G* about which the jaw swivels. The eccentric lever *B* swivels on a stud attached to the base of the fixture and bears against steel pieces, similar to the construction employed in the fixture shown in Fig. 1 and in the stationary part of this fixture.

A somewhat lighter type of duplex milling fixture than that shown in Fig. 2 is illustrated in Fig. 3. The two sets of jaws are operated by a single eccentric lever, which enables a quicker clamping action to be obtained. This fixture also has one side designed to be independently adjusted in a vertical direction; the other side is stationary and designed according to the standards already outlined. In the design of this fixture the wedges *W* extend at the opposite ends of the steel block *I*, but are connected, similar to the construction employed in the fixture shown in Fig. 2, by a steel connecting piece in which the adjusting screw is carried. The two slides *D* are linked together by an equalizer *C*, which is free to swivel on the stud carrying the eccentric lever *B*, the latter being fixed in the base of the fixture. This equalizer is a yoke casting which, being free to swivel, enables the movable jaws *F* in each clamping unit to adjust themselves to any variation in the width of the work. The stud about which the eccentric lever swivels in clamping and releasing the work is reinforced at the top by a strap *G*, against the thrust exerted in operation. The other features of the fixture are the same as described in connection with the other two fixtures.

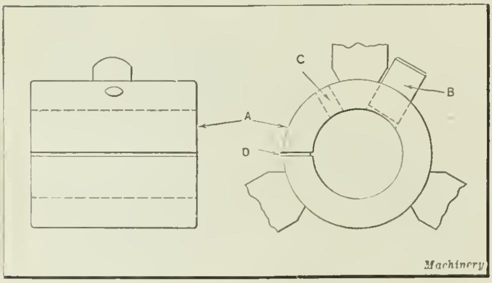
BRONZE BUSHING FOR STEADYREST

By H. H. PARKER

A bronze bushing *A* which can be clamped in the jaws of a lathe steadyrest, as indicated in the accompanying illustration, will prevent scratching or otherwise injuring the finished surfaces of spindles or shafts while facing their ends. When a large number of spindles of the same diameter are to be end-faced, this device is particularly useful, as it eliminates the necessity of placing pieces of flat leather or other material around the work to prevent the regular jaws of the steadyrest from scratching or marring the finished surfaces.

The bushing should be of bearing bronze, and reamed to fit the spindles or work to be faced. To prevent the bushing from rotating in the steadyrest jaws, a hole is drilled in the side and a brass stop-pin *B* driven tightly into this hole. The pin is brought up against the side of the top jaw and thus prevents rotation of the bushing. On the other side of the bushing, near the top, is located an oil-hole *C*. An oil-groove is also chipped out inside the bushing. When the bushing becomes worn it can be split, pressed together slightly, a bronze shim *D* fitted in the slot, and the hole again reamed to fit the work. After this treatment the steadyrest jaws will prevent the bushing from spreading, and it will be a good running fit on the work.



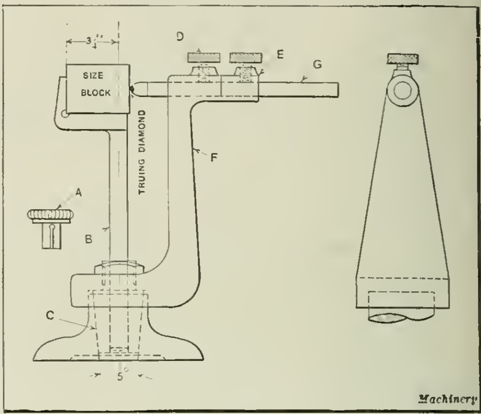
Bronze Bushing for Lathe Steadyrest

RADIUS WHEEL TRUING DEVICE

By WILLIAM C. BETZ

The device shown herewith is designed for truing the grinding wheels used in grinding beads or grooves on punches, dies, gages, and similar work. The fixture is made of tool steel, the swivel stud and base being hardened, and the tapered hole and stud ground and lapped. As the tapered stud has a 5-degree included angle it will not wedge, but will always work freely and smoothly with just the proper amount of friction.

The fixture may be used for grinding wheels having either concave or convex faces by moving the diamond point either side of the center of the stud. The diamond point is moved back for truing a wheel having a convex face, and forward for a wheel having a concave face. To set the diamond to a given radius, the dust-cap *A* is removed and the gage-bar *B* inserted in the hole in stud *C*. A size block of the dimension of the given radius plus 3/4 inch is used in the case of a convex wheel face, and a block 3/4 inch in length minus the given radius for a concave wheel face. The proper size block is placed on bar *B* as indicated. It will be noted that gage-bar *B* is made with the face of the stop 3/4 inch from the center of the stud hole.



Device for truing Radius Grinding Wheels

In setting the device for a convex wheel face, screw *D* is tightened, thus binding the diamond-carrying rod in place. For a concave face, screw *D* is first tightened, after which collar *E* is held against the diamond rod holder *F* and fastened. Screw *D* is then loosened and the rod *G*, with the collar in place is drawn back to permit the removal of the gage-bar *B*. Dust-cap *A* is then replaced in the stud *C* and the diamond-carrying rod slid in to its original position with the collar against the holder *F*. Screw *D* is again tightened and the dresser is ready for service. It will be noted that the base of the device is designed for use on a grinder equipped with a magnetic chuck, but a base may be made to adapt it to any grinder using thin disk wheels.

* * *

A comparative summary of manufacturing conditions in the United States for the years 1919 and 1914, shows that there were 288,376 establishments in operation in 1919, as against 275,791 in 1914. The value of the products of these companies is placed at $61,588,905,000 in 1919 as against $24,246,435,000 in 1914. The value of automobiles increased from $503,230,000 in 1914 to $2,387,833,000 in 1919; cotton goods from $676,569,000 in 1914 to $1,877,919,000 in 1919; foundry and machine shop products from $866,545,000 in 1914 to $2,321,129,000 in 1919; iron and steel rolling mills from $918,665,000 in 1914 to $2,818,775,000 in 1919; woolen goods from $379,584,000 in 1914 to $1,053,875,000 in 1919.

Automobile Crankshaft Repair Work

Last of a Series of Three Articles on Automobile Repair Work

THE regrinding of crankshaft bearings is one of the most common jobs in crankshaft repair work. In the repair shop of Saucke Bros., Rochester, N. Y., the No. 4 Landis machine illustrated in Fig. 1 is employed for this kind of work. The illustration shows the regrinding of a Continental motor four-throw crankshaft, taken from a Republic truck. This machine carries two offset heads as a part of its regular equipment, which are provided with a graduated nut for roughly setting the chucks which the heads carry to agree with the throw of the crankshaft to be ground; a micrometer adjustment is used for obtaining the final settings. It will be noticed that the heads are counterweighted and also that the crankpin bearings being ground are supported by steadyrests from the front and bottom. The steadyrests carry maple bearings in contact with the surfaces to be ground so that there is no possibility of abrasion due to the revolving crankshaft.

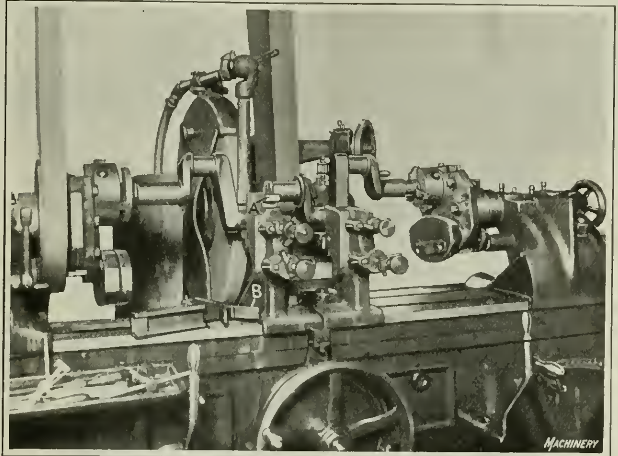


Fig. 1. Crankshaft Regrinding Machine set up for refinishing Crankpin Bearings on a Four-throw Crankshaft

The crankshaft is placed in the chucks of the offset heads after the chucks have been approximately adjusted to suit the throw of the crankshaft, but the chucks are not tightened on the end bearings until the throws are aligned with the centers of the machine. For obtaining this alignment a centering gage which is part of the regular equipment furnished with this type of machine is employed. This gage is shown lying on the ways of the machine to the left of the steadyrest bracket, and is used in the following manner. The gage is made to slide on the top guide *A* of the foremost steadyrest bracket, and when in this position a post carrying a V-block *B* at its lower end is permitted to drop down and engage the bearing of the crankshaft that is to be ground. Then by the use of a feeler 0.001 inch thick the amount of adjustment required to obtain perfect alignment is determined. When the centers of the throws are in alignment with the machine spindles, the chuck jaws are tightened and the wooden steadyrest bearings brought into contact with the crankpin bearing.

In this particular case the throw is 5¼ inches, and it was found that the greatest depth of score was 0.012 inch. In machining the rough surfaces of the bearing, 0.019 inch more stock was removed than was required to clean them up; in other words, 0.031 inch of metal was removed.

It is good practice on crankshaft work first to test the alignment on a lathe, using an indicator, and then if necessary straighten on an arbor press. The shaft should be within 0.007 inch of alignment before grinding. The crankpin bearings must not only be ground to uniform diameter, but they also must not vary more than 0.0025 inch between ends, that is, they must not be tapered. If this condition is found to exist it can be readily remedied by simply turning the entire table to compensate for any slight taper. The table pivots on a central pin, and the proper adjustment can be obtained by means of a graduated scale at the foot end of the machine. The wheel used in this shop for crankshaft regrinding is a 24-inch wheel of proper face width to agree with the length of bearings being ground. This wheel is the regular Landis 246 shape, grade K, and is made by the Abrasive Co., Philadelphia, Pa. The time required for the job illustrated is as follows: Setting up, about 1½ hours; grinding the four crankpin bearings, about 2¼ hours; and grinding the three main bearings, about 1¾ hours.

It is sometimes necessary to repair the end bearing of a crankshaft which has been broken or twisted off, and Fig. 2 shows a job of this kind being performed in the Frostholm Bros. plant at Syracuse, N. Y.

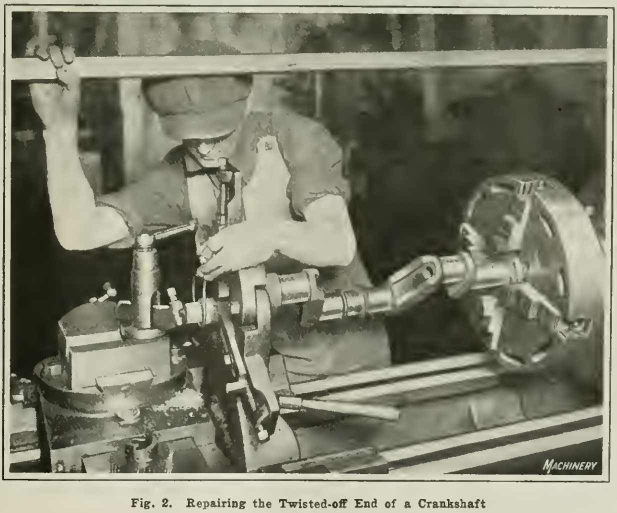

Fig. 2. Repairing the Twisted-off End of a Crankshaft

The machine used is a Whitcomb-Blaisdell engine lathe in which the shaft is chucked by the flywheel flange and supported at the overhanging end by a steadyrest. This is a Duesenberg motor four-throw crankshaft, which has previously been built up on the end by acetylene gas welding. The work illustrated is simply that of turning the welded end to the proper diameter.

METHOD OF FILING REFERENCE PRINTS

By T. H. MORIARTY

In a certain plant the practice of using tracings for reference resulted in many valuable tracings being damaged. In order to overcome this trouble Van Dyke or brown prints of all tracings in common use for reference were made up and folded twice. Each print was placed in a commercial mailing envelope, 13 by 19 inches in size, and the number of the print was blue-penciled in large figures near the top center of each envelope. The envelopes were then filed numerically in a wooden box, which was made for the purpose.

A draftsman, instead of referring to the tracing, would then use the print. Before removing the print, he would write his name on the envelope, and on the return of the print the name would be crossed off. This method is so simple that no filing clerk is necessary, and little difficulty is experienced through draftsmen forgetting to sign their names when removing prints from the file. When the tracings are revised, new prints are automatically supplied to replace the old ones. This system has been in use for over a year and has resulted in a great saving, as no original tracings are worn out through excessive handling. A saving in time is also effected, as there is no waiting for tracings to be returned from the blueprint room.

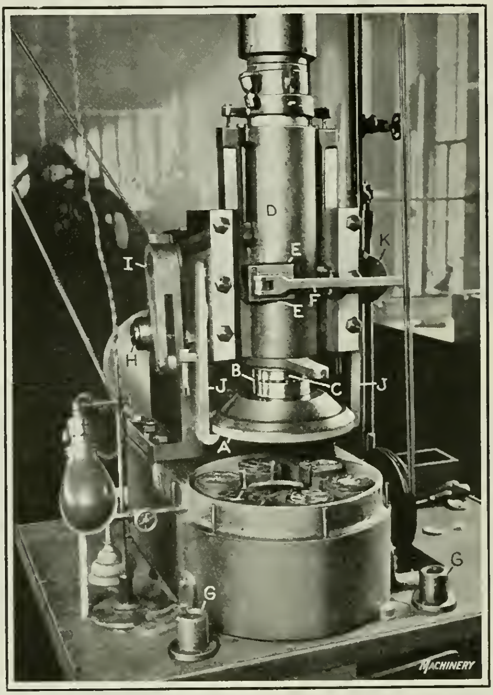
EXPORTS OF MACHINERY DURING 1921

The Industrial Machinery Division of the Department of Commerce, in a special review of the machinery export situation, points out that during the first eleven months of 1921 the United States exported machinery of all kinds to a value of $238,000,000 as against $92,300,000 for the entire year of 1913. While official figures for the entire calendar year of 1921 are not yet available, it is believed that $250,000,000 is a conservative estimate of the total value for the year. The foreign trade in metal-working machinery for the year ended June 30, 1913 was $16,097,315, and for the year ended June 30, 1914, $14,011,359. For the first eleven months of 1921 the total exports of metal-working machinery amounted to $18,766,962 of which $8,468,440 represented machine tools. In comparing the exports for 1921 with the pre-war exports, it should be remembered that the prices in 1921 were nearly double the prices in 1914, so that the relative volume is not in direct proportion to the figures given.

WATCH PLATE STONING MACHINE

A rotary grinding or stoning machine used to finish the surfaces of watch plates in the plant of the Waltham Watch Co., Waltham, Mass., is shown in the accompanying illustration. This machine was developed by A. G. Cassidy, master mechanic of the Waltham Watch Co. The stoning operation is performed with a ring lap *A*, and this lap is carried on a spindle which has a shoulder at *B*, the top surface of which forms the lower raceway for a ball bearing. The upper raceway of the bearing is the lower end of a sleeve *C* through which the main part of the shaft extends. This shaft projects up beyond the beams to which the countershaft is hung, and at the upper end is connected by a clutch to the bevel gear shaft from which it is driven.



Watch Plate Stoning Machine

The vertical feed of the spindle is actuated by air pressure, the air cylinder being located above the countershaft beam. The sleeve through which the spindle operates is contained in the cast-iron bearing *D*. This bearing has an opening at *E* through which a clamping lever *F* passes, by means of which the vertical position of the sleeve and the shaft which carries the lap can be adjusted following each operation to compensate for wear on the face of the lap.

The chucks, of which there are six, rotate slowly during the grinding operation. The machine is operated by air, as previously stated, it being necessary to use both hands on the valves *G* when starting the machine, thus safeguarding against danger to the operator's hand. As soon as the air valve governing the feed movement has operated, shaft *H* which carries the feed-cam is revolved and the arm *I* feeds the entire spindle-bearing unit downward; after the work has been ground to the desired thickness, the lap and the spindle are raised. When the unit has reached its uppermost position and the air valve which controls the feed movement has been closed, the plunger in air cylinder *K* releases lever *F* and allows the sleeve to slip downward and be relocated by the fingers *J* which hang on opposite sides of the spindle slide. These fingers are operated by an air plunger at the top end immediately preceding the release of the spindle sleeve.

As soon as this vertical adjustment has been made, the plunger in air cylinder *K* again advances and holds the sleeve firmly in its new position in bearing *D;* then fingers *J* swing out from under the lap. The release of the clamping section of bearing *D* is by springs interposed in back of the section between the opening for the clamping lever. The various movements just described are all governed by cam-operated air valves in the base of the machine.

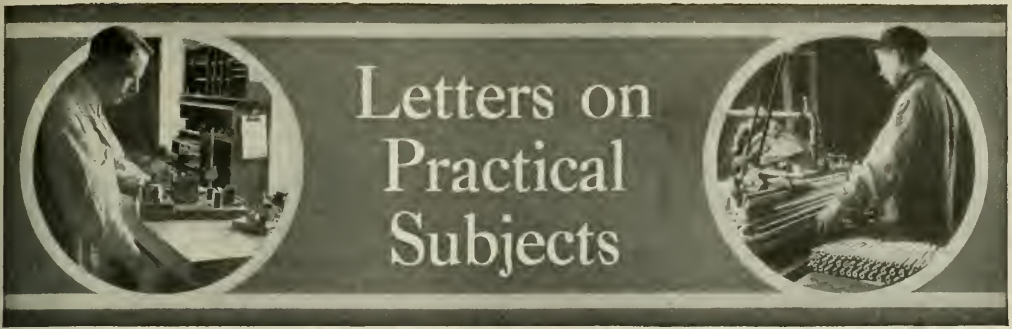
A bulletin on the manufacture, properties, and uses of aluminum alloys is being prepared for publication by the Pittsburg Experiment Station of the United States Bureau of Mines.



COLD RIVETS FOR ELECTRICAL APPARATUS

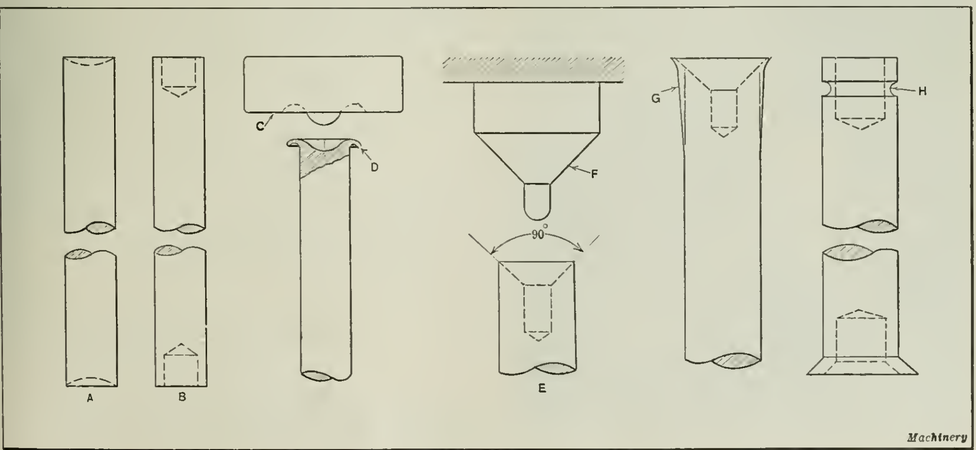
The type of cold rivet usually employed in the manufacture of laminated iron pole-pieces for electrical apparatus is shown at *A* in the accompanying illustration. These rivets are made slightly concave at each end so that they may be readily headed by a pneumatic hammer. Five or six rivets are needed, as a rule, for each pole-piece, and from 100 to 200 blows of the pneumatic hammer are required to head each rivet properly, the number of blows depending on the size of the rivet. This is a very slow process, and the cost of replacing worn and broken parts of the pneumatic hammer is considerable. At *B* is shown a rivet with a drilled hole at each end. The holes are drilled about 1/4 inch deep and of such diameter as to leave a wall from 1/16 to 5/32 inch thick, depending on the size of the rivet. Rivets of this design can readily be upset on both ends at one operation in a hydraulic press by equipping the upper and lower dies with hardened steel buttons like that shown at *C*. The shape of the head after compressing is shown at *D*.

A 1/2-inch rivet, such as shown at *B*, having a wall thickness of 5/64 inch requires an upsetting pressure of three tons. Using five rivets to a unit, the pressure required for the upsetting operation would be fifteen tons. Allowing a pressure of six tons for compressing the laminations, the total pressure for the whole operation would be only twenty-one tons. It will be evident that this method of assembling will effect a considerable saving.

Cold rivets for other purposes are often machined as shown at *E*. The upsetting of these rivets is also accomplished by means of hydraulic pressure. This type of rivet is used in nearly all small motors having laminated iron fields and malleable iron frames. A 3/4-inch rivet of this design requires a 27-ton pressure for upsetting at its ends. This high pressure is necessary because of the 90-degree taper *F* on the punches. As the pressure is applied these rivets have a tendency to expand in the field frame before the heads are formed. This incorrect design of rivet as shown expanded at *G* prevents the two frames from closing in tightly on the laminations. It also causes a great loss in hydraulic power. With this process a pressure of about 250 tons is required to compress one unit of four rivets.

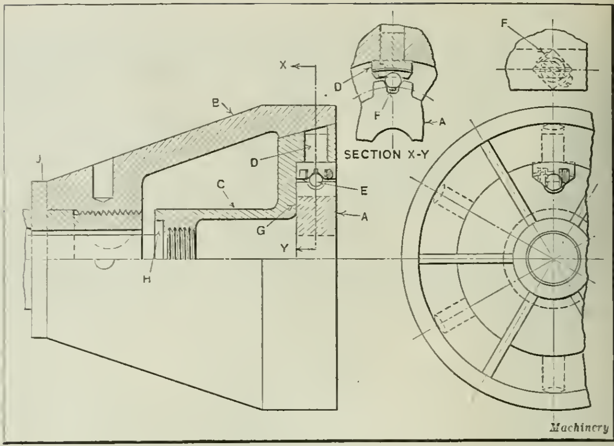
Using the method illustrated at *D* and calculating the pressure required to head the four rivets as $4 \times 27 = 108$ tons, allowing an additional pressure of 12 tons for compressing the field laminations, the total pressure would be 120 tons. The process illustrated at *D* is therefore shown to be more economical, as it requires 130 tons less pressure than when using rivets like that shown at *E*. A 3/4-inch rivet like the one shown in the diagram at *B* could be upset with a pressure of 9 tons. Four rivets would consequently require a pressure of 36 tons. By allowing an additional pressure of 12 tons for compressing the field laminations, a total pressure of 48 to 50 tons would be required instead of 130 tons. Rivets of the type shown at *H*, with grooves cut at the bending points, are preferable for castings with frail frames, although not absolutely necessary. The grooves prevent the rivet from expanding below the head as is the case with the rivet shown at *G*. It will be seen from the foregoing that it is often possible to employ a lighter weight casting by selecting the type of rivet best adapted for the work at hand, and at the same time to effect a reduction in the cost of manufacture and in the expense for tool equipment.

East Orange, N. J. JOHN E. UNGER



Various Designs of Cold Rivets used for Electrical Apparatus

CHUCK FOR SPIRAL GEARS



Chuck designed for locating and holding Spiral Gears

The special chuck illustrated is designed for locating and holding a spiral gear that is required to have the shaft hole ground concentric with the pitch circle. The spiral gear (a section of which is shown at *A*) has a pitch diameter of approximately 4 inches, a 45-degree left-hand spiral, and teeth of 6 diametral pitch. The chuck may be referred to as a "ball-control" type, because steel balls, brought into contact with the teeth at points near the pitch circle, serve to locate the gear and hold it tightly in place. As this chuck has proved capable of accurate work, and can be adapted to nearly all internal grinding machines, it may be of interest to those who have work of a similar nature. The chuck consists essentially of a heavy cast-iron body *B*, which is screwed on the spindle of the machine, and a spring collet *C*, which is split to suit the number of teeth in the gear. The collet carries the ball-holders *D*, which are located between the slots in such a position that the balls *E* come in contact with the gear teeth as indicated.

The ball-holders are made of square stock and have round shanks machined at one end as shown. These holders also have a V-slot cut across the corners in their squared heads, which serves to locate the balls and transmits the required inward clamping movement when the chuck is tightened. The balls are held in holders *D* by small steel straps *F* in such a manner that they are permitted to roll a limited distance in the V-slots in holders *D*.

A rolling or rotary motion is imparted to the gear when inserting it in the chuck. The gear is held against face *G* by the grinding wheel spindle until the collet is drawn up by means of the draw-bar *H*, which is actuated by a handwheel at the end of the machine spindle *J*.

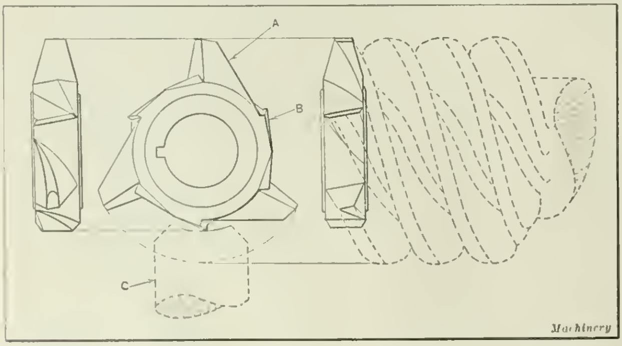
Pittsburg, Pa. WILLIAM OWEN

CUTTING WORM-WHEELS WITH A SPECIAL INVOLUTE CUTTER

It is customary, in shop practice, to use a fly cutter in cutting sample worm-wheels. In using this method to cut worm-wheels having multiple threads, considerable care is required to insure accuracy in the lead and pitch of the threads. In the accompanying diagram is illustrated a unique method which was used successfully in cutting a triple-thread worm-gear. Instead of the usual fly cutter, a regular No. 1 four-pitch involute gear-cutter was used, being ground in such a manner as to leave six teeth, three of which were ground like the one shown at *A* to fit a No. 1 worm pitch gage, and the remaining three, as shown at *B*, like a milling cutter used for milling flat work.

A 3-inch diameter, 1-pitch, left-hand triple-thread worm, with a lead of 3 inches is shown in dotted lines at the side of the milling cutter to make clear the action of the cutter. The three teeth *A* are equally spaced, and there is one tooth for each of the triple threads. As one tooth of the cutter takes a cut and leaves the tooth space of the worm-wheel, the next cutter tooth enters the succeeding tooth space of the worm-wheel being cut. The three teeth which are ground down as shown at *B* are for the purpose of cutting the proper clearance radius at the top of the worm-gear teeth. A section of the worm-wheel which is to be cut is shown by the dotted lines at *C*. The three equally spaced teeth *A* are ground circularly to the same diameter as the worm to be used with the worm-wheel, plus an amount equal to 0.1 times the linear pitch of the worm, in order to provide the necessary clearance. A regular cutter grinder was employed to grind the sides of the teeth *A* to fit the 29-degree worm thread gage. Care was taken to obtain the correct lead and the proper helical and radial angles, and to insure the correct clearance for a 1-inch pitch, 3-inch lead hobbing cutter, as well as to grind the three teeth *B* to the proper size for cutting the worm-gearing to the correct throat depth. It required a little less than ten hours to grind the cutter.

The cutter was mounted on the spindle of a regular hobbing machine, care being taken to have the center of the cutter teeth on a radial line passing through the center of the worm-gear. As the cutter had a tooth for each thread, it was unnecessary to reset the cutter for each lead. The worm-wheels had thirty-three teeth in this case and as three tool settings would have been required had a fly cutter been employed, it can be clearly seen that it would have been difficult to obtain great accuracy with the fly cutter method. It was found that the same feeds as used with a regular hob could be employed when using the reground involute cutter.

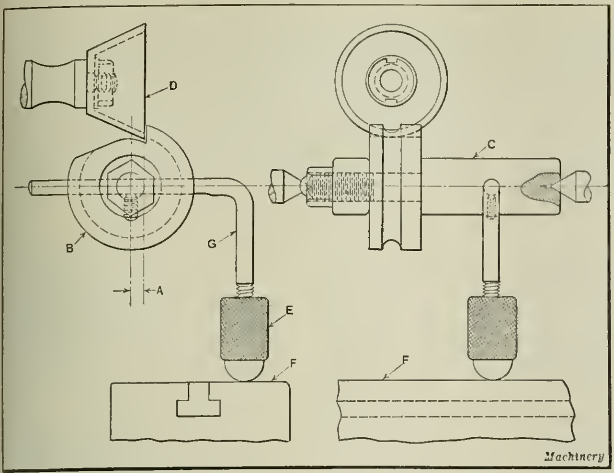


Use of a Specially Ground Involute Cutter for cutting Worm-wheels

Cleveland, Ohio J. E. BAKER

MANDREL FOR GRINDING CIRCULAR FORMING TOOLS

The mandrel shown at *C* in the accompanying illustration is intended primarily for holding circular forming and cutting-off tools while grinding their cutting edges on a toolroom grinder. Ordinarily the cutting edge or



Use of Mandrel for holding Circular Forming Tools while grinding

face of a circular forming tool is milled back from the center line of the cutter a predetermined distance *A*, in order to obtain a better cutting action. A circular cutter of the type shown at *B* is held on the mandrel by means of a collar and hexagonal nut. When performing the grinding operation, mandrel *C* is held between the centers of the grinding machine.

The grinding machine saddle is adjusted until the face of the grinding wheel *D* extends beyond the vertical center line of arbor *C*, the required distance *A*. The knurled adjusting nut *E* is then allowed to come in contact with the top surface *F* of the machine table. Nut *E* is tapped to fit on the threaded end of the bent rod *G* and prevent it from working loose after adjustment. The forming cutter can be revolved toward the working face of the grinding wheel after each cut, by adjusting knurled nut *E*. This method of feeding the work to the grinding wheel serves to keep the distance *A* practically constant. Very slight variations due to the wearing down of the grinding wheel face, however, may occur, but these can easily be compensated for by resetting the grinding wheel.

Conneaut, Ohio F. A. Gross

ASSIGNING DRAWING NUMBERS

In a certain drafting-room each new drawing was assigned a new number in rotation, and as there were a large variety of machines and tools, it was finally decided to make the numbers of all drawings for each job run consecutively. Accordingly it became the practice for each draftsman working on a separate design, to reserve a group of numbers for that particular job, marking the reservation in pencil upon the record book, and being sure to reserve enough numbers to more than cover the number of drawings needed.

This practice led to confusion in some cases, as there was sometimes a blank space of numbers left that were never used, and there was also a tendency to use the same number twice, if anyone failed to mark down a number taken for a small job. To avoid this confusion, it was decided to let the filing clerk keep the drawing record, and make him responsible for the assignment of all drawing numbers. At the same time each draftsman was to be allowed to take as large a group of numbers as he believed would be required for his job.

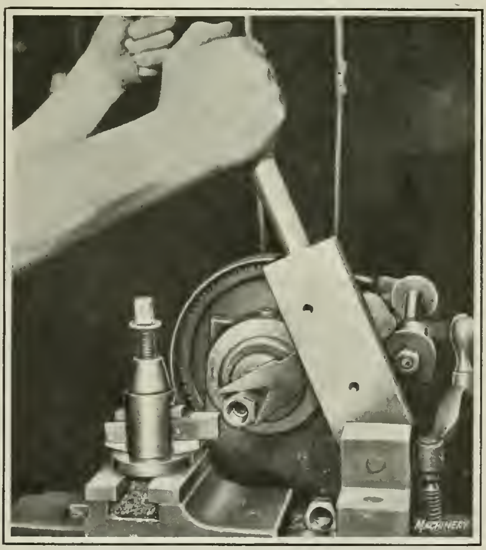
The clerk, instead of directly marking down the name of every drawing for which he assigned a number, took a bunch of old cards from which he made tickets, keeping a hundred or more in reserve. On each of these tickets he marked one of the numbers that followed in rotation, and then looking back over the record, found all the blank numbers that had not been assigned, and made tickets to correspond with them. Whenever a draftsman desired to reserve a group of numbers, he would receive as many tickets as there were numbers wanted, always seeing that the numbers handed out for one job were in consecutive order. The draftsman receiving these numbers would hold the tickets until the job was complete, marking down the title and subtitle of each drawing, with such other information as was to be recorded, on the ticket. When the work was finished, and no more drawings were to be made for that job, the whole group of tickets was returned to the clerk, who entered them on the permanent record, leaving all the blank numbers so returned, to be reissued at the first opportunity.

If a small job came in, the smallest group of consecutive numbers that could be used was issued, and if a very large job was begun, the group was issued from entirely new numbers. The tickets were so kept that it was easy to find a group of numbers that would just about suit the size of the job to be provided for. This was done by keeping the tickets in a box with spacing cards between the groups.

North Judson, Ind. William H. Kellogg

FACING NUTS SQUARE WITH THREAD

It is not always a simple matter to devise a satisfactory and economical method of facing nuts so that their finished faces will be square with the threads, or in other words, so that the face of each nut will be at right angles to the axis of its thread. If a plain threaded arbor is inserted in the lathe spindle and the nut screwed on this arbor and tightened up against a shoulder while being faced, the work will vary considerably in accuracy. If the back face of the nut is at right angles to the thread, the front face will usually be finished true; but if the back face is not square with the thread, the front face will also be out of square when finished. In order to eliminate this trouble and obtain



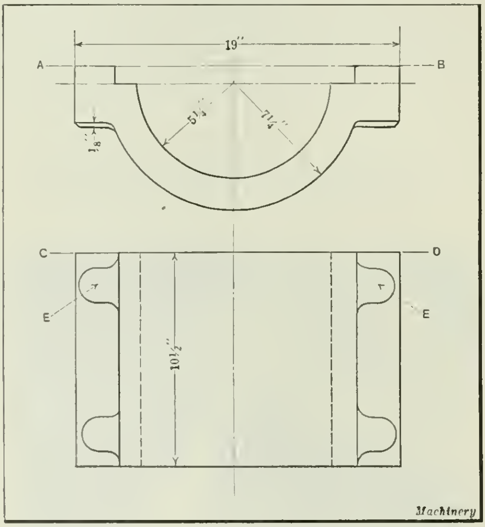
Device for removing Nuts from Threaded Arbor more accurate results, an arbor was made with the threads at the low limit pitch diameter for a length equal to three-fourths of the thickness of the nut, and from this point tapered 0.020 inch per inch for a distance of from four to six threads. The nut can be assembled on this arbor while the machine is in motion. When it reaches the tapered part of the thread on the arbor it locks tight enough to permit a light cut to be taken on the face. The nuts faced while held on this arbor were found to be true within 0.002 inch, when tested with an indicator. However, it was a difficult matter to remove the finished nut from this arbor by means of a hand wrench.

The accompanying illustration shows clearly the method adopted for removing the nuts, which enables the work to be done rapidly and without danger to the operator. With this device the operator reverses the machine with one hand while he operates the nut remover with the other. It will be seen that the device consists simply of an elongated wrench attached to a lever in such a manner that it can be quickly brought forward to grip the work.

Clio, Mich. CHARLES E. HENDRICKS

MOLDING A LARGE BEARING CAP

The breaking of a cast-iron bearing cap of the dimensions shown necessitated supplying a new casting at once. Accordingly, a pattern was made and sent to the foundry with an order to deliver two castings as soon as possible. The molder knew that it would take time to provide sand bars or gaggers that would properly support the body of hanging sand in the cope flask if the mold was made in the customary manner with *AB* as the parting line between the cope and the drag. Consequently, he removed the four bosses *E* from the pattern, leaving it plain and straight so that it could be molded on end in a plain drag and flat cope, with the cope parting on line *CD*.



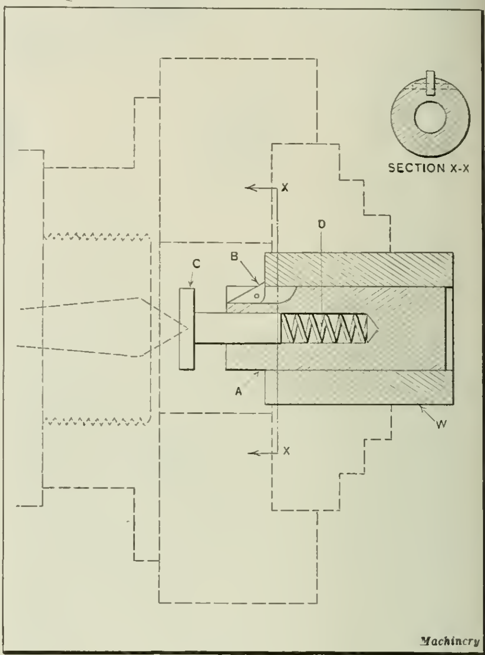
Bearing Cap molded in Upright Position

Kenosha, Wis. M. E. DUGGAN

LENGTH GAGE

The machining of the work or bushing shown at *W* in the accompanying illustration was greatly facilitated by the use of the special gage shown. The work was to be left rough on the outside, but was required to be bored, reamed, and faced on both ends at one chucking. The final facing operation was required to finish the work to a predetermined length. A 14-inch three-jaw chuck, indicated by dotted lines, was employed to hold the work, which was about 4 inches long and 3 inches in diameter.

The gage consists of a cylindrical member *A*, which is made a good sliding fit for the reamed hole in the work; a triangular shaped stop *B* pivoted in a slot cut in part *A*; a plunger *C*; and a compression spring *D*. In chucking the work, care is taken to see that the inner end projects beyond the inner surfaces of the chuck jaws a sufficient distance to permit the use of a back-facing tool.



Gage employed in facing Bushing to Length

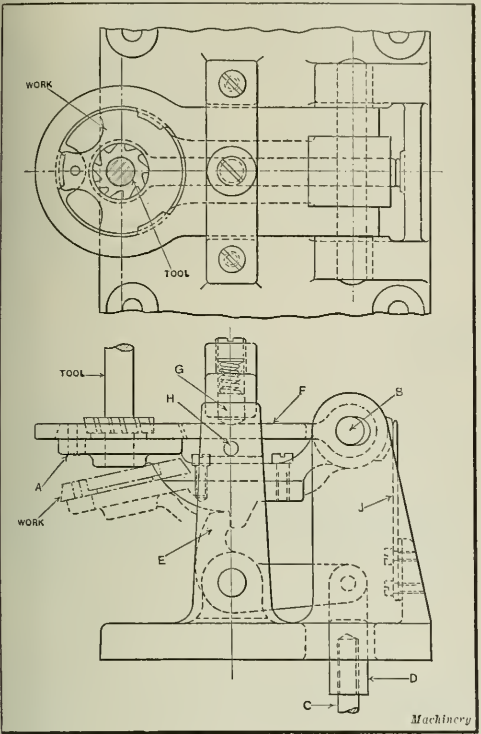
After boring and reaming the work to the required size, the inner end is faced off with the back-facing tool. The gage is then slipped into the reamed hole and pressed inward against the action of spring *D* until the pivoted triangular stop *B* passes the faced end of the work and assumes the position shown in the illustration. It is evident that the stop, when in this position, will prevent any outward movement of the gage, and that spring *D* will hold it in place while the outer end of the work is being faced. The distance from the perpendicular face of stop *B* to the outer end of part *A* corresponds to the length of the finished work. Therefore, a facing tool can be easily set for the final finishing cut by bringing it up until it just makes contact with the end of part *A*.

Rosemount, Montreal, Canada HARRY MOORE

PEDAL-OPERATED DRILL JIG

A drill jig or fixture which permits a high rate of production, and which may be adapted for drilling, tapping, and counterboring, is shown in the accompanying illustration. The locating nest or plug *A* is dropped to the position shown by the dotted lines to facilitate loading and unloading. Part *A* pivots on the pin *B*, and is operated by a foot-pedal through the connecting-rod *C*, yoke *D*, and operating cam *E* which is shown in the raised position. The cam *E* is released by a spring under the bench, allowing the locating nest to drop when pressure is removed from the foot-pedal.

The work is clamped by the upper plate F which is acted upon by spring plunger G. A stop-pin H limits the upward travel of part A. The flat spring J absorbs the slight shock resulting from returning the work-table to the operating position, and thus prevents undue wear of the elongated pivot hole. This type of drilling fixture can be designed with interchangeable locating nests and bushing plates, and



Drill Jig operated by Foot-pedal

when so equipped will be found convenient for a large variety of drilling machine work. A special counterboring tool is shown in the operating position in the illustration.

Waynesboro, Pa. D. A. Nevin

JIG FOR DRILLING COMPANION FLANGES

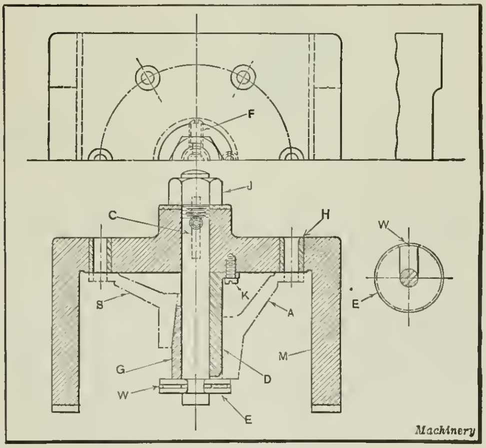
The jig shown herewith was designed for use in drilling six holes in each of two companion flanges. A half section of one flange is shown by heavy dot-and-dash lines at A, and a half section of the other at B. The two finished flanges are bolted together when in use. The holes in each flange must therefore be spaced the same and be of the same size. Being so nearly alike, it was found advisable to design a drill jig that could be used for both pieces. The jig body was made of a channel-shaped casting M in the top of which were pressed six drill bushings like that shown at H. The under side of the top section is finished to provide a locating pad for the flanged face of the work. In the center of the top is a boss of sufficient length to give the required bearing surface for the draw-bolt C, which is a sliding fit in the casting. The bottom of the jig body is finished and relieved, as illustrated, to give a four-point bearing on the drilling machine table.

Let us consider first the drilling of flange A. The hub of this flange has a straight reamed hole in it. The plug D is therefore used when drilling this piece. Plug D is a sliding fit on draw-bolt C, and the outside diameter is a slip fit in flange A. After loosening the nut J on the top of the draw-bolt, the work is placed on the plug and washer E slipped into place in the groove on the draw-bolt. The bolt is then drawn up by tightening the nut J, thus pulling the slip washer against the hub end and clamping the face of the flange firmly against the finished under side of the casting.

In draw-bolt C there is a slot into which enters the pivot end of set-screw F. This set-screw is a sliding fit in the slot and keeps the bolt from turning when the nut is tightened. As it requires but a fraction of a turn to release the bolt enough to permit the slip washer to be easily withdrawn, the slot need not be very long to allow the required adjustment. A small fillister-head screw K passing through the flange of plug D and screwed into the casting keeps the plug from turning while the work is being put in place, and also keeps the plug from being pulled off the draw-bolt when the work is withdrawn from the jig.

Flange B has a tapered hole in the hub. To adapt the jig to this piece, a tapered plug G having a slip fit over the draw-bolt and tapered on the outside to fit the hole in the hub of the flange is used. The length of this plug is such that when it is drawn into the hub, its lower end will be approximately the same distance from the locating surface of the casting as the end of the hub of flange A. In this case the slip washer is pulled up against the plug itself, which is drawn into the tapered hole when the nut J is tightened, thus centering the flange and drawing the face firmly against the locating surface.

As there was no six-spindle drill head available when this jig was first used, the drilling of each flange was done with a three-spindle drill head, which necessitated two operations. The three drills in the head were equally spaced and of the same length, so that they entered the work at the same time, thus bringing all the thrust on the draw-bolt nut. The plugs and the draw-bolt are of hardened steel. To avoid confusion, each plug is stamped to show the work for which



Jig for drilling Companion Flanges

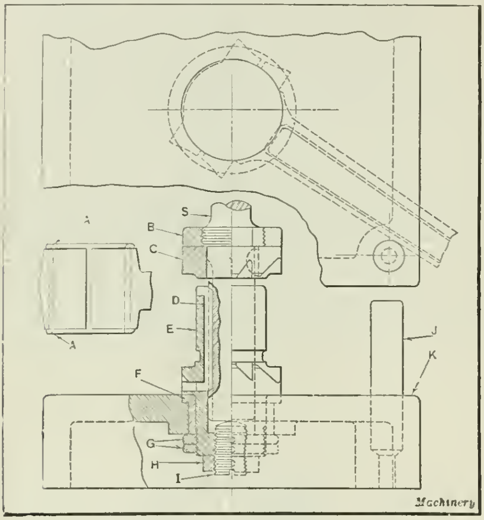
it is intended. When the jig is withdrawn from the tool-crib, the plug required for one piece only is given out. The other plug is left in the crib in the space provided for the jig itself.

To prevent loose parts from becoming lost while the jig is in the tool-crib, the plug D is left attached to the jig, but swung aside, using the screw K as a pivot so that plug G can be placed on the draw-bolt. Slip washer E has a groove turned on the outside into which is snapped a spring wire ring W. When the jig is in use, the wire is slid around until the opening between the ends is on the same center line as the opening in the washer, as shown in the assembly view. When the jig is in the tool-crib, this wire is slid around after the plug *G* is put in place so as to close up the opening in the washer as shown in the detail at the right. When the plugs *G* and *D* and the slip washer are put in place as described, there is little possibility of any parts becoming lost, as they are all assembled in one unit.

Pittsburg, Pa. CLARENCE M. SCHLEH

TOOL FOR FACING CONNECTING-ROD BUSHINGS

The facing tool shown herewith is used to finish-face both sides of a connecting-rod bushing and round the ends to the radii indicated at *A*. Referring to the illustration, *S* is a hardened and ground tool-steel member provided with a tapered shank. A right-hand, formed facing cutter *C* is pressed on part *S* and keyed to it with a Woodruff key as shown. The threaded collar *B* allows the cutter *C* to be removed in case of breakage, or for regrinding. The lower



Facing Tool for Connecting-rod Bushings

end of part *S*, which has a keyway cut in it, acts as a pilot for cutter *C* and as a driver for the lower left-hand cutter *E*. The upper part of cutter *E* is made a slip fit for the bore in the connecting-rod bearing.

A key *D*, pressed into a keyway in cutter *E* is made a slip fit in the keyway cut in *S*. The lower cutter *E* revolves in bushing *F* and is held in place by the lock-collars *G*. The adjustable stop *I*, locked by nut *H*, is set according to the width of the connecting-rod bearing. In operation, the tool body *S* with cutter *C* is withdrawn from the lower cutter *E* and the connecting-rod is placed in position on *E*. The tool body *S* is then lowered, and its pilot introduced for a short distance into *E*. The machine is next started and the upper cutter *C* is fed down until the bottom of the pilot on *S* strikes the stop *I*, thus completing the operation. A stop-plug *J*, pressed into the cast-iron base *K*, prevents the connecting-rod from revolving when the tool is in operation.

When both the cutters *C* and *E* are ground with the same clearance, they will remove the same amount of metal from the top and bottom of the bearing and will not chatter. As the bushings faced by this tool are of babbitt and brass, the cutters can be used a considerable time before requiring regrinding. This tool will hold the bearing width to within 0.0005 inch of the specified dimension.

Chicago, Ill. HAROLD A. PETERS

DETERMINING HEIGHT OF ARC WHEN MILLING KEYWAYS

Formulas for determining the height of arc *A*, Fig. 1, were given in December, 1920, MACHINERY on page 377, and in June 1921 on page 975. A formula similar to the ones given, but which the writer believes to be more convenient to apply is the following:

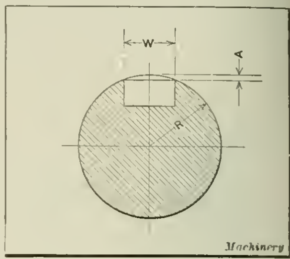


Fig. 1. Diagram used in finding Height of Arc

$$A = \frac{W}{2} \times \tan\frac{a}{2}$$

This formula is derived as follows: Referring to the accompanying illustrations,

$$\frac{\frac{1}{2}W}{R} = \frac{W}{2R} = \sin a;$$

$$b = 90 \text{ degrees} - \frac{a}{2}$$

$$\frac{A}{\frac{1}{2}W} = \cot b; \qquad A = \frac{W}{2}\cot\left(90 \text{ degrees} - \frac{a}{2}\right)$$

But as

$$\text{Cot}\left(90 \text{ degrees} - \frac{a}{2}\right) = \tan\frac{a}{2}, \text{ it follows that}$$

$$A = \frac{W}{2}\tan\frac{a}{2}$$

To use this formula, first find the sine of angle *a* by dividing the width of the keyway by the diameter of the shaft or hole. By consulting a table of trigonometric functions, the magnitude of this angle is found; then the tangent of one-half this angle is multiplied by one-half the width of the keyway. As an example let it be required to find *A*

when $W = \frac{7}{32}$ inch and $R = \frac{7}{16}$ inch.

According to the formula $A = \frac{7}{64}\tan\frac{a}{2}$

Then,

$$\text{Sin } a = \frac{W}{2R} = 0.25, \text{ and } a = 14 \text{ deg. } 29 \text{ min.}$$

Hence

$$\frac{a}{2} = 7 \text{ deg. } 14.5 \text{ min. and } \tan 7 \text{ deg. } 14.5 \text{ min.} = 0.12707$$

Therefore

$$A = 0.10938 \times 0.12707 = 0.01389$$

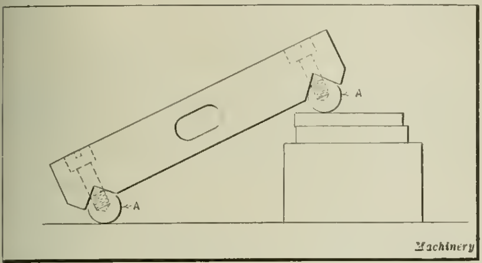
SHOP AND DRAFTING-ROOM KINKS

CONVENIENT SINE BAR

The accompanying diagram illustrates a sine bar which may be accurately and quickly set up by the use of gage-blocks. Two plugs *A* are held in the vees of the sine bar



Convenient Sine Bar

by means of fillister-head machine screws. These plugs project beyond one side of the sine bar a sufficient distance to permit the use of the latter in the same manner as one of the ordinary type. The construction is such that the sine bar can be readily made to the required accuracy, it being simply necessary to grind the vees after hardening in order to secure the desired distance between the two plugs.

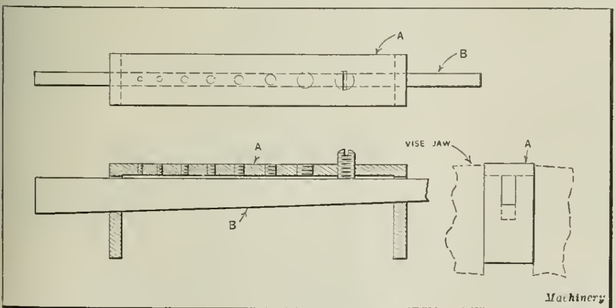
Rosemount, Montreal, Canada STANLEY ALMOND

HOLDER FOR SMALL SCREWS

Most mechanics find it difficult to hold small screws while slotting their heads, shortening them, rounding their heads, or performing any of the operations required to adapt them for various purposes. Holding them in the vise usually results in flattened threads and frequently the screw flies from between the vise jaws and is lost as soon as the file touches it.

A useful device for holding small screws can, however, be made as shown in the accompanying illustration. A device of this kind will well repay one for the time spent in making it. A piece of 1/8-inch steel is tapped for different sized screws along its center, and the ends bent down at right angles, forming the holder shown at *A*. Next a taper wedge *B* is made from the same stock. Two slots are then cut in holder *A* to accommodate this wedge. The piece *A* is held in the vise as indicated in the view at the lower right-hand corner of the illustration. A screw which is being operated upon is screwed into holder *A* until it projects on the under side. The wedge *B* is then lightly tapped into place, thus holding the screw securely.

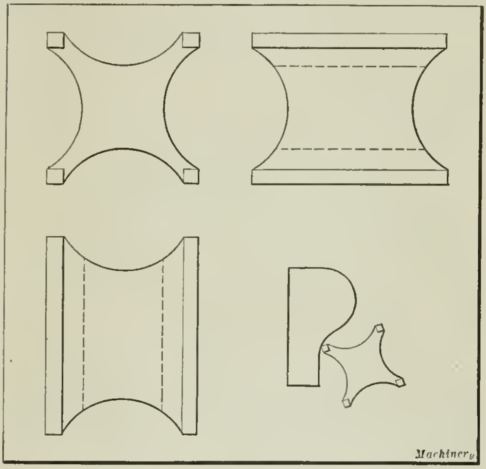
Rosemount, Montreal, Canada HARRY MOORE



Convenient Device for holding Small Screws

TEMPLET SCRAPER

In making templet and profile gages, it is often difficult to produce the working surface of the templet or gage with assurance that it will be exactly perpendicular to its parallel flat sides. This difficulty is caused mainly by the fact that much hand work is required in perfecting the profile of the tool. A scraping tool which will greatly assist in working down the contour surface of a templet or profile gage is shown in the accompanying illustration. This tool should be made of tool steel, and hardened and ground on all its working surfaces. It is used in the manner indicated in the lower right-hand corner of the illustration. The templet is laid on a surface plate, and the scraper, which will



Scraper for finishing Edges of Profile Gages and Templets, and Method of Use

always rest so as to bring the working edges absolutely perpendicular to the surface plate, used to scrape down all slight imperfections until the desired profile is obtained.

Ilion, N. Y. D. R. GALLAGHER

CUTTING KEYWAYS IN A BORING MILL

In the shop where the writer was employed, a 22-inch blower fan hub was to be rebored and resplined, and as there was no suitable keyseating machine for cutting the keyway, it was decided to perform the work on a 24-inch Bullard vertical turret lathe by making use of the vertical friction-driven head employed to raise and lower the turret slide. A standard boring-bar equipped with a high-speed steel tool bit, was used, and by taking light cuts the job was finished in a satisfactory manner.

New Britain, Conn. W. C. BETZ

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

DETERMINING ALTITUDE OF AN ACUTE-ANGLED TRIANGLE

A. A. G.—Will you please show how to find the distances x and y from the dimensions given in the illustration?

ANSWERED BY LEO LAUBMEYER, HAMILTON, MICH.

The following method of solving the problem stated requires only an elementary knowledge of trigonometry and

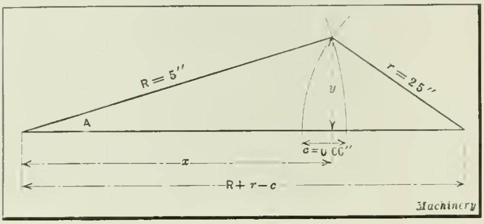


Diagram for calculating Distances x and y

the use of a table of trigonometrical functions. Referring to the illustration,

$$R + r - c = 5 + 2.5 - 0.66 = 6.84 \text{ inches}$$

According to trigonometry (see MACHINERY'S HANDBOOK, page 152)

$$\text{Cos } A = \frac{R^2 + (R + r - c)^2 - r^2}{2R\,(R + r - c)}$$

Substituting the known values and solving,

$$\text{Cos } A = \frac{5^2 + 6.84^2 - 2.5^2}{2 \times 5 \times 6.84} = \frac{25 + 46.7856 - 6.25}{2 \times 5 \times 6.84}$$

$\text{Cos } A = 0.9581228$ and $A = 16$ deg. 38 min. 24.8 seconds

$$\text{Sin } A = 0.28636$$

$$x = R \times \cos A = 5 \times 0.9581228 = 4.790614 \text{ inches}$$

$$y = R \times \sin A = 5 \times 0.28636 = 1.4318 \text{ inches}$$

[While this solution involves the use of trigonometrical functions, it requires less mathematical computations than the one given in September MACHINERY, page 61. A solution similar to the one here given was also submitted by George Warmington, Beverly, Mass.—EDITOR]

ANSWERED BY GEORGE H. SUESS, PHILADELPHIA, PA.

The writer believes that the following solution to the problem submitted by A. A. J. is simpler and involves less calculation than the one given in September MACHINERY on page 61. Referring to the illustration we have:

$$x + N = R + r - c = 5 + 2.5 - 0.66 = 6.84 \text{ inches}$$

Also the sum of the two shorter sides is:

$$R + r = 5 + 2.5 = 7.5 \text{ inches}$$

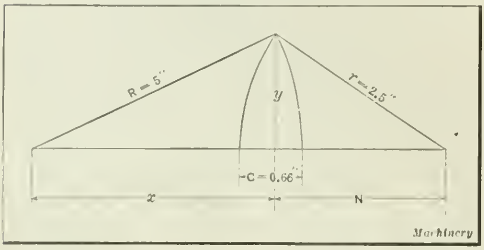

Diagram for determining Altitude y

and the difference between the two shorter sides is:

$$R - r = 5 - 2.5 = 2.5 \text{ inches}$$

Then

$$x + N : R + r :: R - r : x - N$$

or

$$6.84 : 7.5 :: 2.5 : x - N$$

Therefore

$$x - N = \frac{7.5 \times 2.5}{6.84} = 2.74123 \text{ inches}$$

According to arithmetic, if the sum of two numbers and their difference be given, the greater of the two numbers is equal to one-half the sum of their sum and difference.

$$x = \frac{(x + N) + (x - N)}{2} = \frac{6.84 + 2.74123}{2} = 4.79062 \text{ inches}$$

$$y = \sqrt{5^2 - 4.79062^2} = 1.43176, \text{ or } 1.4318 \text{ inches}$$

[Solutions similar to the one here given were also submitted by C. N. Pickworth, Manchester, England, and Herbert Bold, Ecorse, Mich.—EDITOR]

ANSWERED BY LEWIS D. CASTOR, ELIZABETHPORT, N. J.

This solution involves the application of a simple formula that is seldom given in handbooks, but which the writer has found useful in solving problems involving oblique triangles. Referring to the illustration, the formula is as follows:

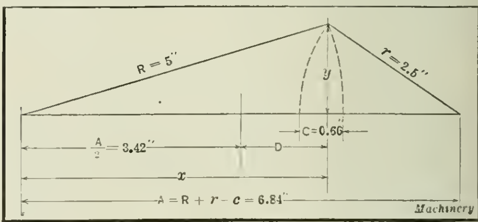

Diagram for determining Altitude of an Acute-angled Triangle

$$D = \frac{R^2 - r^2}{2A}$$

This formula is derived from the following equations:

$$\sqrt{R^2 - y^2} = \frac{A}{2} + D \qquad (1)$$

$$\sqrt{r^2 - y^2} = \frac{A}{2} - D \qquad (2)$$

Squaring both sides we have,

$$4R^2 - 4y^2 = A^2 + 4AD + 4D^2 \qquad (1)$$

$$4r^2 - 4y^2 = A^2 - 4AD + 4D^2 \qquad (2)$$

Subtracting (2) from (1) we have,

$$4R^2 - 4r^2 = 8AD \text{ or}$$

$$R^2 - r^2 = 2AD$$

$$D = \frac{R^2 - r^2}{2A}$$

Substituting the numerical values of the given problem.

$$D = \frac{25 - 6.25}{13.68} = 1.37061 \text{ inches}$$

$$x = 3.42 + 1.37061 = 4.79061 \text{ inches}$$

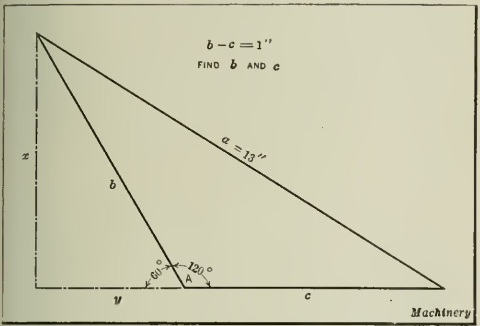
$$y = \sqrt{R^2 - x^2} = \sqrt{25 - 22.9441} = 1.4318 \text{ inches}$$

DETERMINING THE LENGTHS OF TWO SIDES OF AN OBLIQUE TRIANGLE

H. W. P.—The accompanying illustration shows an oblique triangle in which the difference between the lengths of sides b and c = 1 inch; the length of side a = 13 inches; and angle A = 120 degrees. How can the lengths of sides b and c be found?

ANSWERED BY J. W. JONES, CLEVELAND, OHIO

In the following are given two solutions, both of which the writer believes are simpler than that presented on page 238 of November MACHINERY. It will be noted that a well-known formula in trigonometry is employed in the first solution.



Oblique Triangle in which the Difference between Sides b and c, and Angle A are known

Solution by Trigonometry

Referring to the accompanying illustration:

$$a^2 = b^2 + c^2 - 2bc \cos A$$

Now as $\cos A = -\frac{1}{2}$, we have $a^2 = b^2 + c^2 + bc$

According to the conditions of the problem, $b = c + 1$. Therefore

$$a^2 = c^2 + 2c + 1 + c^2 + c^2 + c = 169$$

Then

$$c^2 + c = 56 \text{ and } (c + \tfrac{1}{2})^2 = 56\tfrac{1}{4} \text{ or } 225 \div 4$$

and

$$c + \tfrac{1}{2} = \frac{15}{2} = 7 \text{ inches and } b = 7 + 1 = 8 \text{ inches}$$

Solution by Geometry

Referring to the accompanying illustration, $x^2 + y^2 = b^2$; $y = \frac{1}{2}b$; and $b = c + 1$.

Further

$$a^2 = x^2 + (c + y)^2 = x^2 + c^2 + 2cy + y^2$$

and

$$a^2 = b^2 + c^2 + 2cy = c^2 + b^2 + cb$$

Then by substitution

$$a^2 = c^2 + c^2 + 2c + 1 + c^2 + c = 3c^2 + 3c + 1 = 169$$

Thus

$$c^2 + c = 56 \quad \text{and} \quad c^2 + c + \tfrac{1}{4} = 56\tfrac{1}{4} = 225 \div 4$$

and

$$c + \tfrac{1}{2} = \frac{15}{2} = 7 \text{ inches; } b = 7 + 1 = 8 \text{ inches}$$

FINISHING HANDWHEEL RIMS

B.—What method is employed in finishing the rims of machine handwheels?

A.—Ordinarily this operation is performed by turning on a lathe, followed by polishing, although the use of a rotary milling machine and a formed milling cutter is considered by some to be superior to turning. In one shop the polishing is done by spinning the handwheels on an arbor held by the hands, against a fabric wheel which is provided with a facing of abrasive. The surface speed of the rim is slackened to less than that of the buffing wheel by pressure against the workman's leather apron.

VOLUME SOLVED BY PAPPUS OR GULDINUS RULES

F. F.—Please show how to find the volume of the solid shown in the accompanying illustration, any cross-section of which, perpendicular to the axis, is circular. Length c = 18 feet, and the middle diameter d = 20 inches.

ANSWERED BY W. W. JOHNSON, CLEVELAND, OHIO

A.—Referring to the illustration, this solid is produced by the revolution of the segment of a circle XYZ about its chord XZ. The volume of any solid of revolution may be found by means of the Pappus or Guldinus rules given on page 144 in MACHINERY'S HANDBOOK.

Thus

$$V = 2\pi m A \qquad (1)$$

in which

V = volume of the figure;
A = area of segment XYZ; and
m = distance from the axis of revolution to the center of gravity of segment XYZ

The area of a segment of a circle is found by the formula

$$A = r^2(\alpha - \sin\alpha \times \cos\alpha) \qquad (2)$$

In this case,

$$r = \frac{c^2 + 4h^2}{8h} = \frac{46656 + 400}{80} = 588.2 \text{ inches}$$

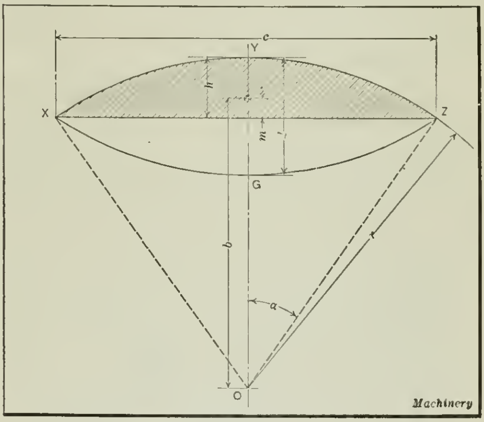


Diagram used to illustrate Method of calculating the Volume of a Solid of Revolution

$$\sin\alpha = \frac{c}{2r} = \frac{216}{1176.4} = 0.183611$$

$$\alpha = 10 \text{ degrees } 34 \text{ minutes } 49 \text{ seconds}$$

$$\alpha \text{ (in radians)} = 0.1846586$$

$$\cos\alpha = \frac{r - h}{r} = \frac{588.2 - 10}{588.2} = 0.982999$$

Inserting the numerical values in Formula (2), we get

$$A = 1442.46 \text{ square inches}$$

The distance from the center O to the center of gravity of the segment is obtainable by a formula given in MACHINERY'S HANDBOOK on page 267 which is as follows: $b = c^3 \div 12A$, from which we find b = 582.20539 inches.

Now

$$m = b - (r - h) = 4.00539 \text{ inches}$$

Inserting the numerical values for m and A in Formula (1), we find the volume of the solid to be 36,302 cubic inches or 21 cubic feet.

The Machine-building Industries

THERE are definite indications of a gradual resumption of activity in the machine-building industries and of a revival in buying of manufacturing equipment and tools. One of these indications is that some fair-sized orders have been placed for highly productive automatic and semi-automatic machinery, and another is that there is a steady increase in the volume of buying in the small tool field. It is generally recognized that the type of machine tool most likely to find a ready sale in the near future is one that it will be economical to buy, either because it gives greater production per dollar put into operating costs, or because it gives greater accuracy, or both. Much of the business done in this line of machinery during the present year will be replacement business—that is, the replacement of older types of machines by more efficient ones, in order to reduce manufacturing costs and improve the quality of the product.

The Effect of Improved Machinery

Examples of the effect of installing high-production machinery are growing more numerous every day. A case recently noticed was the production of a part used in great quantities, which is now being turned out at the rate of 1½ minutes, compared with 7 minutes by the older equipment. New equipment of this type was installed in one factory with the result that the manufacturer was enabled to undersell his competitors immediately, and now his competitors are negotiating for similar equipment, this being the only solution of their problem.

In another case an automatic machine which cost $7000 is producing parts in 40 seconds which used to require 3 minutes on a $12,000 machine. Still another interesting comparison will illustrate the point. By former methods an automobile manufacturer employed ten machines and eight men for the machining operations on one of the important parts of his engine. The total cost of the equipment was $25,000. This equipment has been replaced by modern automatic machinery at a cost of only $15,000, and two men and two machines are giving the same production as was formerly obtained. The quality of the product has not suffered.

These examples indicate better than general statements the lines along which there are possibilities for developing business in the machine tool field. The great need and the demand today is for the highly productive automatic or semi-automatic machine that will replace the less productive machinery of former days and relegate it to the scrap heap.

The Small Tool Industry

The increased buying in the small tool field constitutes one of the most cheerful signs at the beginning of 1922, although this industry is operating only at about 30 to 40 per cent of capacity. Most of the manufacturers of small tools continued to operate with full, or nearly full forces, for several months—in many cases for half a year—after the depression had started, and for that reason their stock-rooms are well filled. They are able to fill present orders chiefly from these stocks, so that the shops run mainly on special orders.

One of the plants manufacturing small tools reports 1921 sales equal to 45 per cent of the 1920 business; another reports 42 per cent; while the average of the majority of plants in this field is about 35 per cent. In most cases the lowest point in the small tool business was reached in June and July last year, and one of the important concerns in the field reports that December, 1921, and January, 1922, both showed increased sales over the corresponding months of a year ago. One concern equalled its 1916 business in 1921, and there are many reasons for the belief that 1922 will equal the 1917 business. There has been an improvement in exports too, especially to Australia. In the small tool field it is confidently expected that March will show up unusually well, compared with the last eighteen months. One of the plants has added 10 per cent to its force and increased the working hours about 30 per cent, compared with January 1.

In the grinding wheel field, similar conditions exist. There are numerous orders, although each is small, but the tendency now is toward bigger orders. For example, one well-known manufacturer who used to order about 250 wheels at a time two years ago but who cut down his orders to a dozen at a time, has recently increased them to 50 wheels per order, which is encouraging.

The Machine Tool Situation

In the machine tool field immediate prospects are not quite so promising, but they are very much brighter than at any time during the last eighteen months. Many new ideas are being worked out, new machines are being developed, and practically every machine tool builder has something new in mind. These new machines with their valuable new features will make it hard for manufacturers to keep on operating with old equipment. In the meantime, many machine tool builders are turning to other fields in order to utilize the excess capacity of their plants. Machines being built in machine tool works at the present time include printing machinery, laundry machinery, domestic washing machines, ice cream freezers, automatic refrigerators, motorcycles, and Diesel engines.

Stability in machine tool prices seems to have been reached in most instances, substantial reductions having been made from time to time during the past year. An investigation made by MACHINERY into the condition of the used machine tool market definitely shows that the fear that second-hand machine tools will seriously interfere with the sale of new equipment is not well founded. While there are many second-hand machines on the market, most of them are of old types, and as business improves many of them will be scrapped—they cannot compete with the later and far more efficient equipment available. A complete review of this situation will be found on page 539.

The Automobile Industry—The Railroad Situation

In this review, in February MACHINERY, it was stated that the total number of passenger cars and trucks built in 1921 was 1,680,000, a decrease of 24 per cent from the production in 1920. The factory prices of these cars and trucks aggregated $1,222,350,000, which was 45 per cent less than the factory prices of 1920. The average factory price of an automobile in 1921 was $702, compared with $897 for the previous year. The average factory price of motor trucks in 1921 was $968, as against $1273 in 1920. Automobile manufacturers are moving cautiously, and are not planning any material increase in production until there is greater evidence of a steady and increasing market. There has been a slight increase in exports of both passenger cars and motor trucks, but these exports are still far below the 1920 figure.

The greatly improved financial results during the last six months are encouraging; and as equipment and supplies in general have materially decreased in price, a considerable number of orders has been placed by the railroads in the last few months. Rolling stock can now be purchased at from 30 to 35 per cent less than peak prices, and the contracts for locomotives and cars placed during December and January are providing substantial employment for several of the shops in this field.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW AMERICAN METAL-WORKING MACHINERY

Peerless Universal Shaping Saw

A UNIVERSAL shaping saw having the general characteristics of a hacksaw machine, but designed along lines that adapt it for many operations impossible to perform with the common type of hacksaw machine, is being introduced to the trade by the Peerless Machine Co., 1611 Racine St., Racine, Wis. From Figs. 1 and 2 it will be seen that this saw is built to machine tool standards, accuracy in construction being essential to fit the machine for the class of work for which it is intended. Samples of the work that is handled by this machine are illustrated in Fig. 3.

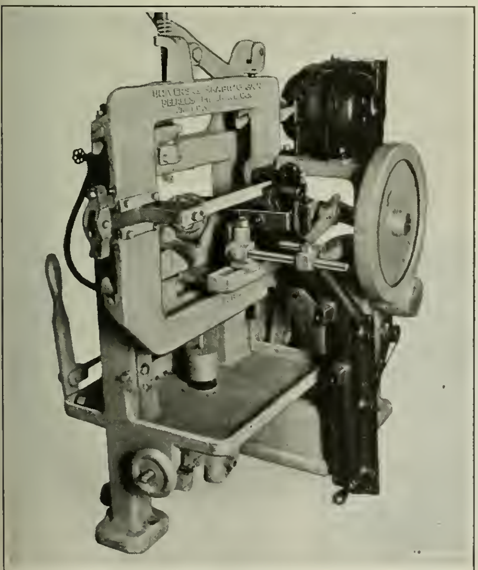

Fig. 1. Universal Shaping Saw manufactured by the Peerless Machine Co.

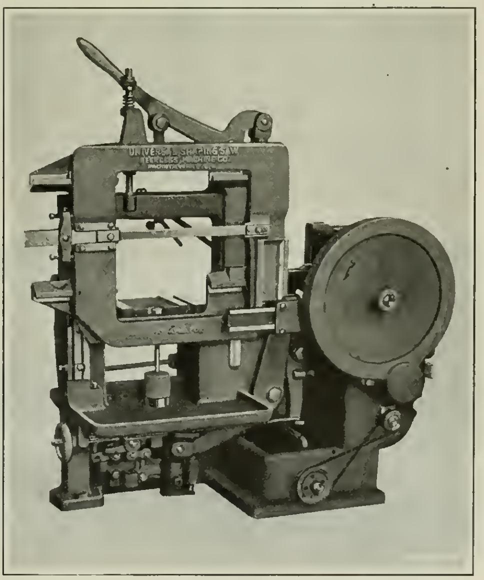

Fig. 2. Side View, showing Mechanism for feeding Saw and lifting it on Return Stroke

The saw blade is carried by a four-sided frame which permits the blade to be placed under ample tension without danger of distorting the bearings. The saw frame is supported on the horizontal bearings or ways of a vertical slide which, in turn, is mounted on vertical ways on the main frame of the machine. The saw frame is reciprocated through a crank and connecting-rod, and during the draw or cutting stroke of the blade the connecting-rod is always approximately parallel with the line of blade travel. This gives a direct pull on the blade and allows the cutting stroke to take place when the angle of the crank is such that the cutting speed is reduced to the minimum of the cycle period, although this speed is the maximum suitable for the work being handled. Then, during the return stroke, the change in the angularity of the crank causes the blade to be returned to the starting point at a high rate of speed. A speed-box having a cone of gears provides three changes of cutting speed to meet the requirements of different jobs.

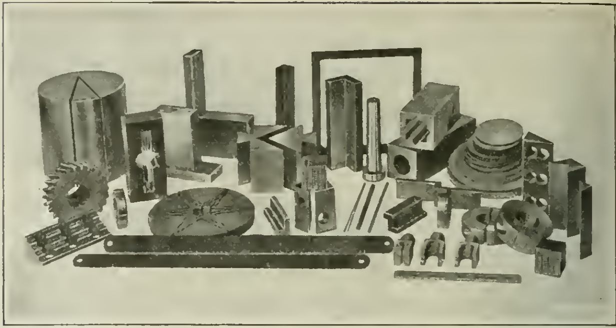

Fig. 3. Typical Examples of Work cut on the Peerless Universal Shaping Saw

Another important feature of this shaping saw is the positive power-feed mechanism with which it is provided. At the end of the draw or cutting stroke, a cam on the crankshaft actuates a lever, which raises the vertical slide on which the saw frame reciprocates and thus lifts the blade clear of the work while the saw is being returned to the starting position. After it has been returned, the saw is lowered to the cutting position by means of the same cam and lever. Simultaneously, a second cam on the crankshaft becomes operative, and through a link and lever mechanism and a ratchet and pawl, a worm meshing with a rack connected to the vertical slide on which the saw frame is mounted, is turned in such a way that it pulls the rack and saw frame down slightly. The repetition of this cycle of movements at the beginning of each cutting stroke provides for feeding the saw into the work at a predetermined rate. The rate of feed is adjusted by turning the small handwheel near the base at the front of the machine.

The feed is regulated automatically by a spring that compensates for the resistance of the material being cut. For instance, if a feed pressure of a certain number of pounds is required for cutting a given material at the rate of 1/32 inch per cut, each cut will be made to that depth as long as the composition of the material remains the same, but if a harder substance is encountered, the depth of cut is automatically decreased proportionately. When a cut has been completed, the feed worm is automatically tripped out of engagement with the rack, after which a spring lifts the saw frame to its upper position and stops the machine. This makes it unnecessary for an operator to watch the work.

For the performance of angle-cutting operations, a special fixture is furnished on which the work may be clamped to either a horizontal or a vertical face. A typical angle-cutting operation is illustrated in Fig. 4. Another useful fixture which adds to the range of the machine is a cross-feed mechanism secured to the table. A piece of work can be placed in this fixture and fed transversely under the reciprocating saw, the latter acting much like a shaper tool and producing a smooth finish on the surfaces machined. Fig. 5 shows a job accomplished by means of this mechanism, a screw-adjusted depth gage being employed for controlling the downward movement of the saw blade.

A reservoir in the base of the machine may be filled with a cooling solution for delivery in a copious amount by a pump and piping to the saw blade and work, after which it is returned to the reservoir. The machine has a capacity for work 6⅝ inches square, takes blades from 10 to 14 inches in length, and has a stroke of 5½ inches. The maximum number of strokes per minute is 132, and the minimum number 50. When equipped with a standard vise, the machine weighs approximately 750 pounds.

BOYE & EMMES CONELESS ENGINE LATHE

The 18-inch geared-head engine lathe shown in the accompanying illustration is being introduced to the trade by the Boyé & Emmes Machine Tool Co., Cincinnati, Ohio. All gears in the headstock are constantly in mesh, the various speeds being obtained through positive clutches operated by means of levers on the headstock. There are twelve selective spindle speeds, ranging from 9 to 350 revolutions per minute. The drive from the pulley shaft is through a friction clutch. The spindle is a heat-treated chrome-nickel steel hammered forging. The top cover of the headstock has a removable plug which affords a convenient means of filling the headstock with oil, a glass oil-tube showing the level of oil at any time in this unit. The number of threads which may be cut per inch ranges from 2 to 56.

The apron is of the double-plate type, which permits the shafts and studs to have a bearing on each end. All feeds are reversible in the apron, and the mechanism is so arranged that the longitudinal and cross feeds cannot be engaged while cutting threads. Attached to the right-hand end of the apron is a lever that slides along a rod, the operation of which controls the starting, stopping, and reversing of

Fig. 4. Cutting Angular External Surfaces

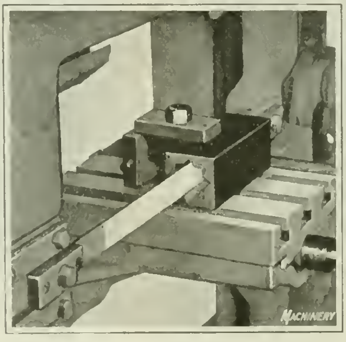

Fig. 5. Use of the Cross-feed Mechanism

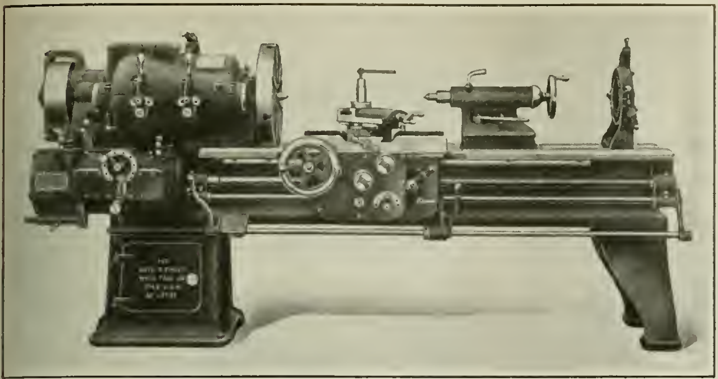


Coneless Engine Lathe built by the Boye & Emmes Machine Tool Co.

the headstock spindle. A second lever is mounted on this controller rod at the left-hand end. The tailstock is of the cut-away type, so as to permit the compound rest to be swiveled parallel with the ways of the bed. Double plug clamps are employed to lock the tailstock spindle in position. This spindle is also made from chrome-nickel steel and accurately ground. The tailstock has a sidewise adjustment to provide for taper-turning operations.

The motor is attached to a baseplate mounted on two planed surfaces on the back of the cabinet leg. Constant-speed motors of from 3 to 5 horsepower, and of a speed not exceeding 1160 revolutions per minute are recommended for driving this machine. Its principal dimensions are as follows: Actual swing over bed, 19½ inches; swing over carriage, 13¼ inches; diameter of hole in headstock spindle, 1½ inches; distance between vees of carriage, 14 inches; and distance between centers on a lathe having an 8-foot bed, 4 feet 2 inches. This lathe, when furnished with an 8-foot bed, weighs about 4275 pounds.

LANDIS PIPE THREADING AND CUTTING MACHINE

A pipe threading and cutting machine recently added to the line of products manufactured by the Landis Machine Co., Waynesboro, Pa., is shown in the illustration. This machine may be equipped for threading oil-well casing and high-pressure pipe in addition to ordinary line pipe. It regularly accommodates from 4- to 12-inch pipe, but it may be equipped to thread and cut pipe as small as 2½-inch. Two die-heads of the stationary type are employed, a 6-inch die-head for pipe less than 6-inch, and a 12-inch die-head for pipe ranging from 6- to 12-inch. The entire range of each of these heads is covered by one set of Landis chasers. The chucks for gripping the pipe have three jaws; these jaws are geared, have universal adjustment, and are self-centering on the pipe. The rear chuck is equipped with grips to provide for fitting up flanges.

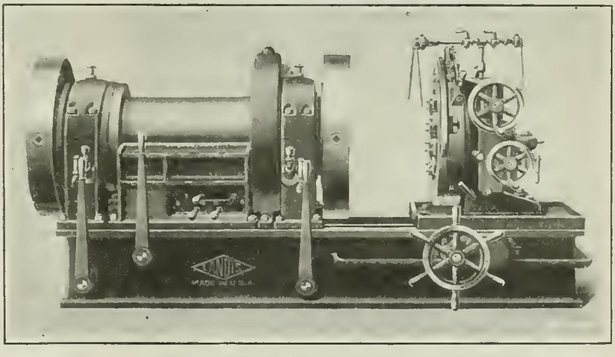
The carriage supports the die-head, cutting-off tool, and reaming tool, and may be moved either by power or hand. Both forward and backward power traverses are controlled by a lever located on the operating side of the carriage. In advancing the carriage toward the chuck, this lever is operated and held until the threading position for the die-head is reached. To reverse the movement of the carriage, the lever is moved in the opposite direction and held there. The carriage may be stopped at any point along its traverse by releasing the lever. Automatic stops prevent the die-head from coming in contact with the chuck in the forward movement and the carriage from running off the guides of the machine in the backward movement. The reaming tool is quickly set to the desired position and locked by means of a lever, and it is fed to the pipe by rotating the cutting-off feed handwheel in a counter-clockwise direction.

The machine has a single-pulley drive, eight speeds being obtainable through a gear-box under the main spindle, by shifting levers located on the side of the gear-box. The machine is started and stopped through a friction clutch operated by either one of two levers at the ends of the headstock. This arrangement enables the operator to stop or start the machine conveniently when threading or when fitting up flanges. The lever midway between the starting and stopping levers is manipulated to reverse the operation of the machine. A motor drive may be quickly arranged by substituting a sprocket for the pulley and fitting a plate to the side of the machine for mounting a motor, a silent chain being used to drive from the sprocket on the motor to the sprocket on the machine. The machine weighs 13,000 pounds.

STEVENSON DOWN-STROKE GEAR SHAPER

A gear shaper made by the Stevenson Gear Co., Indianapolis, Ind., on which all or a number of the teeth of a spur gear, sprocket, etc., are cut simultaneously by a tool-head having a series of radially disposed tools spaced about the circumference of the blank to be cut was described in August, 1921, MACHINERY. It will be recalled that in this machine the tools are fed radially after each reciprocation of the work-holding ram, at which time the work is also indexed a distance of one tooth space. The tool-head is placed above the ram so that the gear blanks are cut on the upward stroke. As the work-holding arbor is passed through the tool-head in putting work in place, the machine is suitable for cutting plain work only. To accomplish the rapid cutting of internal and cluster gears and splines, the same company has developed the machine shown on the following page.

This machine is known as Model 6-A, and is of a down-stroke type; that is, the tool-head is placed beneath the ram and the teeth are cut on the downward stroke instead of on the upward stroke as in the machine referred to. On the

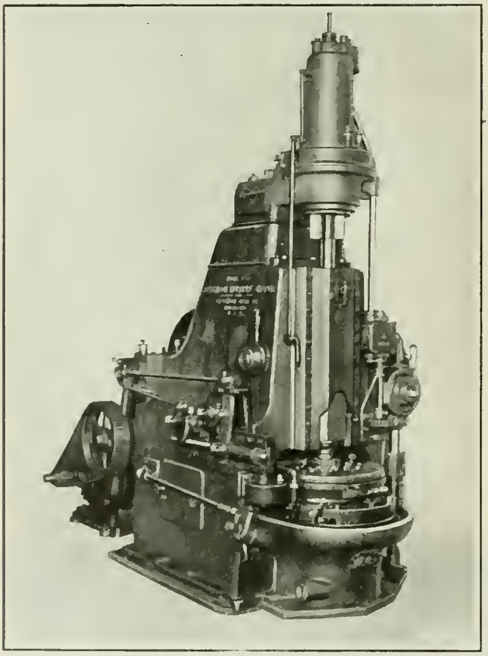


Twelve-inch Pipe Threading and Cutting Machine brought out by the Landis Machine Co.

new machine, the ram is elevated a sufficient distance to enable the arbor of completed gears to be removed and an arbor of blanks to be inserted in the spindle socket of the ram. After the taper shank of the arbor has been inserted in the socket, the operator, by means of a convenient lever, engages a power-driven clutch, which causes a draw-bolt passing through the center of the spindle to revolve and securely draw the arbor into the socket. This clutch is automatically disengaged the moment that the arbor has been tightened a predetermined amount.

After the ram has again been lowered by power to the operative position, at which point it stops automatically, the operator starts the machine by means of an electric push-button switch. As the entire machining operation is automatic, the operator has sufficient opportunity to place blanks on a second arbor while the machine is in operation. In this manner an arbor of cut gears may be replaced by an arbor of blanks with a minimum loss of time. At the completion of an operation the machine is stopped by means of a push-button switch that controls an electric brake. The operator then temporarily elevates the ram, reverses the draw-bolt lever previously mentioned, to eject the arbor, after which the procedure is the same as before.

The tool-head is almost identical with that used on the up-stroke machine, the tool bits and other important parts being interchangeable on the two machines. Two tool-heads are provided, so that while one is in use, the tools of the other may be resharpened and reset. The mechanism for

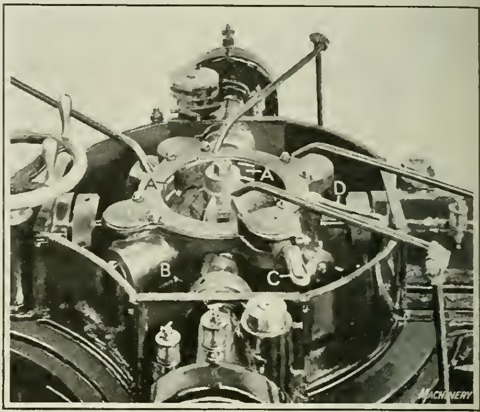


Model 6-A Down-stroke Multiple-tool Gear Shaper designed by the Stevenson Gear Co. for cutting Internal and Cluster Gears

driving the ram and elevating and lowering it consists of a crank which reciprocates a worm during the operation of the machine. This worm transmits its reciprocatory movements through a worm-wheel mounted on a rock shaft. However, when it is desired to elevate the ram, the worm is kept from reciprocating and given a rotary movement, causing the worm-wheel and rock shaft to revolve and elevate the ram. Power for this rotary movement is derived from a small motor which also furnishes power for actuating the draw-bolt mechanism. This machine will be built in a number of sizes.

REED-PRENTICE FOUR-WAY DRILLING MACHINE

In October, 1914, MACHINERY, was described a four-way drilling machine built by the Reed-Prentice Co., 677 Cambridge St., Worcester, Mass., for simultaneously drilling four holes in automobile universal-joint rings and for turning the four arms of differential spiders. This machine has now been built for drilling four bearing holes in the upper and lower sections of tractor rear-axle housings, a special work-holding fixture being provided, which has several novel features that permit rapid handling of the work. Four hardened steel strips *A* placed around the inside of this fixture locate the work centrally, while the bosses in which the bearing holes are to be drilled are properly located by means of guide pins in the lower part of the fixture which engage two holes previously machined in the flanges of the housing members.



Work-holding Fixture of Special Four-way Drilling Machine built by the Reed-Prentice Co.

The lower half of the housing is dropped into position first, after which four plungers in bearings spaced 90 degrees apart, as at *B*, are forced toward the center of the fixture by operating lever *C*. The second or upper half of the housing is then placed in the fixture and the work clamped tight on the plungers by means of a center bolt that passes through both housing members. This arrangement supports the work rigidly during the drilling operation. When this has been completed, the upper housing section is removed, and after withdrawing the four main plungers, the lower half is raised by operating lever *D* to actuate four vertical plungers which bring the lower half of the housing into a position from which it is easily lifted out of the fixture. Hardened steel bushings inserted in the main body of the fixture guide the drills properly and insure accuracy in drilling the bearing holes.

HANNIFIN ADJUSTABLE BORING-BARS

A complete line of boring-bars in which the cutters can be accurately adjusted by means of a scroll has been developed by the Hannifin Mfg. Co., 621-631 S. Kolmar Ave., Chicago, Ill., for rough- and finish-boring, reaming, and line-reaming operations. Various combinations of standard cutters may be included in one bar for boring to different diameters, counterboring, and facing in one operation. By using angle- and straight-type cutters, several sets can be spaced close together on a bar. This possibility will be apparent by reference to Fig. 1, which shows the front end of a bar equipped with sets of angular and straight cutters. A phantom detail view of the angle-type cutter is shown in Fig. 2, while Fig. 3 shows a similar view of the straight type.

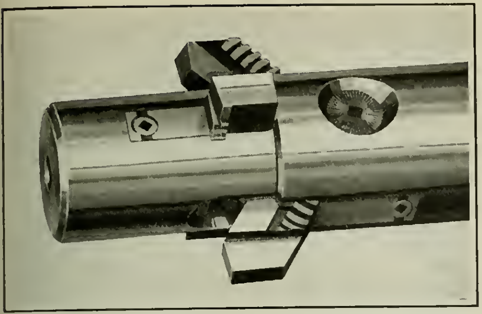


Fig. 1. End of an Adjustable-cutter Boring-bar made by the Hannifin Mfg. Co.

One side of the cutters is provided with curved teeth for engagement with the thread of a scroll, and as the latter is revolved by applying a wrench in the square hole at its center, the cutters are either advanced or drawn back. Graduations on the scroll enable accurate settings to be made, and two locking screws are utilized to keep the cutters in position. The inner ends of the cutters overlap each other, which permits greater expansion and rigidity. The cutters are backed metal to metal and cannot work loose.

The angle-type cutters are particularly adapted for facing and counterboring operations, because they are also adjusted forward as they are adjusted radially. Grinding the cutter faces after they have been set out, keeps them in the original position. This style of cutter is also especially suitable for boring to the bottom of blind holes. With a combination of the angle and straight types, the cutters can be adjusted to machine to a common diameter, thus making a four-point cutting tool. The cutters are quickly replaceable and adjustable to size without removing the bar from the machine.

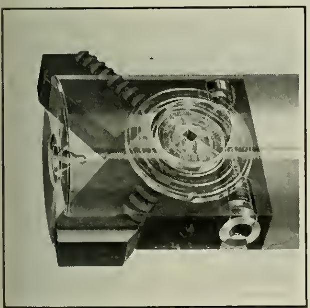

Fig. 2. Phantom View, showing Construction of the Angle-type Cutter

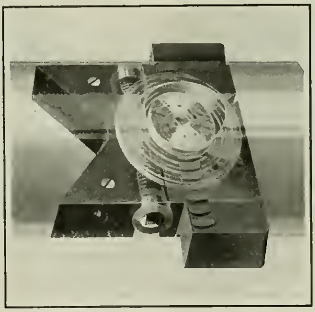

Fig. 3. Adjustable and Locking Details of the Straight-type Boring-bar Cutter

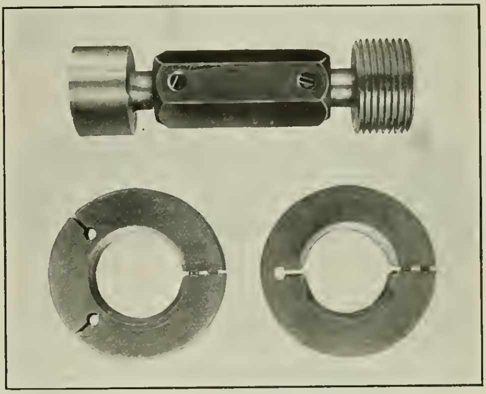
This company also manufactures boring-bars in which the blocks holding the scroll-adjusted cutters may be quickly removed from the bar to permit the substitution of another block having cutters for a different operation. By this arrangement rough-boring, finish-boring and reaming may be rapidly performed in succession without removing a bar from the machine. Bars with these removable blocks are particularly adapted for the line-boring and reaming of crank-cases and transmission cases, and the rough- and finish-boring of cylinders. Strip pilots can be furnished on any bar, and when worn they may be shimmed up and reground to fit the pilot bushing. Boring-bars can also be provided with hardened and ground pilots. In addition to line boring-bars, the company makes straight- and taper-shank boring-bars suitable for use on turret lathes, drilling machines and engine lathes. The angle-type, straight-type and removable block cutters are regularly made in different sizes for boring and reaming holes from 1 to 10½ inches in diameter.

PLUG AND TEMPLET THREAD GAGES

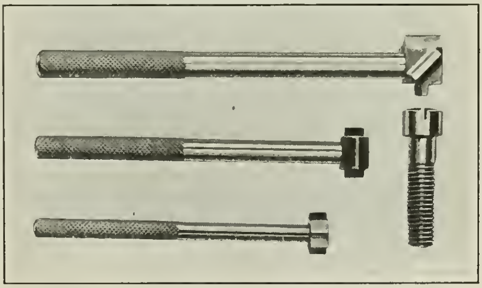
A line of plug and adjustable templet thread gages, several of which are shown in the accompanying illustration, is being placed on the market by the Superior Thread Gage Mfg. Co., Inc., 1985 Troy Ave., Brooklyn, N. Y. The templet gages are made in two styles, either with one half-way slot on the inside of the gage, or two half-way slots leading to the periphery. The latter style furnishes a fuller contact for the threads of the work, a feature of interest especially to the users of small-size gages. The plug gage is fitted at one end with a thread plug, and at the opposite end with a plain plug equal in diameter to the root of the thread that it is intended to gage. These plugs are readily replaceable as they become worn. The gages are regularly made for all sizes of standard threads, U. S. standard, Whitworth, S. A. E., etc., from 3/16 inch in diameter up. They can also be made for special threads.



Thread Gages manufactured by the Superior Thread Gage Mfg. Co., Inc.

PORTER OFFSET SCREW-DRIVER

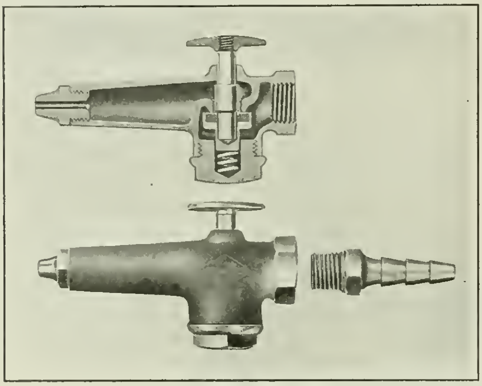
The assembly or disassembly of machine parts is often difficult due to the fact that the holding screws are located so close to walls or projections that an ordinary screwdriver cannot be readily engaged in the screw-head slot. To enable a machinist to reach such screws conveniently, the Porter Products Corporation, Keith Theater Bldg., Syracuse, N. Y., has brought out the offset screwdrivers shown in the illustration. Each screwdriver consists of a handle having a square forged end. On the four sides of this end are long, narrow projections with which the slots



Offset Screwdriver Set made by the Porter Products Corporation of screw-heads may be engaged. In use, the handle is held at right angles to the screw axis. The projection on any of the four sides is at an angle of 45 degrees to the projection on each of its adjacent sides. Therefore, if a screw is located in a cramped position, after turning the screw as far as space will permit, the screwdriver is given a quarter turn by the fingers and again applied. The screwdriver may be used in places so cramped that only an eighth turn of the screw is possible at a time. The design also has the advantage of enabling a considerable leverage to be applied to screws rusted in place. The manner of using this screwdriver will be understood by referring to the machine screw shown in the illustration.

JENKINS AIR GUN

A brass compressed air gun now being placed on the market by Jenkins Bros., 80 White St., New York City, finds application in machine shops for blowing chips and dirt from the tables of machines, and cleaning taps, dies, and other tools. To eliminate loss of air through leakage, the gun is designed with a disk that can be readily renewed as



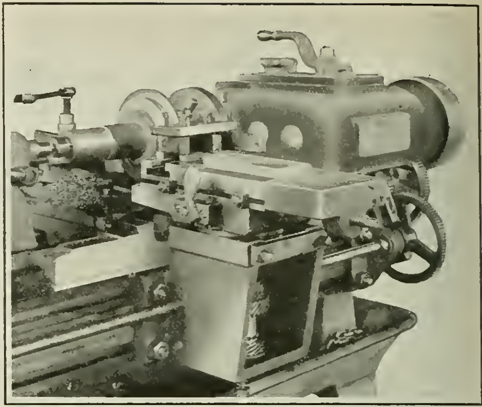
Compressed Air Gun for blowing Chips from Machines, etc., which is made by Jenkins Bros.

it becomes worn after removing the cap at the bottom of the gun. The sectional view in the illustration clearly shows the gun construction. Air is allowed to pass through the device when the user presses on the knob at the top, and the moment pressure is released from this knob, the coil spring at the bottom forces the disk previously referred to upward and against its seat, thus shutting off the passage of air. The gun may be used with 1/8-, 1/4-, 3/8-, and 1/2-inch hose by providing the proper size nipple. A nipple of the type used is shown to the right in the lower part of the illustration.

BACK-FACING ATTACHMENT FOR ADAMS "SHORT-CUT" LATHE

To accomplish the back-facing of work at any desired angle, the Seneca Falls Mfg. Co., Inc., 381 Fall St., Seneca Falls, N. Y., has recently brought out a universal power-operated back-facing attachment intended for use on the Adams "Short-cut" lathe. The attachment is especially suitable for turning bevel gears. It is a simple matter to set the device for machining the gear to the proper angle, the bevel surfaces being machined simultaneously with the turning of the gear hubs. Nine in-feeds are obtainable, ranging from 0.003 to 0.050 inch per spindle revolution. These feeds are secured through gearing connected to a splined shaft at the rear of the machine.

Reversal of the mechanism is accomplished by sliding positive clutches which engage with worm-gearing. There are

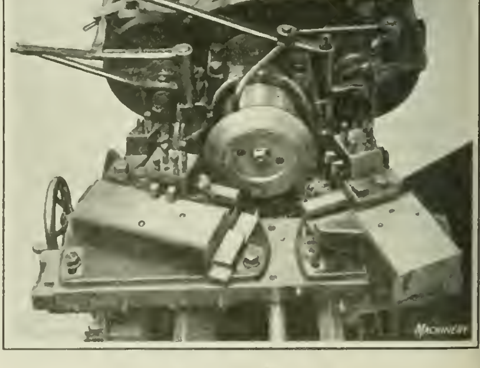


Back-facing Attachment made by the Seneca Falls Mfg. Co., Inc., for Use on the Adams "Short-cut" Lathe

twenty-seven automatic reverse feeds, ranging from three to fifteen times the forward feed that happens to be engaged. These feeds enable the operator to secure the proper timing necessary for back-facing, necking, under-cutting, and grooving work. The in-feed stop causes the mechanism to reverse automatically while the out-feed also stops automatically at the completion of a cycle. The back-facing tool is actuated by a screw and nut arrangement, which gives a smooth even motion. The relation of the back-facing feeds to the turning and facing feeds of the lathe permits innumerable combinations and puts the lathe into the semi-automatic class because, when equipped with this device, several machines may be run by one operator.

WARNER & SWASEY TURRET LATHE ATTACHMENT

The rapid machining of forged bevel gear blanks sometimes presents a troublesome problem to automobile manufacturers, because of the special metals from which the gears employed in automobiles are generally made. To facilitate such operations, the Warner & Swasey Co., Cleveland, Ohio, has brought out the attachment illustrated, which is adaptable to the No. 3-A universal hollow hexagon turret lathe manufactured by this concern. The attachment has two tool-slides and interchanges with the top slide of the regular carriage, so that the machine may be used either for bevel gears or for the other classes of work regularly handled on the turret lathe. The attachment is suitable for machining work up to 14 inches in diameter to all standard angles.

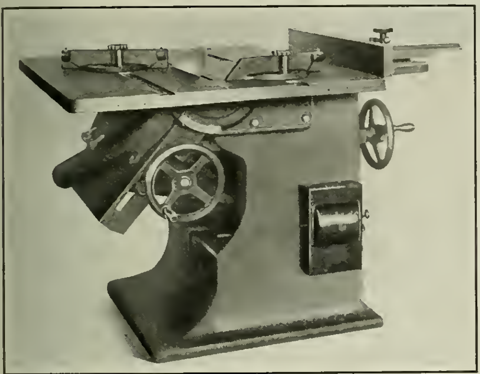


Attachment for machining Bevel Gear Blanks on a Turret Lathe built by the Warner & Swasey Co.

The two tool-slides are operated by the hexagon turret and saddle. A rack extending forward from the turret engages a double pinion on the attachment, and when the turret is advanced, this double pinion drives a second rack, transmitting a sliding motion to it, toward the rear of the machine, and causing it to rotate two other double pinions which drive racks fastened to the tool-slides. Thus, the two tools operate simultaneously.

TANNEWITZ TILTING-ARBOR SAW

A wood-cutting saw on which the saw arbor can be tilted to any angle up to 45 degrees, and which is therefore particularly adapted for service in pattern shops, is a recent product of the Tannewitz Works, Grand Rapids, Mich. The table of the machine is always in a horizontal plane. The tilting of the arbor is accomplished by operating the handwheel at the right, which is also used to lock the arbor in the positions to which it is adjusted. The handwheel at the left is employed to raise and lower the table, and lock it in place. The motor and saw are mounted on a sliding bracket



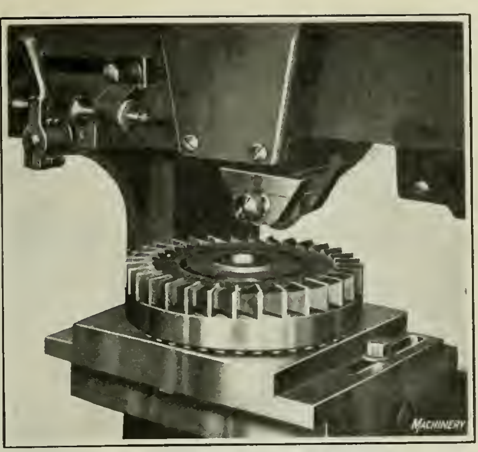
Saw developed by the Tannewitz Works for cutting Wood at Any Angle up to 45 Degrees

which is supported by a yoke, the latter being hinged on the housing. The motor has a speed of 3600 revolutions per minute, and is operated by an enclosed safety switch mounted on the outside of the housing. A complete set of graduated gages forms part of the equipment.

MARTIN HYDRAULIC MARKING MACHINE ATTACHMENT

A hydraulically operated machine built by the Martin Machine Co., Inc., Turners Falls, Mass., for the rapid marking of names, trademarks, etc., on metal products was described in detail in February, 1918, MACHINERY. Attachments recently developed for this machine enable marking to be done around a circle on the flat sides of cutters, rings, and similar parts, as shown in the illustration. The object to be marked is placed on a fixture mounted on the table of the machine, the top of this fixture being free to revolve on ball bearings. The fixture can be adjusted for marking to any radius, so that the marking will conform to the space provided on the work.

A plain roll die is used, and it is held in one position and revolved about its axis by means of a rack fastened to the slide of the machine. As the work is brought into contact with the revolving die, the top plate of the fixture is revolved. A plug set into the center of the revolving plate and fitting the bore of the work keeps the latter in the proper position. At the end of a marking stroke, the die is returned to its starting position by the return stroke of the slide.



Circular Marking Attachment for Machine manufactured by the Martin Machine Co.

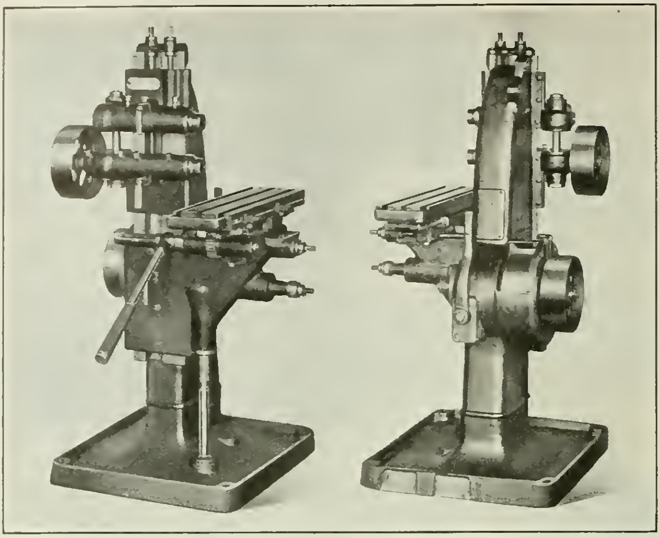
The hydraulic operation of the table results in satisfactory marking, regardless of variations in the thickness of the work.

REED INSIDE MICROMETER CALIPERS

An inside micrometer set having five rods that enable measurements to be made ranging from 3 to 8 inches, in increments of 0.001 inch, is now being introduced to the trade by the Reed Small Tool Works, Cherry and Vine Sts., Worcester, Mass. This set will be found useful not only in determining the internal diameters of cylinders and rings, but also in taking linear measurements, testing the parallelism of surfaces, comparing gages, etc. The barrel, spindle, and thimble are similar in construction and diameter to like members of the outside micrometer made by this company. A feature of this micrometer is the provision of a detachable handle, which may be instantly set to permit easy reading of the graduations, whether the work is right- or left-hand.

The extra rods allow quick changes to suit the length of the part to be measured, the substitution being made by simply unscrewing the rod on the threaded stud of the barrel and then screwing the proper rod in place. Each rod is ground square at the hardened end so as to seat in the proper relation to the barrel shoulder. The point of measurement is fitted with a hardened tool-steel anvil which is adjustable to lengthen the rod and to compensate for anvil wear. The faces of the anvils are ground to a small radius. Rods of lengths permitting measurements other than in the range specified can also be supplied.

Set of Inside Micrometer Calipers added to the Line of Measuring Instruments made by the Reed Small Tool Works



Front and Rear Views of a Double-spindle Hand Milling Machine brought out by the Superior Machine & Engineering Co.

fastened to the base of the machine. This milling machine weighs approximately 900 pounds.

DUPLEX HAND MILLING MACHINE

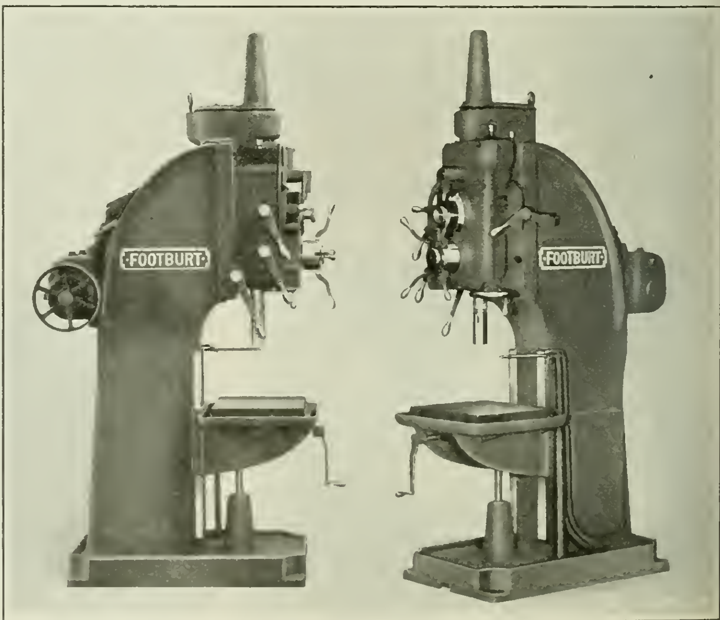
A machine for rapidly slitting automobile piston-rings of the step-cut type, splitting babbitt-lined bearings for automobile crankshafts, milling slots and keyways, and similar operations has been developed by the Superior Machine & Engineering Co., 451-457 E. Fort St., Detroit, Mich. The machine has a single-pulley drive, which is engaged and disengaged by operating the clutch lever. On the driving pulley shaft is mounted a change pulley, from which power is transmitted by belt to a pulley on the lower spindle and then through spiral gears to the upper spindle. The spiral gears are hardened and run in oil. The number of teeth on the two gears of a pair are prime to each other so as to insure a uniform distribution of wear. The spindles are made of high-carbon steel and run in oiled bronze bearings.

The two spindle heads are adjustable and can be clamped in any position on the column without disturbing the gibs. The vertical positioning of the work relative to the lower spindle is done by raising or lowering the knee. This member can be clamped in any position on the column. In making a set-up, the upper spindle head is adjusted relative to the lower one, after which both heads are clamped to the column. Graduated dials are provided on all adjusting screws for securing accurate settings. The saddle of the table can be adjusted toward and away from the column by means of a screw, while the table is traversed past the spindles by operating the hand-feed lever seen in the illustration. The machine can also be driven by a 1½-horsepower motor which may be mounted on a bracket fastened to the base of the machine. This milling machine weighs approximately 900 pounds.

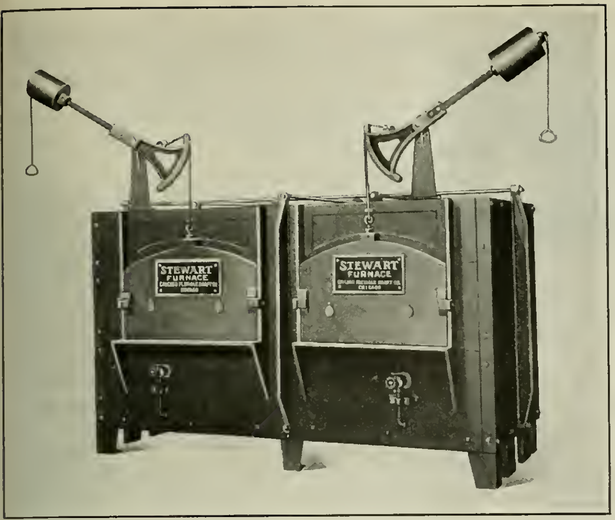
FOOTE-BURT HIGH-DUTY DRILLING MACHINE

Simplicity of construction and operation has been the aim of the Foote-Burt Co., Cleveland, Ohio, in redesigning the No. 23 high-duty drilling machine shown in the accompanying illustration. This machine has a capacity for drilling a hole 1½ inches in diameter through solid steel. Practically all operating members are contained in the head, which can be readily dismantled, should trouble of any nature be experienced, and carried by a crane to a convenient place for repairs. The head is bolted on the vertical face of the heavy box-section upright to bring the bolts into shear. The upright, base, and jack-screw support are cast integral to insure rigidity. Convenient control is provided, all operating levers being located at the front of the head. The single screw of the table permits a 12-inch vertical movement of this member without the necessity of providing a hole in the floor for the screw.

The machine is driven through a single pulley, from which power is transmitted to the driving members through a friction clutch. Nine spindle speeds, ranging from 75 to 610 revolutions per minute, and three feeds, of 0.006, 0.012, and 0.026 inch, respectively, are instantly available through sliding change-gears. Helical gears transmit power to the spindle which has a double-rack feed that eliminates side friction on the sleeve. Either Hyatt or taper roller bearings are supplied in all driving shaft bearings, and ball bearings take the thrust of the spindle. The speed change-gears run in an



No. 23 High-duty Drilling Machine redesigned by the Foote-Burt Co.



Double-chamber Semi-muffle Heat-treating Furnace recently brought out by the Chicago Flexible Shaft Co.

oil bath, while the feed gears are lubricated by a splash oiling system. The upper driving helical gears and their bearings are packed in grease and covered by a cap large enough to contain several months' supply of grease. Some of the principal specifications of the machine are as follows: Distance from center of spindle to face of column, 10 inches; maximum distance from nose of spindle to top of table, 28⅝ inches; length of power feed, 12 inches; taper of spindle socket, Morse No. 4; working surface of table, 20 by 16 inches; and approximate weight of machine, 2700 pounds.

WODACK PORTABLE ELECTRIC DRILL AND GRINDER

A portable electric drill on which two separate speeds may be obtained, which adapt the equipment for grinding operations in addition to drilling, has been brought out by the Wodack Electric Tool Corporation, 23-27 S. Jefferson St., Chicago, Ill. This equipment greatly resembles the drill illustrated in January, 1921, Machinery. It has a drilling capacity of from ⅛ to ⅝ inch in steel, and is supplied with a 6- by ¾-inch wheel for grinding operations. The slow speed is intended for use in drilling, and the high speed for grinding. The motor is of ½ horsepower and is of the universal type, operating on either alternating or direct current of the same voltage. It is controlled by a quick make-and-break switch in the handle. This combination drill and grinder weighs about 18 pounds.

STEWART HEAT-TREATING FURNACES AND OIL-PUMPING SYSTEM

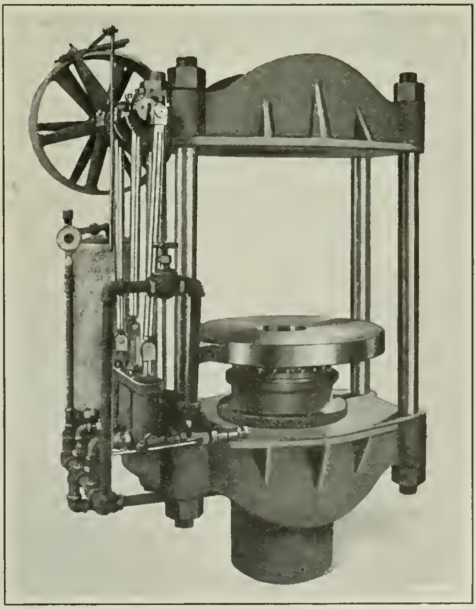
The Stewart double-chamber, semi-muffle heat-treating furnace here illustrated has been added to the line of heat-treating equipment lately developed by the Chicago Flexible Shaft Co., 1154 South Central Ave., Chicago, Ill. Both chambers of this furnace are individually controlled, enabling different operations to be carried on simultaneously. For instance, it is possible to carburize or anneal work in one chamber and at the same time reheat or preheat work in the second chamber. The furnace is underfired, combustion taking place under the floor and the products of combustion passing up along both walls to the arch and then down on the work. Either gas or oil may be used for fuel, or the furnace may be fitted up with combination gas and oil burners. A line of furnaces is also built in which the casing is made of sheet steel instead of cast iron.

Another recent development of this company is an oil-pumping system, which delivers fuel oil at a uniform pressure and free from foreign matter, the latter being removed from the oil by strainers. Spring-load relief valves prevent injury to the system in case the discharge should become closed. These valves also furnish variations in the operating pressure. A pressure dome dampens pulsations in the pump, and serves as a settling chamber in which the water and sediment settle before the oil is delivered to the burners. Gages provide easy readings of the pressure on the oil. This pumping system is regularly made with a capacity for delivering 100 gallons of oil per hour, but special sizes can also be built.

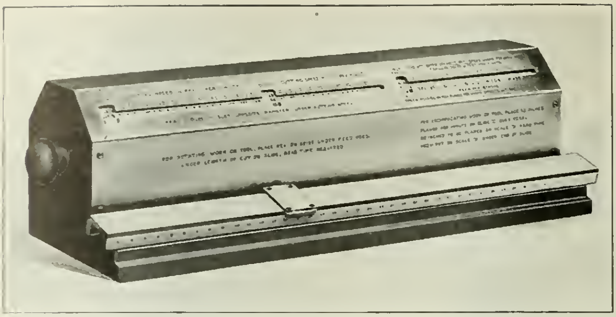
WEST HYDRAULIC PRESS

The 250-ton hydraulic press shown in the accompanying illustration is intended primarily for pressing solid rubber truck tires on or off wheels, but it is also adapted for a variety of other uses. This machine is a recent development of the West Tire Setter Co., Rochester, N. Y. The frame and top platen are steel castings. The ram area is sufficient to produce the required tonnage with the comparatively low initial pressure of 2000 pounds per square inch. The pump is of the three-plunger type with an automatic cut-out for the larger plunger. It is equipped with a 2-inch low-pressure plunger for filling the pipes and cylinder quickly.

When a pressure of approximately 200 pounds per square inch has been obtained, the larger plunger is automatically cut out by a special by-pass valve, leaving the two smaller plungers in operation for obtaining the higher pressure re-



Hydraulic Press developing a Pressure of 250 Tons, which is a Recent Product of the West Tire Setter Co.



Instrument for calculating Operation Time, which has been placed on the Market by the Simplex Calculator Co.

quired for the maximum tonnage. The pressure is applied or released by closing or opening, respectively, a globe valve located in the by-pass piping taken out of the main-pressure pipe. When this valve is opened, the oil or water used as the medium of pressure is returned to the supply tank instead of being delivered to the cylinder of the machine for applying pressure to the ram.

The tank is of the enclosed type, and when desired a compressed air line can be connected to the top of the tank to furnish means of forcing the oil or water quickly into the cylinder to move the ram up to the point where high pressure is required. In cases where air pressure is used for this purpose, the pump furnished has all high-pressure plungers instead of being of the type previously mentioned. A safety valve prevents overstraining of the press when it is run by a careless operator. The bottom platen is 42 inches in diameter, and the maximum distance between the top and bottom platens is 37 inches. The ram has a stroke of 33 inches.

SIMPLEX MACHINE TIME CALCULATOR

A calculator intended for use in computing the time required for operations performed with machine tools, and which is applicable to either rotating or reciprocating work or tools is shown in the accompanying illustration. This instrument is a recent product of the Simplex Calculator Co., Box 184, York, Pa. It consists of a cylinder enclosed by an aluminum case, and a slide-rule of special design attached to an extension of the base. For use in connection with rotating work or tools on such machines as lathes, boring mills, and drilling or milling machines, the cylinder has tables giving the number of revolutions per minute made by work or tools of diameters from 1/4 inch to 10 feet, at all ordinary cutting speeds. The range of speeds is shown above the slot at the left-hand end of the case.

The number of revolutions per minute made by a given piece of work is read in the slot opposite its diameter and directly under the cutting speed selected. This number is then transferred to the slide-rule which has four scales marked Feed, R.P.M., Length, and Time. The number found on the cylinder is located on the R.P.M. scale on the slide, the slide then being moved until the number of revolutions is brought directly under the number on the feed scale corresponding to the feed of the work in inches per minute. The runner is then moved along the length scale to the number representing the length of the cut. Directly under this number on the time scale is found the time in minutes required for the operation. All such problems require but one setting of the cylinder and one movement of the slide and runner.

In connection with planers, shapers, slotters, or other machines having reciprocating tools or work, the procedure is quite similar. The number of square inches planed per minute at various forward and return rates of speeds and different feeds are read on the cylinder through the slot at the right-hand end of the case. After determining the total number of square inches of surface to be planed, either mentally or by the use of the rule, it only remains to divide this number by the number of square inches planed per minute. With one setting of the slide on the rule, the time required for the operation may be read on the time scale under the end of the slide. This instrument was designed primarily for rate setters, estimators, and others whose duties require a study of machine operations. It is about 16 inches long and weighs approximately 3 pounds.

DAVENPORT SLOTTING ATTACHMENT

The slotting of screw heads may now be readily accomplished on the five-spindle automatic screw machine built by the Davenport Machine Tool Co., Inc., 167 Ames St., Rochester, N. Y., by the use of a recently designed attachment. Fig. 1 shows the head containing the saw by means of which the screws are slotted, this unit being mounted on the machine directly above its revolving head. The saw is driven by pulley *A* through the regular change-gears of the machine, thus providing for a number of different speeds. The saw head is covered by a guard, which has been removed in the illustration.

The unit shown in Fig. 2 is mounted on a bracket bolted to the machine. It receives each screw as it is cut off the stock, and carries it through the slotting operation. Turret *B* has three plungers *C* held in bosses spaced equidistantly around a circle struck from the center of the turret. These plungers are fitted at their front end with a bushing that fits the screw to be slotted, while the rear end is machined with a T-head. On support *D* are mounted three sliding spindles which are yoked together by spider *E*, the spindles thus being slid forward in unison by a motion imparted to the spider by a cam-lever. Two of the spindles have a head *F*

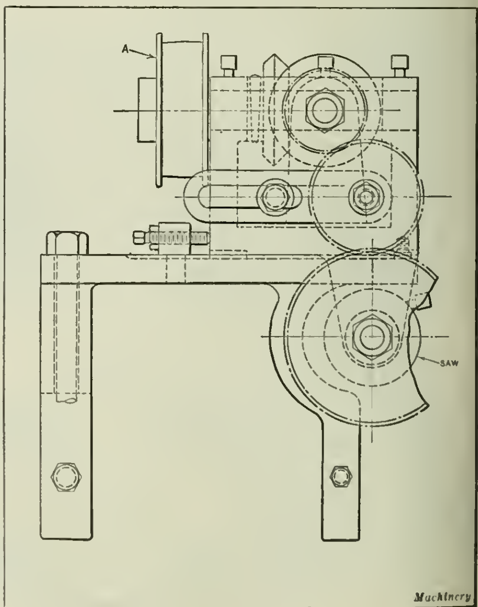


Fig. 1. Saw Head for Five-spindle Automatic Screw Machine built by the Davenport Machine Tool Co., Inc.

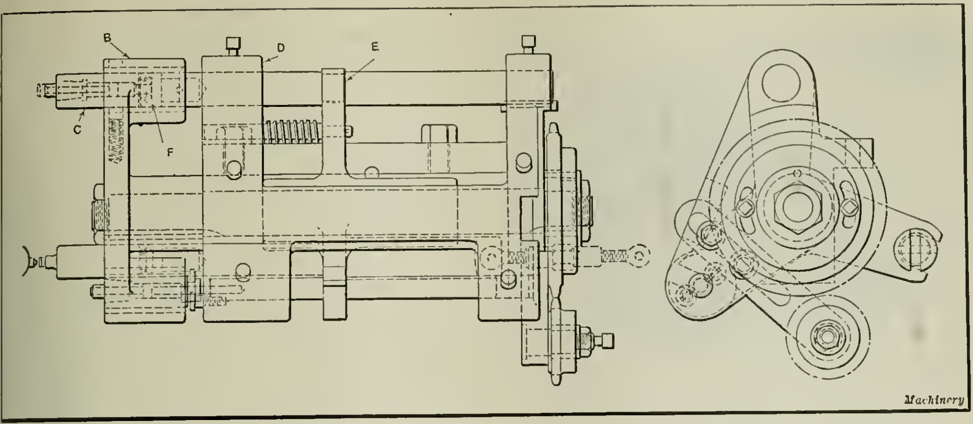

Fig. 2. Attachment employed in Connection with the Saw Head shown in Fig. 1 for slotting the Heads of Screws

provided with a T-slot that fits the rear end of the plungers, while the third spindle carries an ejector that is forced through the plungers as they are indexed to this position.

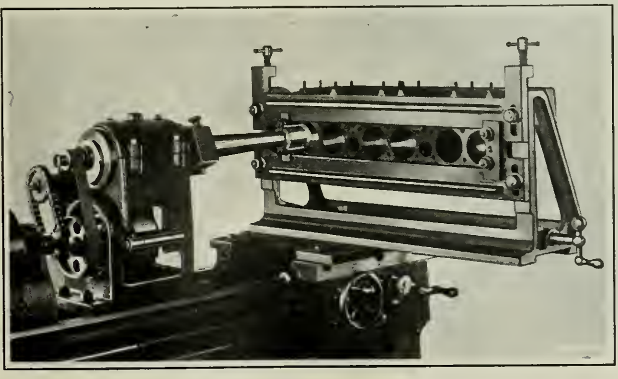
The turret is indexed one-third of a revolution for each revolution of the crankshaft of the machine. After each indexing, two of the plungers are forced forward by the sliding spindles, while the ejector slides through the other plunger, as previously mentioned, one of the plungers receiving a cut-off screw. After the two plungers have been drawn back by the spindles to a stop, the turret is again indexed one-third of a revolution. Then, as the plungers are advanced again, the screw previously received is brought into contact with the saw and slotted, while a second screw is received by the plunger bushing indexed into the loading position.

At the next forward movement of the spindles, which occurs after another indexing of the turret, the slotted screw is ejected, the second screw is slotted, and a third screw is received by the remaining plunger. This cycle is continuous. When the work does not require it, the attachment can be quickly dismantled after removing two bolts. By making slight modifications, the attachment can also be used for milling, cross-drilling and burring.

"ELTECO" LATHE CYLINDER-GRINDING ATTACHMENT

To enable small machine shops and garages to equip themselves at slight expense for regrinding automobile cylinders, the Liberty Tool Co., 1080 Springfield Ave., Irvington, N. J., has brought out the attachment illustrated, which is applicable to lathes of 14-inch and larger swing. The driving motor is mounted beneath the wheel-spindle in a housing placed on the bed close to the headstock. The motor is of ½ horsepower and is intended to be driven from an ordinary lamp socket. The cylinder block is held on an angle-plate mounted on the regular lathe carriage, and is fed to the grinding wheel by means of the carriage feed, the feed gearing being driven through sprockets and a silent chain by the motor of the attachment. This arrangement permits all the different feeds of the machine to be utilized. The wheel-spindle is driven at the rate of 5600 revolutions per minute.

The eccentric throw of the wheel from dead center is adjustable by a hand-screw graduated to 0.0005 inch. The holder will accommodate the largest-size six-cylinder block, having an inside length of 33 inches. Cross movements of the holder are obtained through a screw, and the holder may be raised or lowered by means of two vertical screws. The attachment weighs about 500 pounds.

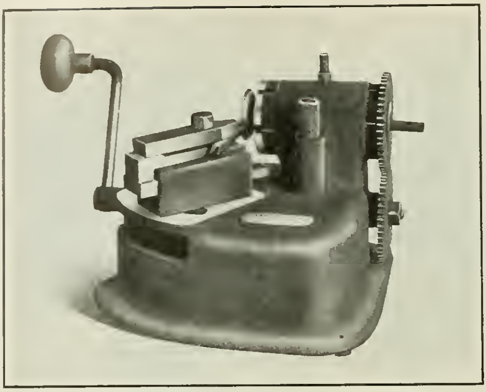


Lathe Attachment made by the Liberty Tool Co., for regrinding Automobile Cylinders

STEINER VALVE FACER

A hand-operated bench machine for accurately and quickly refacing valves of internal combustion engines has been placed on the market by Steiner Bros., Lima, Ohio. It is called by the manufacturers the "Peerless valve lathe." The mechanism for holding the valve consists of two collars having three cam surfaces on the inside which, when the collars are turned, operate three pins at each end of the hollow spindle through which the valve stem is inserted and cause these pins to advance toward the center of the spindle and bear on the stem. The latter is inserted from the left-hand end of the spindle, the hole of which is sufficiently large to accommodate the fillet, which is quite pronounced on some valves. The cams are then turned by applying a spanner wrench to the slots on their periphery. A nut provides for locking one cam, while the gear that rotates the spindle also serves as a locking device for the second cam. The spindle is driven through this gear by revolving the crank on the driving shaft.

A pin at the top of the machine functions both as an oil plug and a locking device for the spindle, the locking being accomplished by inserting the long end of the pin through holes in the body and the spindle. It is necessary to lock the spindle when manipulating the cams and locknut. The tool is fed

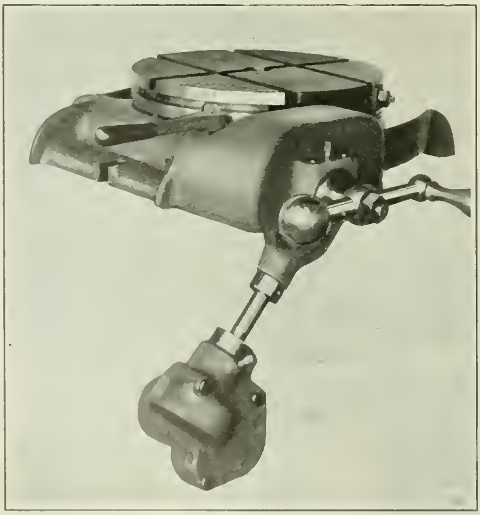


"Peerless" Valve Facing Machine made by Steiner Bros.

uniformly through a worm on the driving shaft which meshes with a worm-wheel on a vertical shaft. Near the lower end of this shaft and immediately above the worm-wheel a pinion engages a segment mounted on another vertical shaft, at the top of which is fastened a second segment that operates a rack attached to the tool carrier. When positioning the tool, the worm-wheel is disengaged from the driving shaft by depressing the knurled knob at the top of the machine. Provision is made for quickly returning the tool to the starting position when it is found that more than one cut is necessary on a valve face. The uniform rate of feeding the tool is said to produce a satisfactory face and reduce grinding-in to the minimum.

TAYLOR & FENN CIRCULAR MILLING ATTACHMENT

To adapt the high-speed vertical milling machine of its manufacture to circular milling operations, the Taylor & Fenn Co., Hartford, Conn., has designed the attachment shown in the accompanying illustration. This attachment is mounted on the regular table of the machine and driven from the telescopic shaft which furnishes the longitudinal table power-feed. By this means the thirty-three different feeds of the machine may be quickly obtained for the circular table, and in addition the circular feed may be varied by transposing two gears in the lower driving bracket. This provides a wide range of feeds which will be found especially useful in continuous milling operations. It is possible to drive both the longitudinal and circular tables simultaneously, this being of advantage on some classes of work. Some of the principal specifications of this attachment are as follows: Diameter of working surface, 10½ inches; maximum height from nose of machine spindle to table, 9 inches; ratio of table revolution to turning of handle, 40 to 1; and weight, about 110 pounds.



Circular Milling Attachment intended for Use on the Vertical Milling Machine built by the Taylor & Fenn Co.

HOFFMAN DRAWING TABLE

A line of drawing tables in which the supporting members are tubular, as shown in the accompanying illustration, has been developed by the Hoffman Drawing Stand Co., 189 N. Water St., Rochester, N. Y. This design provides a light construction without sacrificing strength or rigidity. The table can be quickly raised to any height from the floor up to 44 inches by revolving the handwheel on the vertical screw; and, in addition, the table can be tilted from the horizontal plane to almost a vertical position. Large corks inserted in the feet of the stand prevent the marring of polished floors or slipping of the stand. The drawer tray may be attached to either the left- or right-hand vertical supporting rod and held in any position on the rod.

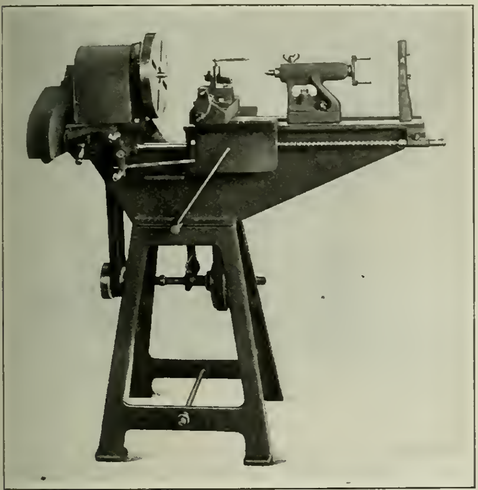
Drawing Table placed on the Market by the Hoffman Drawing Stand Co.

ARTISAN SMALL-SIZE GAP LATHE

An 11-inch gap lathe having a maximum distance of 24 inches between centers, which may be used as a portable equipment, has recently been brought out by the Artisan Mfg. Co., Cincinnati, Ohio. From the illustration it will be noted that a quick-change feed-box is furnished, the feed-box containing a clutch for engaging and disengaging the feed. This clutch is operated by the lever below the double crank-handle. The crank-handle is used for traversing the carriage by hand when working on short jobs with the carriage close to the faceplate. The shelf below the gap serves as a support for the carriage when it is run over the gap, an adjustable plug on the left end of the apron bearing upon the planed surface of the shelf to withstand the downward pressure.

When the carriage is required near the tailstock end of the bed the double crank-handle may be put on the right-hand end of the lead-screw where the screw extends from a bearing. The feed-box offers a wide range of feeds which enable all standard threads to be cut from 8 to 224 per inch, inclusive, and also 11½ pipe threads per inch. Reverse gears providing for the cutting of both right- and left-hand threads are contained within the swinging quadrant at the end of the headstock. This quadrant also contains compound gears for cone gears within the feed-box. A sliding tumbler lever engages any of the cone gears, while a direct-reading index-plate on top of the feed-box designates the proper position of this lever for a desired feed.

The cross-slide may be swiveled for angular turning, and when set for straight facing, taper dowel-pins serve to locate it in the correct position. The countershaft is mounted in self-aligning bronze bearings secured to the rear legs, and may be driven direct from a lineshaft through its friction pulley or by a motor mounted on the bed. The friction pulley is of the cone type having a spring that keeps it in engagement. A vertical rod at the rear of the machine has a fork which engages a flange of this friction clutch. This rod is



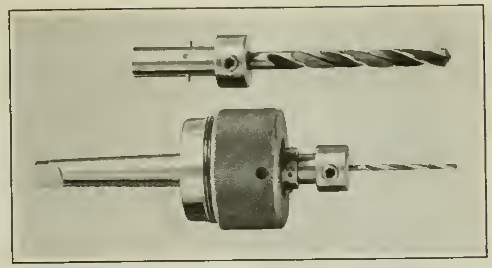
Eleven-inch Gap Lathe produced by the Artisan Mfg. Co.

operated by a shaft extending through the bed which has a lever at the front end. When this lever is pushed downward, the friction cone is withdrawn from the pulley and the fork that engages the flange of the disk serves as a brake to stop the countershaft instantly.

The drive from the countershaft to the headstock is through three-step cone pulleys. The cone pulley on the headstock is geared to the main spindle and in combination with a sliding back-gear gives six changes of speed in geometrical progression. A motor of ½ horsepower is recommended for driving this lathe, and the current may be supplied from an ordinary light socket. The swing of this machine at the gap is 16 inches, and over the carriage 8¾ inches.

"SAVE-ALL" SAFETY DRILL AND TAP CHUCK

A positive safety chuck for straight-shank drills, taps, reamers, counterbores, etc., which is intended for operations in which the feed is by hand, has just been placed on the market by the Save-All Tool Co., 59 River St., Waltham, Mass. It has been designed with the purpose in mind of eliminating the breakage of small tools. The safety device by means of which such breakages are prevented consists of two friction members and a soft steel driving pin, which is



Safety Chuck for Hand-fed Tools, made by the Save-All Tool Co.

sheared when the tool is overloaded. The tool is held in a hardened collet by means of a "Bristo" hollow safety set-screw which bears on a flat on the tool shank.

The soft steel driving pin is inserted through the collet and a hardened male friction member which is adjusted by the knurled nut on the outside of the chuck body. The female friction member is keyed to the body, the nut bearing on it and thus preventing it from tightening or loosening when the tool is run forward or backward. When the resistance to the tool becomes too great so that it sticks, the pin is sheared. There are three sizes of pin holes in the standard collet, the smaller ones being used with high-speed drills. The pin is held in place by a spring plunger.

MARQUETTE SPRING CUSHION FOR PUNCH PRESSES

With the view of eliminating wrinkles when drawing shells on punch presses and of reducing the pressure on the draw-ring, the Marquette Tool & Mfg. Co., 321 W. Ohio St., Chicago, Ill., has brought out an even-pressure spring cushion that differs somewhat in design from the spring cushion developed for the same purpose, which was described in October, 1921, MACHINERY. The new type is designed primarily for use on small and medium-size presses and under conditions requiring that a device of this kind be quickly attachable and detachable. Fig. 1 shows the cushion applied to a press. It is unnecessary to provide holes on the machine for attaching it, the cushion being simply held in place by screwing the upper threaded end of the suspension bolt, clearly seen in Fig. 2, into a tapped hole in the bottom of the die or bolster plate.

This suspension bolt extends through a sleeve having teeth cut on its outer surface near the upper end which are engaged on opposite sides by the teeth of two compensating cams. These cams swivel about their bearings when the draw-pins of the die are forced downward, the draw-pins

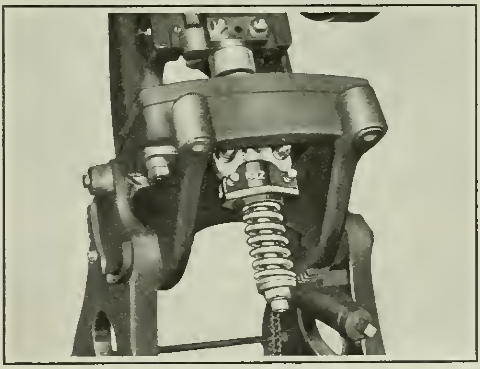


Fig. 1. Application of the Even-pressure Spring Cushion introduced to the Trade by the Marquette Tool & Mfg. Co.

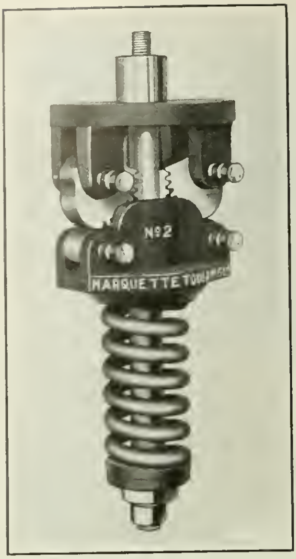

Fig. 2. Even-pressure Spring Cushion

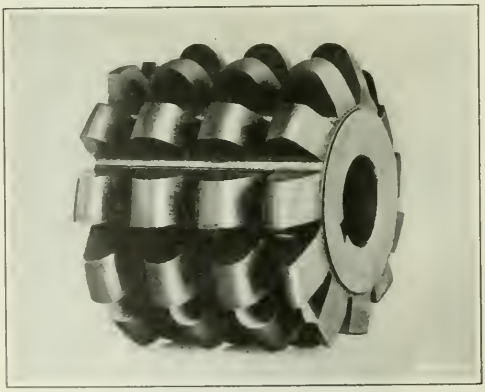
resting on a plate and spacer block placed on top of the cam housing. Another housing directly below the cam housing has two rollers that contact with the cams. The swiveling of the cams on their bearings causes a vertical movement of the rollers and so controls the compression of the spring in an operation, this compression, of course, being less than if the spring was not provided with compensating members.

When pressure is released from the draw-ring, the friction between the rollers and cams caused by the spring forces the cams to return to their original positions. The initial pressure on the spring may be regulated by means of an adjustable nut placed on the lower end of the sleeve. Grease cups provide for adequate lubrication of the roller and cam bearings. It is said that presses equipped with this die cushion will produce in one operation work generally performed in two, and that the wear on the dies is less severe.

DIAMOND SPROCKET-TOOTH HOBS

The accompanying illustration shows a hob of a set manufactured by the Diamond Chain & Mfg. Co., Indianapolis, Ind., each of which is suitable for cutting any number of sprocket teeth of a given pitch and roller diameter. Thus each hob will do work that ordinarily requires from six to nine cutters. In addition, there is the advantage of em-



Hob manufactured by the Diamond Chain & Mfg. Co. for Cutting Sprocket Teeth

ploying a hobbing machine which permits high production rates and convenient and accurate indexing. These hobs are designed to cut sprocket teeth in conformity with the specifications for the "American Standard" sprocket-tooth form, which has been approved by manufacturers of roller transmission chains, the Society of Automotive Engineers, the American Society of Mechanical Engineers, and the American Gear Manufacturers' Association. This tooth form is particularly adapted for production by hobbing. Its space angle gradually decreases as the number of teeth increases, while its tooth angle, and hence its pressure angle, gradually increases. The generating action of a hob tends to produce these changes although not at the same rate. The pitch of each hob is greater than the circular pitch of the sprocket for all above a certain number of teeth, and less than the circular pitch for all under that number.

NIAGARA COMPOUND-SEAM CLOSER

Air-tight side seams can be made on such articles as drums for calcium carbide and cans for calcium chloride by employing the seam-closing machine developed by the Niagara Machine & Tool Works, 637-697 Northland Ave., Buffalo, N. Y., which is illustrated in Fig. 1. The seam produced may be filled with a sealing compound, although the seam as closed by the machine is practically air-tight. Offsets

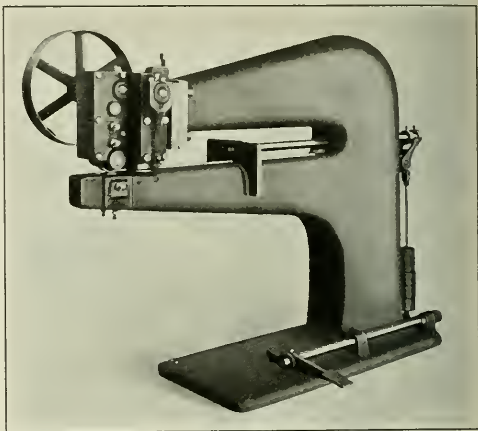


Fig. 1. Seam-closing Machine built by Niagara Machine & Tool Works

are first formed on the ends of the sheet to be joined, as shown at *A* and *B* in Fig. 2, after which the sheet is rolled to a cylindrical shape and placed over the horn of the machine with the offsets lying on the guide piece set into the top of the horn.

The machine runs continuously, and therefore does not require tight and loose pulleys or a clutch, the pulley being run at the speed of 100 revolutions per minute. The treadle at the front of the machine is connected to a sliding member, and by depressing the treadle the work is moved forward along the horn and fed between the first set of rolls which squeeze the seam together at the bottom. After these rolls take hold of the work, the latter is automatically fed through the machine, the second set of rolls flattening and thus closing in one operation the double-lock seam shown at *C*. The maximum length of work that can be handled is 42 inches, and the minimum diameter for this length is 13½ inches. The machine has a capacity for No. 22 gage soft steel, and weighs approximately 2700 pounds.

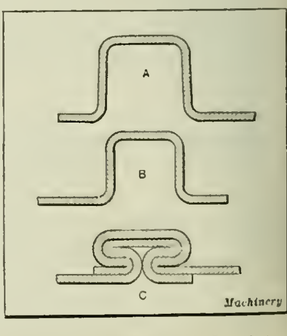

Fig. 2. Three Stages in the Seam-closing Operation

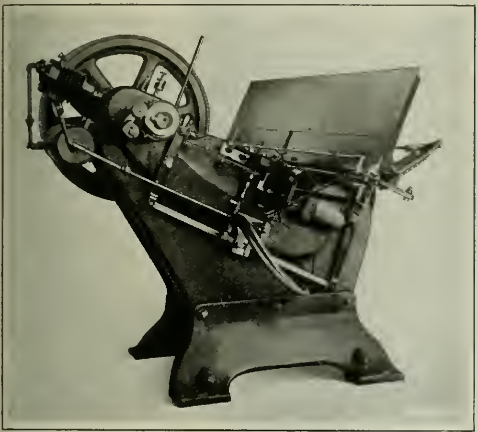
ADRIANCE STAGGER-FEED PRESS

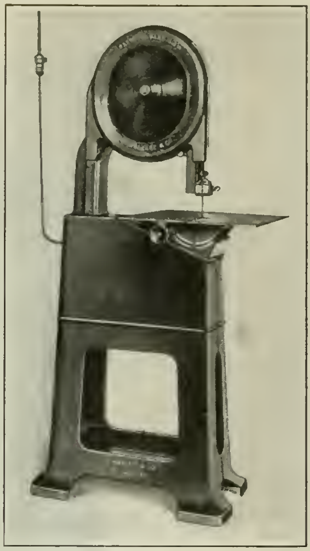
An automatic punch press on which the punch operates continuously and cuts blanks in a staggered relation to one another, leaving a mere thread of metal between the holes is shown in the accompanying illustration. This machine has been recently developed by the Adriance Machine Works, Inc., 78 Richards St., Brooklyn, N. Y., and is especially suitable for the production of such parts as can tops and bottoms and other small shells. The sheet stock is held in a carrier which travels in either direction past the reciprocating punch. It is not necessary for the carrier to be returned to the starting point after punching a row of blanks, because the moment the end of a row has been reached the action of the carrier is automatically reversed and the next row may be punched as the carrier returns to the starting point. After the last blank has been punched from a sheet the carrier stops automatically. It is thus possible for an operator to run several presses at one time. His safety is assured, because at no time do his fingers come near the die. The scrap stock is ejected automatically. The machine will cut blanks from 1 to 4 inches in diameter and has produced them at the rate of 100 per minute.



Automatic Stagger-feed Punch Press placed on the Market by the Adriance Machine Works, Inc.

WALLACE BENCH BAND SAW

A machine primarily of interest to patternmakers is the 16-inch portable band saw illustrated, which is a recent development of J. D. Wallace & Co., 1421 W. Jackson Blvd., Chicago, Ill. This saw is driven by an enclosed motor built into the machine and direct-connected to the lower saw wheel by a fabroil gear and a steel pinion, both of which run in oil. The motor is of ½ horsepower, and runs at a speed of 1750 revolutions per minute, operating on current obtained from a lighting circuit. The machine is equipped with steel disk wheels. The table is a ground plate mounted on a rocker bearing which is adjustable from 45 degrees in one direction to 5 degrees in the opposite direction. An indicator shows the angle at which the table is tilted. All adjustments are obtained by means of handwheels or thumb-screws. The saw blades are made from a special steel, and are operated at a speed of 3150 feet per minute. The table has a surface of 19 by 21 inches, and is located 42 inches above the floor. The height of the machine is about 6 feet.



Wallace Sixteen-inch Band Saw

MONITOR "THERMALOAD" MOTOR STARTER

A thermal-limit starter known as the "Thermaload," which is intended for controlling the operation of alternating-current, single-, two-, or three-phase motors of from ¼ to 10 horsepower, has been placed on the market by the Monitor Controller Co., Baltimore, Md. This starter (see Fig. 1) is peculiarly adapted to machine tool application in that a number of control stations, which are of the push-button type, may be mounted in several convenient locations on a machine so that the operator can instantly stop the machine when he desires. If the load on a cutting tool becomes too great, the appliance immediately stops the motor. It allows the motor to exert six or seven times its normal power for a limited period, but at the same

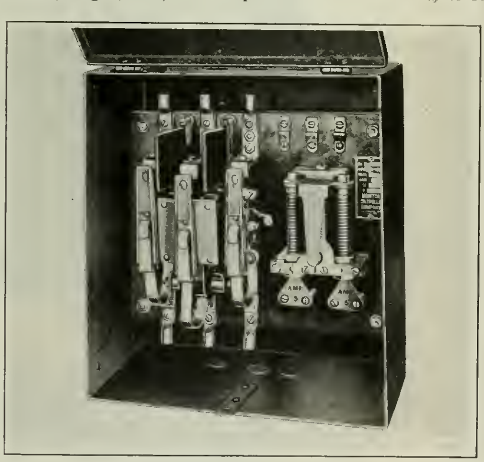


Fig. 1. "Thermaload" Starter for Induction Motors made by the Monitor Controller Co.

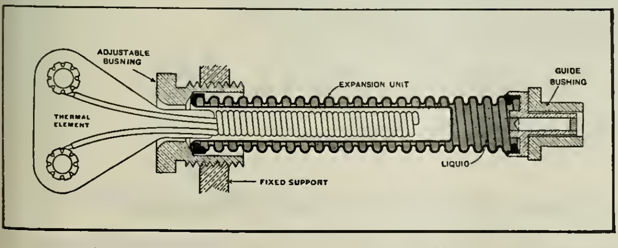

Fig. 2. Sectional View of the Thermal Unit in the Monitor Starter

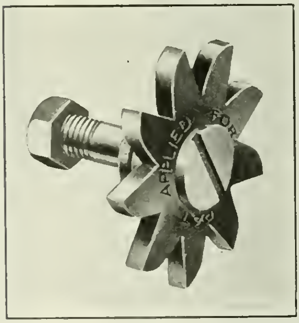
time will protect it from a prolonged overload as small as 25 per cent and from overheating sufficiently to cause injury to insulation. It prevents polyphase motors from running on single-phase current.

The starter consists of a three-pole magnetic contactor and a thermal-limit relay, mounted on a slate panel and enclosed in a metal cabinet which may be locked or sealed and placed in a remote location, as on the ceiling. The thermal-limit relay consists essentially of two units which expand between a fixed support and a hinged contact arm, the latter being arranged in such a way as to multiply the motion of the expansion units several times at the contact. The construction of an expansion unit is shown in Fig. 2. It will be seen that a unit consists of a double-walled tubular receptacle, the inner wall of which is smooth and closed at one end, while the outer wall is corrugated and closed at both ends.

The space enclosed between the two walls is filled with tetrachloride of carbon, a non-corrosive, non-freezing liquid used in fire extinguishers. The thermal element which operates the expansion unit consists of a coil of asbestos-insulated wire attached to a piece of insulating material by means of brass eyelets. These eyelets register with brass binding posts to which they are securely clamped by means of brass screws. The binding posts, in addition to serving as electrical connections to the element, also furnish its support. A relay can be changed from one rating to another by merely inserting the proper elements.

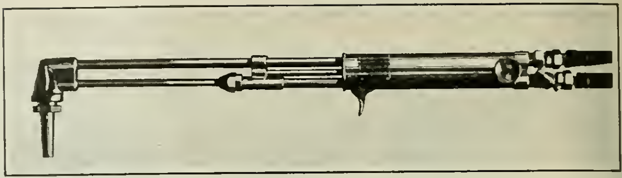
DISSTON SAW-CHIP REMOVING DEVICE

Breakage of the teeth of metal-cutting saws is frequently caused by the clogging action of the chips, which causes a heavy strain to be placed on the teeth. With a view to eliminating such trouble, Henry Disston & Sons, Inc., Tacony, Philadelphia, Pa., has brought out the special wheel illustrated, which has teeth spaced to suit the teeth of the saw with which it is intended to be used. This wheel is attached by means of the stud, to some member adjacent to the saw; it is placed at right angles to one side of the saw in such a position that the teeth of the wheel engage the tops of the saw teeth as the saw revolves and push the chips from these surfaces. As the saw teeth are kept free from chips when this device is used, the saw can be operated at faster speeds and heavier feeds.



Saw-chip Remover made by Henry Disston & Sons, Inc.

DAVIS-BOURNONVILLE CUTTING TORCH



New Type of Cutting Torch brought out by the Davis-Bournonville Co.

A cutting torch in which two tubes instead of three connect the head with the handle, and in which the preheating gases, which may be oxygen and acetylene or some other combustible gas, are mixed in a chamber between the handle and the head, is a new product of the Davis-Bournonville Co., Jersey City, N. J. This design requires a new style of tip, inasmuch as the mixture of the gases is accomplished before they reach the tip. The tubes are silver-soldered in the head, the latter being a copper forging, which, besides being free from pin holes and similar defects, will withstand higher temperatures than bronze or brass castings.

The ratio of the mixed gases is controlled by two needle valves, one of which has a cross-bar handle and the other a knurled disk handle. The cutting-oxygen valve is operated by a finger-lever connected to a linkage so designed as to hold the lever in either the closed or the open position. Thus the operator may cut work without holding his finger on the trigger after the operation has been started, and when he wishes to stop cutting, a reverse pressure on the trigger closes the valve. A spring holds the trigger in the closed position until the trigger is operated again. Provision is made for easily removing the back end of the torch in case it becomes necessary to clean the screen or to remove the oxygen-cutting valve seat.

The tips are made of copper and held in a taper seat by a bushing nut, this construction being identical with that of the Davis-Bournonville standard torch. The tips are made with the cutting-oxygen hole at the center and the preheating holes surrounding it. The number of preheating holes in a tip varies from two to six, depending on the combustible gas used, the manner in which the torch is applied, and the metal being cut. Bent tips are furnished for cutting off rivets. Gases of low calorific value such as butane, hydrogen, carbo-hydrogen and even illuminating gas, may be used, although acetylene is recommended when cost is not the prime consideration and smooth even cutting is required.

PANGBORN SAND BLAST

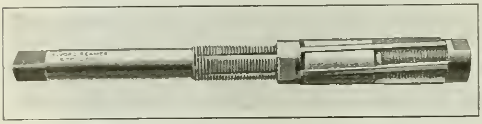
A small size sand blast, which can be easily conveyed from place to place about a plant, is a recent addition to the line of sand-blast equipment manufactured by the Pangborn Corporation, Hagerstown, Md. This sand blast has a suction type gun in which the blast action is controlled by a trigger in the handle. Compressed air passing through the air jet creates a vacuum by which the abrasive, either sand or metallic, is brought from the hopper to the gun body, which has a mixing chamber where the air and the abrasive are given a swirling action similar to the movement given a bullet by the rifling of a gun barrel.

Quickly interchangeable nozzles make the equipment suitable for use under a number of conditions. It may be operated at any pressure between 5 and 100 pounds per square inch. The small cabinet set over the hopper of the sand blast in the illustration provides an economical means of cleaning small parts. The sand blast, however, may be used without this cabinet.

Small Sand Blast and Cabinet manufactured by the Pangborn Corporation

ALVORD HELICAL INSERTED-BLADE REAMER

An adjustable inserted-blade reamer incorporating the unusual feature of having the blades set at an angle so as to produce a shearing cut is a recent product of the Alvord Reamer & Tool Co., Millersburg, Pa. This tool is sold under the trade name of "X-Cel." The purpose of the design is primarily to eliminate chatter in operation. Its construction is similar to the straight-fluted adjustable reamer manufactured by the same company. The body is made of a tough alloy steel and heat-treated on the shank end to withstand rough treatment. The threads that control the adjustment feature are accurately chased and finally checked



"X-Cel" Shear-cut Adjustable Blade Reamer made by the Alvord Reamer & Tool Co.

by a gage. The tapered slots that receive the blades are milled to close limits and at the proper angle to produce the desired shearing effect.

The blades are made of a special steel and accurately ground all over. Both ends of a set of blades are ground to the correct angle for contact with the nuts in one setting on a grinding machine, which also insures that all the blades will be produced to exactly the same length. Thus they are locked securely in their seats when the nuts are tightened. The nuts are made of crucible steel, and are also hardened and ground. This reamer is especially recommended for use with bearing metals, particularly bronze. It produces satisfactory results when employed with split bearings and holes provided with oil-grooves or keyways. The reamer is made in seventeen standard sizes to cover a range of diameters from 15/32 to 4 1/16 inches.

NEW MACHINERY AND TOOLS NOTES

Worm-gear Drive for Lineshafting: Cleveland Worm and Gear Co., Cleveland, Ohio. An enclosed worm-gear unit for driving lineshafting direct from a motor attached to the ceiling, the armature shaft of the motor being at right-angles to the lineshafting. This driving method permits the use of smaller, higher speed motors. Large ratios of reduction can be obtained.

Buffing and Grinding Machines: Valley Electric Co., 3157 South Kingshighway, St. Louis, Mo. A line of floor-type buffing and grinding machines on which the motor is totally enclosed and its shaft is extended and threaded at both ends for accommodating the buffing and grinding wheels. The motor is mounted on a cast-iron pedestal on the front of which is a safety switch. A pulley on the motor shaft provides for driving an air compressor.

Lathe Chucks: Cushman Chuck Co., Hartford, Conn. An improved line of lathe chucks made in all sizes from 10 to 30 inches. A special feature is the thrust bearings which are made in two parts and completely encircle the screws at a point about midway of their length. The stems of the thrust bearings are driven into round holes in the chuck body and are therefore self-aligning. The bearings hold the screws in place whether the jaws are assembled or not. All parts are finished to gages and are interchangeable.

Automatic Cutting Machine: General Welding & Equipment Co., 74 Brookline Ave., Boston, Mass. An automatic cutting machine intended for cutting such metal parts as dies, cams, crankshafts, and drop-forge tools directly from steel plates. The machine has two carriages, one of which is mounted on the other. The upper carriage has on one side an oxy-acetylene cutting torch, and on the opposite side it supports the driving and tracing system. Any movement on the pattern is transmitted directly to the torch. A motor on the top carriage transmits its power through a friction wheel.

PERSONALS

Charles B. Siner has been made treasurer and general manager of the T. C. Dill Machine Co., Philadelphia, Pa.

T. H. Hays has been appointed manager of the Indianapolis office of the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa.

J. J. Wittenburg has been placed in charge of the St. Louis office of the Chicago Flexible Shaft Co., Chicago, Ill. The office is located in the Railway Exchange Building, as it has been heretofore.

L. E. Salom has been appointed district representative for the New York territory of the Cleveland Electric Tramrail Division of the Cleveland Crane & Engineering Co., Wickliffe, Ohio. He will make his headquarters at 50 Church St., New York City.

Kenneth MacNeal, formerly secretary-treasurer of the Jones, MacNeal & Camp Co., Warsaw, Ind., has become president of that concern, succeeding L. E. Jones. Arthur MacNeal has been elected vice-president and treasurer, and D. B. MacNeal assumes the duties of secretary and general sales manager.

H. L. Carpenter, Jr. has been appointed traveling representative in western Pennsylvania for the Ajax Metal Co., Philadelphia, Pa. He has been associated with this company for over twenty years, having had charge of the Pittsburg office and later being connected with the main office in Philadelphia.

L. A. Carter has been made president of the Lehmann Machine Co., St. Louis, Mo. He became connected with this company several years ago, starting as engineer and designer, and advancing to the position of general manager and now to the presidency. He is the designer of the lathes made by this company.

A. E. Hitchner, assistant to the manager of the industrial department, in general charge of the mining and electrochemical industries, of the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., has been placed in charge of the sections formerly handled by W. H. Patterson, who recently resigned to become vice-president of the Kaestner & Hecht Co., Chicago, Ill., elevator manufacturer, who handles Westinghouse direct traction elevator equipment in the Middle West.

H. D. James, manager of the control engineering department of the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., has been re-elected president of the Engineers' Society of Western Pennsylvania. The other officers elected at the annual meeting were Frederick Crabtree, vice-president, and J. C. Hobbs and C. D. Terry, directors. Mr. James had served as director of the society for three years, and has been president for the last two years. He is a graduate of the University of Pennsylvania and a member of the American Institute of Electrical Engineers.

William J. Cleary has been appointed assistant general sales manager of the Sharon Pressed Steel Co., Sharon, Pa., manufacturer of pressed-steel frames, axle housings, brake drums, and heavy pressed steel stampings for automobiles, railroads, mines, mills, and factories. Mr. Cleary has been connected with the automotive industry for the last fourteen years, having been associated with the Studebaker Corporation as assistant general purchasing agent for twelve years and with the Willys Corporation, Elizabeth, N. J., as general purchasing agent for the last two years. His headquarters will be 1214 Dime Bank Bldg., Detroit, Mich., and his duties will cover the automotive industry in general.

NEW BOOK ON FORGING

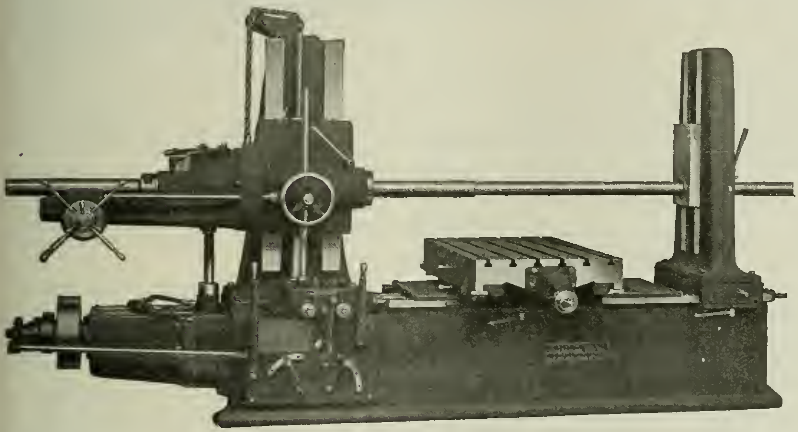
Machine Forging. By Douglas T. Hamilton. 106 pages, 6 by 9 inches; 85 illustrations. Published by The Industrial Press, 140-148 Lafayette St., New York City. Price, $1.

For many years inventors rarely crossed the threshold of the blacksmith shop. Hand-manipulated tools were used for many forging operations now performed in a fraction of the time entirely by mechanical means. A great deal has been accomplished during recent years in developing forging machines and various other classes of power-driven equipment for forge shops. The forging of bolts and rivets by machinery is an old method, but the use of machines for forging, welding and upsetting operations on machine parts of numerous shapes and sizes is a relatively modern development. The making of bolts, nuts, and rivets is an important and specialized branch of machine forging, and the construction and use of the machines and dies employed for this work are described in this treatise, as well as the application of machines designed for general forging operations. Dies designed for various typical operations are also described.

"Art stays the relentless hand of time"

The "PRECISION"

Boring, Drilling and MILLING MACHINE



Makes a good OLD Machine

Almost like SLEIGHT OF HAND is the ease and quickness with which our new

Vertical Push-Broaching Machine

handles the broach.

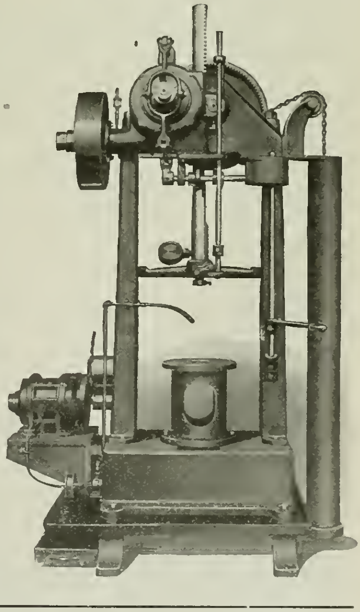
Less floor space—More production



LUCAS MACHINE TOOL CO. NOW AND ALWAYS OF **CLEVELAND, OHIO, U.S.A.**

FOREIGN AGENTS: Alfred Herbert, Ltd., Coventry. Societe Anonyme Belge, Alfred Herbert, Brussels. Aux Forges de Vulcain, Paris. Allied Machinery Co., Turin, Barcelona, Zurich. Benson Bros., Sydney, Melbourne. V. Lowener, Copenhagen, Christiania, Stockholm. R. S. Stokvis & Zonen, Rotterdam. Andrews & George Co., Tokyo, Japan.

OBITUARIES

John H. Streeter, secretary and treasurer of the Riverside Iron Works, Chicago, Ill., died January 26.

A. B. Hiler, for many years New York representative of the Jones & Lamson Machine Co., Springfield, Vt., died January 28, after a long period of suffering borne courageously and cheerfully. Mr. Hiler was born in Rockaway, N. J., in 1874, and received his early mechanical training at the Liberty Bicycle Works at Rockaway. Later he was employed in the screw machine department of the Thomas A. Edison Works in Orange, N. J., where he soon became foreman. About fifteen years ago he left the Edison plant and entered the employ of the Jones & Lamson Machine Co., remaining with this firm until the time of his death.

Howard V. Lewis, of the Fitchburg Machine Works, Fitchburg, Mass., died from meningitis on January 26 at the Burbank Hospital in Fitchburg. He was born in Cincinnati in October, 1878, and graduated from Harvard University in 1900. Upon leaving college he was employed for a number of years by the American Tool Works of Cincinnati, and later was connected with the Fairbanks Co. of New York. After severing his connection with the Fairbanks Co. he became a manufacturers' representative, with headquarters in New York City, and subsequently was associated with the Allied Machinery Co. of America for about a year, six months of which he spent in Paris. He went to the Fitchburg Machine Works in November, 1915, and during his residence there built up a wide acquaintance and was highly respected by his business associates and many friends. He held the position of vice-president, secretary, and sales manager at the time of his death. Mr. Lewis is survived by his widow and four children.

George William Peck of the Miner & Peck Mfg. Co., Derby, Conn., died at his home February 1, of kidney trouble. His father established the Miner & Peck Mfg. Co. in 1850 under the name of Milo Peck. At the death of his father in 1876, George W. Peck assumed active managership and continued as manager until his death. During his lifetime the concern was renamed, successively, Milo Peck & Co., Beecher & Peck, and the Miner & Peck Mfg. Co. In November, 1920, the company was purchased by the Birmingham Iron Foundry and removed to Derby. The firm name was retained, and Mr. Peck continued to serve as manager. In his years as manager he had continually developed the design of the Peck drop press and the Peck automatic lifter. He was well known and respected in the trade, and his passing will be regretted by a wide circle of friends. The Miner & Peck Mfg. Co. will continue its operation as before.

William C. Sargent, for twenty-two years secretary and also a director of the Chain Belt Co., Milwaukee, Wis., died suddenly on February 5 from heart failure. He was seventy-three years of age, and had been in ill health for several years. Mr. Sargent, prominent in industrial circles of Milwaukee and St. Paul, had a wide national acquaintanceship. He was born at Troy, N. Y., February 2, 1849. In 1871 he moved West, locating at St. Paul, where he organized the De Cou, Corliss & Sargent Co., manufacturer of sash and doors. He later became affiliated with the St. Paul Harvester Co., and it was while he was with this concern that he met C. W. Le Valley who subsequently founded the Chain Belt Co. of Milwaukee. This meeting was the beginning of a long business association, for in 1900 Mr. Sargent went to Milwaukee to become secretary and later a director of the Chain Belt Co. He was also a director of the Federal Malleable Co., West Allis, Wis. His father was one of the founders of the Terre Haute, Alton & St. Louis Railroad. Mr. Sargent established many of the early business connections of the Chain Belt Co., a large proportion of which are still among the company's jobbers.

COMING EVENTS

March 3—Sectional meeting of the American Society for Steel Treating in the Hotel McAlpin, 34th St. and Broadway, New York City. Secretary, W. H. Eisenman, 4600 Prospect Ave., Cleveland, Ohio.

March 15—Meeting of the Pittsburg section of the American Institute of Electrical Engineers in Pittsburg, Pa. Chairman, H. W. Smith, General Engineering Dept., Westinghouse Electric & Mfg. Co., East Pittsburg, Pa.

March 16-18—Mid-winter meeting of the Taylor Society at the City Club, Philadelphia, Pa. Address of secretary, 29 W. 39th St., New York City.

April 19-20—Annual meeting of the National Metal Trades Association in New York City; headquarters, Hotel Astor. Secretary, Homer D. Sayre, Peoples' Gas Bldg., Chicago, Ill.

April 20-22—Sixth annual convention of the American Gear Manufacturers' Association in Buffalo, N. Y.; headquarters, Lafayette Hotel. Secretary, F. D. Hamlin, 4401 Germantown Ave., Philadelphia, Pa.

April 22-May 2—Sixth annual Swiss sample fair at Basle, Switzerland, in the Great Exhibition Bldg. For further information apply to F. Dossenbach, Director of the Official Information Bureau of Switzerland, 241 Fifth Ave., New York City.

May 8-11—Spring meeting of the American Society of Mechanical Engineers in Atlanta, Ga. Assistant Secretary (Meetings), C. E. Davies, 29 W. 39th St., New York City.

May 10-12—Ninth National Foreign Trade Convention in Philadelphia, Pa. Secretary, O. K. Davis, 1 Hanover Square, New York City.

May 18-20—Annual conference of the National Association of Office Managers in Washington, D. C. Secretary, F. L. Rowland, Gilbert & Barker Mfg. Co., Springfield, Mass. Guests are invited to attend.

June 5-9—Annual convention and exhibit of the American Foundrymen's Association and allied societies in Rochester, N. Y. Secretary, C. E. Hoyt, Marquette Bldg., 140 S. Dearborn St., Chicago, Ill.

June 15-24—International exhibition of foundry equipment and materials in Birmingham, England, in connection with the annual convention of the Institution of British Foundrymen.

June 26-July 1—Twenty-fifth annual meeting of the American Society for Testing Materials in Atlantic City, N. J.; headquarters, Chalfonte-Haddon Hall Hotel. Secretary, C. L. Warwick, 1315 Spruce St., Philadelphia, Pa.

August 28-September 2—Annual Safety Congress of the National Safety Council in Detroit, Mich. Secretary, S. J. Williams, 168 N. Michigan Ave., Chicago, Ill.

SOCIETIES, SCHOOLS AND COLLEGES

California Polytechnic School, San Luis Obispo, Cal. Bulletin of information containing calendar and courses of study for 1921-1922.

American Welding Society, 33 W. 39th St., New York City, issued the first number of the proceedings of the society in January. It is the intention to issue the proceedings monthly, and they will include news items and reports of the society, local sections, the American Bureau of Welding, and the welding industry in general, as well as technical papers relating to the art of welding and its industrial application. Certain sections of the journal will be devoted to employment service, bibliography of current welding literature, names of new members, etc.

NEW BOOKS AND PAMPHLETS

Results of a Survey of Elevator Interlocks and an Analysis of Elevator Accident Statistics. 30 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Technologic Paper No. 202 of the Bureau of Standards. Price, 5 cents.

Friction and Carrying Capacity of Ball and Roller Bearings. By H. L. Whittemore and S. N. Petrenko. 34 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Technologic Paper No. 201 of the Bureau of Standards. Price, 10 cents.

State Laws Affecting Working Women. 49 pages, 6 by 9 inches. Published by the Women's Bureau of the United States Department of Labor as Bulletin No. 16.

This report covers the state laws affecting working women which were in effect in the United States July 1, 1921. The majority of the laws affecting working women have been charted, and five maps have been made of the charts to give a picture of conditions of the country as a whole. The laws covered are those regulating the length of the working day or week; laws providing for a day of rest, one shorter work day, time for meals, and rest periods; night work laws; laws regulating home work; minimum-wage laws; and mothers' pension laws.

The Modern Gas Tractor. By Victor W. Page. 590 pages, 5 by 7 inches. Published by the Norman W. Henley Publishing Co., 2 West 45th St., New York City. Price, $3.

This is the fourth edition, revised and enlarged, of a book which treats exclusively of the design and construction of farm tractors and tractor power plants, and gives instructions relative to their care, operation, and repair. It illustrates and describes the different types and sizes of gasoline, kerosene, and oil tractors. The chapter on engine repairing has been considerably enlarged, and instructions are now given for repairing well-known and widely used tractor power plants, many new forms of which are described. The book is not written as a technical treatise, an endeavor having been made to present the principles of design in such a manner that they may be readily understood by those without technical knowledge. It is intended to bridge the gap between the purely technical work and the manufacturer's instruction book dealing with one specific construction.

Involute Spur Gears. By Earle Buckingham. 91 pages, 6 by 9 inches. Published by the Niles-Bement-Pond Co., 111 Broadway, New York City.

In this treatise the author has aimed to present in concise form an analysis of the problems involved in designing, producing, and testing involute spur gears. The five chapters cover the involute curve and its properties; the design of involute gear tooth profiles; methods of production; methods of testing gears; and the strength of gears. Chapter I deals with the equation of the involute curve; the action of one involute against another; the action of an involute against a straight line; the duration of contact between meshing gears; sliding and rolling contact; undercutting of the involute, and teeth and bearing pressures. This chapter on the characteristics of the involute curve is followed by a study, in Chapter II, of the best method of utilizing these characteristics. The requirements are considered first, and then the interchangeability of involute gear tooth forms and representative standard tooth forms, including a comparison of the Brown & Sharpe, Fellows, and Maag standards. In Chapter III methods of production are summarized, and mathematical analyses of the hob and pinion-shaped cutter are given. Chapter IV is descriptive of several appliances for testing gears to check the size, accuracy of tooth form, or running qualities. The last chapter gives representative formulas for calculating the strength of gears, including empirical formulas for determining the increment load for gears running at high speeds under heavy loads. This book is a valuable addition to the literature of gearing, and the author is well known to the readers of Machinery, especially in connection with his series of articles on the general subject of interchangeable manufacturing.

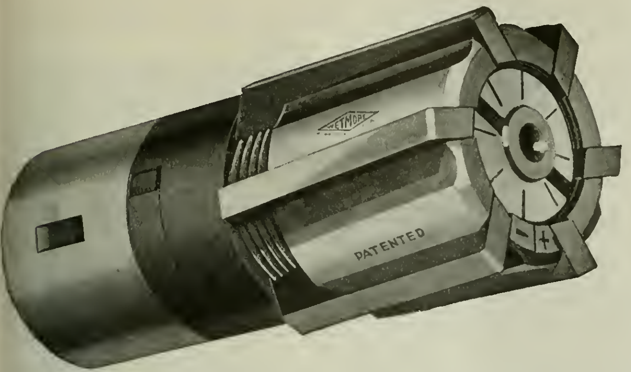
NEW CATALOGUES AND CIRCULARS

Porter Products Corporation, Keith Theater Bldg., Syracuse, N. Y. Leaflet illustrating and describing the Porter "Utility" offset screwdriver, for use in cramped quarters.

Hardinge Co., 120 Broadway, New York City. Bulletin 12, on Quigley fuel systems, describing the preparation, transportation, and burning of pulverized fuel.

Sprague Electric Works of General Electric Co., 527 W. 34th St., New York City. Bulletin 48716, descriptive of the Sprague electric dynamometer of the research type.

Cleveland Crane & Engineering Co., Wickliffe, Ohio. Circular showing applications of the Cleveland electric tramrail system for transporting material in garages, foundries, warehouses, factories, boiler rooms, etc.



Where extreme accuracy and a glass-like finish are required, this Wetmore Expanding 6-Blade Standard Reamer has no superior.

More Holes to a Grind

Wetmore Expanding Reamers

SUPERINTENDENTS, production men and mechanics in many of America's largest plants say that Wetmore Expanding Reamers are more durable—and hence more economical—than any other expanding reamers they know of.

Combined with this greater capacity for day-in, day-out hard service, every Wetmore Reamer—from the 6-Blade Standard Reamer shown above to the new Wetmore Expanding Small Machine Reamers which are now being made in sizes under one-inch—has a proved reputation for guaranteed accuracy and quality of reaming.

DISTINCTIVE WETMORE FEATURES

Among the advantages of Wetmore Expanding Reamers that are strongly appealing to users are the following:

Adjustments to the thousandth of an inch can be made in less than a minute. In fact, workmen say the Wetmore is the quickest and easiest adjusting reamer made. Cone expansion nut keeps blades always parallel with axis.

Solid, heat-treated alloy steel body—guaranteed against breakage.

Left Hand Angle Cutting Blades that prevent digging in, chattering, and scoring of the reamer while backing out.

No grinding arbor required for regrinding. Wetmore Reamers can be reground on their original centers.

AN INTERESTING JOB

Four hundred and fifty holes to a grind in 3½% chrome nickel steel! That is the performance of a Wetmore Standard Expanding Reamer (6-blade) in the shops of The Lodge & Shipley Machine Tool Co., Cincinnati, Ohio.

Such service, though remarkable, is not unusual for Wetmore Reamers. In fact, many of America's largest manufacturing plants have found that Wetmore Expanding Reamers have a longer life—a greater durability which enables them to stand up longer under constant punishment of peak production in small-tolerance machining.

If you are not using Wetmore Reamers, you should know more about them. Send us your name and we will mail you a valuable "hand-book" on expanding reamers, arbors and cylinder reaming sets—*free*. No obligation to you, of course.

WETMORE REAMER COMPANY

MILWAUKEE Box 21 **WISCONSIN**

(Manufacturers of Expanding Reamers and Cylinder Reaming Sets, Arbors and Thread Gauges)

WETMORE EXPANDING REAMERS

"THE BETTER REAMER"

Arva Stroud, 327 Broadway, New York City. Circular illustrating the application of R. V. 1-horsepower portable universal electric grinders for general work. The technical details are described, and instructions are given for upkeep and use.

New Departure Mfg. Co., Bristol, Conn. Loose-leaf sheets XV, XVI, and XVII containing dimensions and price lists for New Departure double- and single-row ball bearings, new "Radax" ball bearings, and magneto type ball bearings.

Monitor Controller Co., Baltimore, Md. Bulletin 101, discussing the starting of small alternating-current motors, and illustrating and describing Monitor "Thermaload" starters which are equipped with thermal-limit relays to protect against overload.

R & C Lap Co., Inc., Davenport, Iowa, has issued three new booklets covering the R & C line of laps for tool-room and production work, two of which have special reference to the lapping of automobile cylinders. Copies of the booklets will be sent upon request.

Cutter Co., Philadelphia, Pa. Circular illustrating and describing the "U-Re-Lite"—a circuit breaker for protecting electric motors and power and lighting circuits from overloading. The device is enclosed in a specially constructed steel case to insure safety of the operator.

Thwing Instrument Co., 3339 Lancaster Ave., Philadelphia, Pa. Bulletin 10, describing Thwing thermo-electric pyrometers of the indicating and multiple-recording types, as well as Thwing multiple-record high-resistance recorders, for use in connection with indicating instruments.

Bryant Chucking Grinder Co., Springfield, Vt. Circular containing specifications for the Bryant No. 2 semi-automatic double-head hole grinder. Illustrations are presented showing the method of grinding pistons on this machine, as well as plan views of typical work-holding fixtures.

Sundh Engineering & Machine Co., 1105 Frankford Ave., Philadelphia, Pa. Circular describing the Sundh cable draw-bench, which is an electrically operated automatically controlled machine for producing rods, tubes, moldings and bars of various shapes by drawing through a die.

Edison Lamp Works of General Electric Co., Harrison, N. J. Bulletin LD 130, containing an article on "The Eye as Affected by Illumination." Bulletin LD 134, discussing the lighting of metal-working plants and containing illustrations showing examples of adequate illumination in machine shops.

Mansfield Steel Corporation, 954 E. Milwaukee Ave., Detroit, Mich. Loose-leaf circulars illustrating a trailer hitch, or hook, designed to couple with the standard trailer eye recommended by the Society of Automotive Engineers, and Mansfield front bumpers and radiator guards for automobile trucks.

Olson Mfg. Co., Worcester, Mass. Circulars illustrating the Olson magazine screwdriver, which is made with a hollow handle for holding the different sizes of blades that can be used with this tool. The tool is regularly furnished with three blades and one awl, which adapts it for handling both large and small work.

L. S. Starrett Co., Athol, Mass. Supplement to catalogue No. 22, containing illustrations, specifications and price lists of several new Starrett tools, including metal case for micrometers, micrometer depth gage, inspector's micrometer caliper gage, standard end measuring rods, squares, vernier height gages, thickness gages, etc.

Shepard Electric Crane & Hoist Co., Montour Falls, N. Y. Circular announcing a new and smaller Shepard electric hoist, which is known as the "Liftabout" and which may be operated by one man. The hoist is made in ½- and 1-ton capacities, for operation on either alternating or direct current. A few of the many applications for which this hoist is adapted are shown.

Pawling & Harnischfeger Co., 38th and National Aves., Milwaukee, Wis. Bulletin HD501, describing P & H contractors' and builders' hoists and derricks. The illustrations show the single-, two-, and three-drum types of hoists, which are furnished for electric, gasoline or belt drive. The structural details of the P & H steel derrick are illustrated, and complete data in tabular form are included.

Cincinnati Grinder Co., Cincinnati, Ohio. Bulletin containing a description and illustrations of the Cincinnati automotive parts grinding machine, which has been especially developed for the repair shop, for use in grinding internal combustion engine parts. The machine is made in two styles, power feed and hand feed, and can be furnished for belt or motor drive. Copies will be sent to those interested upon request.

Mehl Machine Tool & Die Co., Roselle, N. J. Catalogue containing a prospectus of the tool service rendered by this company, which embraces the designing and manufacturing of jigs, fixtures, dies, gages, special machines, patterns and precision equipment. The book contains a large number of illustrations, showing examples of the work produced and interior views of the designing, pattern, manufacturing, and inspection departments.

Service Engineering Co., Inc., 25 Church St., New York City. Folder containing an outline of the activities and personnel of the company, which has been reorganized. The field covered is designing automatic machines; jigs and fixtures for economical manufacture; listing operations on parts; establishing tolerances or limits and gaging systems; planning lay-outs of machinery for increased production; and reorganization and appraisal.

Norton Co., Worcester, Mass. Form 907, containing information relative to alundum safety tile for stair treads, floors, and other uses where a slip-proof surface is desired. There are eleven pages of illustrations showing installations of alundum safety tile for different classes of service, and specifications for installing are included. A separate pamphlet is issued, which gives specifications for the proper installation of Norton alundum safety tile under various conditions.

Neidow-Cummings Co., 9 S. Clinton St., Chicago, Ill. Leaflet illustrating and describing "Airgrip" expanding mandrels, which can be loaded or unloaded without stopping the machine. The circular also illustrates the "Airgrip" piston manufacturing outfit, which includes an expanding piston arbor, a collet chuck, and an equalized drive arbor. This equipment may be used on any standard hand-operated, semi-automatic or full automatic machine, and will handle all sizes of pistons.

Mummert-Dixon Co., Hanover, Pa., is distributing a booklet to the trade entitled "Something Interesting about Stars," containing a study of some of the principal autumn and winter stars and constellations, besides a number of other subjects of general interest. The last pages of the book contain illustrations of the product of the company (which comprises oilstone grinders, radial grinders, oilstone wet tool grinders and facing heads) as well as a view of the pattern shop, which is equipped to handle all classes of pattern work.

Fellows Gear Shaper Co., Springfield, Vt. Booklet entitled "A New Development in Gear Cutting," describing a new type of gear shaper known as the No. 7, which has been developed for high production. The principle of operation and the mechanism of the machine are described in detail, as well as the method of operating, and other essential details. The construction is made clear by the liberal use of illustrations. The last chapter of the book shows examples of work, which indicate the possibilities of this type of machine for high production.

Cincinnati Milling Machine Co., Cincinnati, Ohio. Booklet entitled "Locomotive Repairs," containing data showing the adaptability of Cincinnati millers to the requirements of railway shops, and the reduction in costs that can be effected by milling this class of work. This book is of considerable interest, as the data is a record of actual performance in machining a large number of locomotive parts, and includes type of machine, speed, feed, material, stock removed, type and size of cutter, and time required for milling. The last few pages of the book are devoted to the use of Cincinnati universal millers in railroad tool-rooms.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Circular Reprint No. 104, containing an article on "Babbitting Motor Bearings," by J. S. Dean of the railway motor engineering department of the company. The article is illustrated with a number of photographs showing equipment used in the manufacture of babbitt metals, and diagrams showing the results of various tests of samples of alloys. The cost of Westinghouse lead-base babbitt metal is discussed in Folder 4475. This publication also describes the properties and applications of the lead base babbitt metal known as Westinghouse alloy No. 25 and the babbitt known as Westinghouse alloy No. 14.

Joseph T. Ryerson & Son, Chicago, Ill., has published the second issue of its "Machinery Quarterly" which forms the machinery and tool section of the "Ryerson Steel Service Book." It is not intended that this book should be regarded as a complete machinery catalogue, the purpose being to place before machinery users condensed descriptive material covering the line of equipment furnished. Each issue shows a representative line of Ryerson equipment, including one or more machines or tools of each of the various classes with a brief description and specifications. This section shows lathes, planers, drilling machines, milling machines, grinders, power hammers, saws, bulldozers, punches and shears, bending rolls, riveters, threading and cutting-off machines, and many other types of metal-working machinery and equipment.

Torchweld Equipment Co., Fulton and Carpenter Sts., Chicago, Ill. Instruction book covering the assembly and use of oxy-acetylene welding, cutting, lead-burning, and carbon-burning equipment. The booklet presents the basic principles of oxy-acetylene welding and cutting, and is illustrated by views of "Torchweld" equipment. It is written in a style that can be easily comprehended by the shop man, and contains eighteen chapters dealing with the following subjects: Production of the Gases; Welding Materials and Supplies; Gas Pressure Regulators; "Torchweld" Welding Torches; the Welding Flame; Fundamentals of Welding; General Information for Welding; Welding Shop Suggestions; General Repair Work; Steel Welding; Production Work on Steel; Boiler Welding; Cast Iron, Copper, Brass and Aluminum Welding; "Torchweld" Cutting Torches; Metal Cutting; Lead Welding; and Carbon Burning.

TRADE NOTES

Cashman Tool Co., Waynesboro, Pa., has sold its property, building, and equipment to William H. Strauss, manager of the Wayne Tool Mfg. Co., Waynesboro.

Dale Machinery Co., 56 Lafayette St., New York City, dealer in machinery and tools, has moved its offices to 17 E. 42nd St. in the National City Bank Bldg., where larger quarters have been secured.

F. A. Calhoun Co., Lincoln Trust Bldg., Jersey City, N. J., has been appointed eastern representative in the New England and Middle Atlantic states for "Case-Hardo," a casehardening compound used for performing the same work as cyanide.

Surface Combustion Co., Inc., 366-368 Gerard Ave., Bronx, New York City, industrial furnace engineers and manufacturers, have secured the exclusive license for exploiting the Andrews rust-proofing process in the United States and foreign countries.

International Purchasing & Engineering Co., Inc., 506 McKerchey Bldg., Detroit, Mich., announces that it has made a reduction of approximately 15 per cent on the price of Van Dresser electric driven machines. No change has been made in the price of the hand or drill press types.

Sundh Engineering & Machine Co., Philadelphia, Pa., manufacturer of finishing machinery for brass, copper, and steel strip mills, has closed its branch office at 11th Ave. and 26th St., New York, and opened a downtown office in Philadelphia in the Otis Bldg., 16th and Sansom Sts.

Hauck Mfg. Co., 126 Tenth St., Brooklyn, N. Y., manufacturer of portable oil burners, torches, furnaces, etc., has moved its Philadelphia office to 1726 Sansom St., (Bell telephone, Spruce 5626). Herbert Vogelsang, who has been connected with the company for six years, will be in charge of the office.

Frank G. Payson Co., 9 S. Clinton St., Chicago, Ill., general sales agent for the Logan air-operated chucks, has discontinued business, and the general sales office of the **Logansport Machine Co.** has been moved to the factory at Logansport, Ind. Frank G. Payson will be located at Logansport as manager of sales.

Royersford Foundry & Machine Co., 54 N. 5th St., Philadelphia, Pa., manufacturer of Sells roller bearings, hangers, and other products, has made arrangements to have its full line of hangers handled in Chicago by the Clinton Supply Co., Inc., 110-112 S. Clinton St. This company will also act as distributor of Sells roller bearings.

Ingersoll-Rand Co., 11 Broadway, New York City, has been appointed general sales agent for the gas engines manufactured by the Rathbun Jones Engineering Co. of Toledo, Ohio. The Rathbun gas engines are of the vertical multi-cylinder type and are built to operate on natural, illuminating, producer, coke oven, oil still and other forms of gases that can be used in an internal combustion engine. The sizes range from 100 to 1450 brake horsepower.

Jones, MacNeal & Camp, Inc., formerly located at 522 S. Clinton St., Chicago, Ill., have moved to Warsaw, Ind., where they have acquired the factory previously occupied by the Blackhawk Tire & Rubber Co. This plant has 31,000 square feet of floor space, which will be devoted to the manufacture of a full line of "Power King" portable electric drills, having capacities for tools from 3/16 to 1 inch in diameter. A business office will be maintained in Chicago.

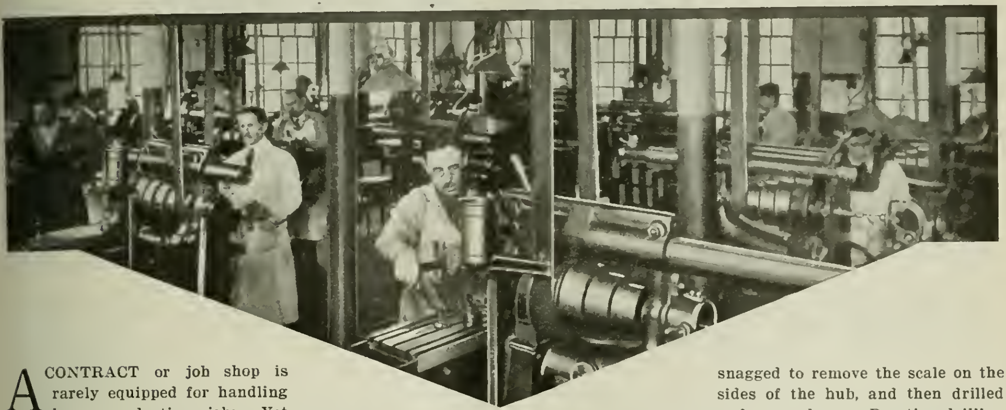
Quigley Furnace Specialties Co., Inc., 26 Cortlandt St., New York City, announces that its pulverized fuel department has been acquired by the Hardinge Co., 120 Broadway, New York City, which will continue the conduct of the business along the same lines as heretofore, the organization of the engineering department having been taken over practically intact. The rapid growth of the refractory specialties business of the Quigley company has made it advisable for the company to devote its entire attention to this branch of the work.

Oliver Machinery Co., Grand Rapids, Mich., manufacturer of woodworking machinery and machine tools, has established a new branch office at 716 Lincoln Bank Bldg., Minneapolis, Minn., in order to provide more efficient service for industrial plants, pattern shops, metal-workers, and woodworkers in the Northwest. George C. Ramer, who has had a wide experience in the sales department of the company, is manager of the office. The territory served by the new office consists of Minnesota, North and South Dakota, Nebraska, western Iowa, and western Wisconsin.

Cadillac Tool Co., Detroit, Mich., has been dissolved and is succeeded by a new concern which has been incorporated under the name of the Cadillac Machinery Co. The new company will retain the personnel of the Cadillac Tool Co., which was engaged in the sale of machine tools and which also did some manufacturing, but it will devote its entire efforts to selling machine tools. The president of the company is C. L. Campbell, and the other members of the organization are C. E. French, L. E. Bugbee, C. G. Valentine, and R. J. Borneman. The territory will be the same as that covered by the Cadillac Tool Co. The salesroom is located on the ground floor of the Boydell Bldg., East Lafayette and Beaubien Sts., Detroit.

APRIL MACHINERY 1922

Production Work in a Contract Shop



Manufacturing Methods Employed in the Plant of the Taft-Peirce Mfg. Co., Woonsocket, R. I., in Machining Automobile Parts—First of Two Articles

By FRED R. DANIELS

A CONTRACT or job shop is rarely equipped for handling large production jobs. Yet there are exceptions, and the present article deals with an instance where a contract shop has successfully solved the problems met with in quantity production. Many of the tools, jigs, and fixtures used in the manufacture of the Wills Sainte Claire eight-cylinder V-type automobile engine were made in the Taft-Peirce Mfg. Co.'s shop in Woonsocket, and in addition some thirty-five or more parts of this engine are being actually manufactured in this factory. Some of these parts include the valve follower assembly and shaft; camshaft drive pinion shaft bearing; fan assembly and shaft; distributor driven gear; intermediate shaft; piston-pin; and complete parts for the assembly of the camshaft drive shaft bearing retainer, oil-pump, oil relief valve, and connecting-rods. The present article deals with some of the more interesting operations employed in the manufacture of a number of the parts mentioned. Practically every finished dimension of these parts is held to close limits, which requires accurate manufacturing methods.

The parts of the valve follower assembly which involve the use of interesting equipment are the valve follower housing cover shown in Fig. 2, and the valve follower shown in the upper left corner of Fig. 3. These small forgings are assembled into the cover as shown at *A*, Fig. 5, four being used in the right-hand housing and four in the left. The forgings are first heat-treated, sand-blasted, and snagged to remove the scale on the sides of the hub, and then drilled and reamed on a Prentice drilling machine which carries a special multiple drill-head and an indexing fixture accommodating three pairs of forgings.

This machine is illustrated in Fig. 4, from which it will be seen that two followers *A* may be loaded at one station of the fixture while two other pairs are being drilled and reamed. It will be noted by referring to Fig. 3 that the reamed hole is held to a tolerance of 0.0005 inch. At every index movement of the fixture, two completely drilled and reamed forgings are removed. While the next two pairs of forgings are being machined, ample time is afforded the operator to reload and keep close watch on the condition of the holes by the frequent use of a plug gage.

The index device is released for revolving the turret of the fixture by the handle at the right of the loading station. This handle operates a rack and pinion, which withdraws the index-pin, and after it has been withdrawn it is snapped back ready to engage the next index-hole when the turret is revolved to the proper position. The work is located on the fixture by V-blocks that engage the hub of the work, and is secured in place by a wedge that is operated by a crank-handle.

The operation of rough- and finish-grinding cheek *A* of the forgings, Fig. 3, is performed on two Taft-Peirce cylindrical grinders, equipped with a special head and multiple grinding fixtures. One of these

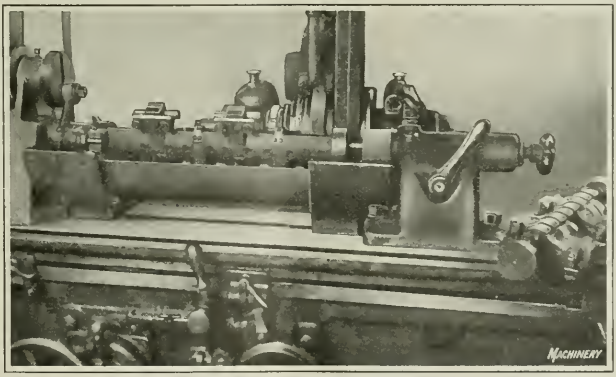


Fig. 1. Cylindrical Grinder with Special Equipment for grinding the Curved Surface of Valve Followers

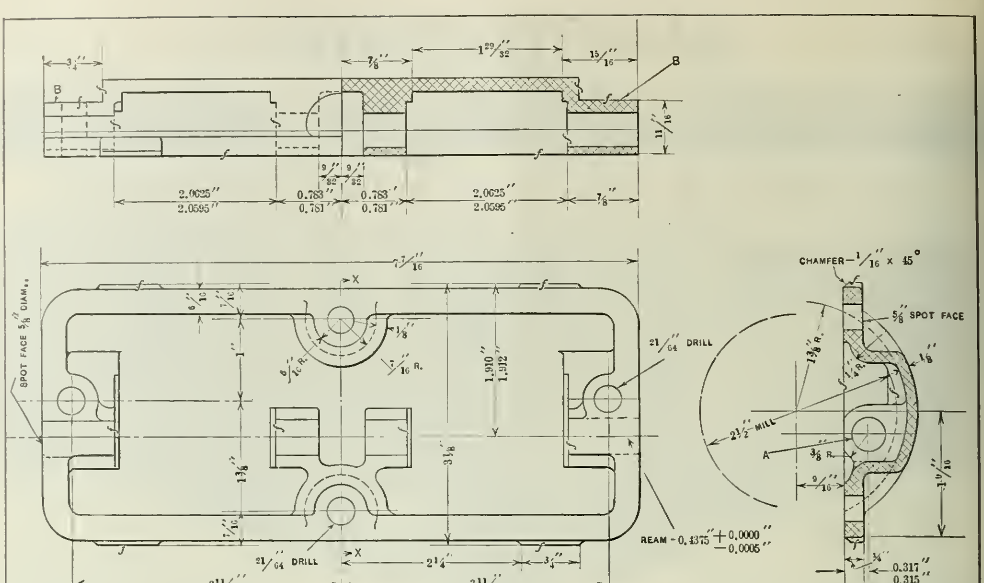

Fig. 2. Detailed Views of the Valve Follower Housing Cover

machines set up for the operation is shown in Fig. 1. The head transmits an oscillatory motion to the fixture and work; thus the machine practically performs the service of a radial grinder. The grinding fixture carries eight followers at a time in pairs, two machines and three fixtures being in use at once on this operation. A loaded fixture is shown on the table of the machine. As soon as one set of followers has been rough-ground, the fixture carrying the rough-ground work is transferred to the finish-grinding machine and replaced with another fixture. While the two machines are in operation the finished work is removed from the idle fixture and reloaded.

Fixture Used in Grinding Valve Follower

An assembled view of this special equipment is shown in Fig. 6, from which it will be seen that the spindle carries a

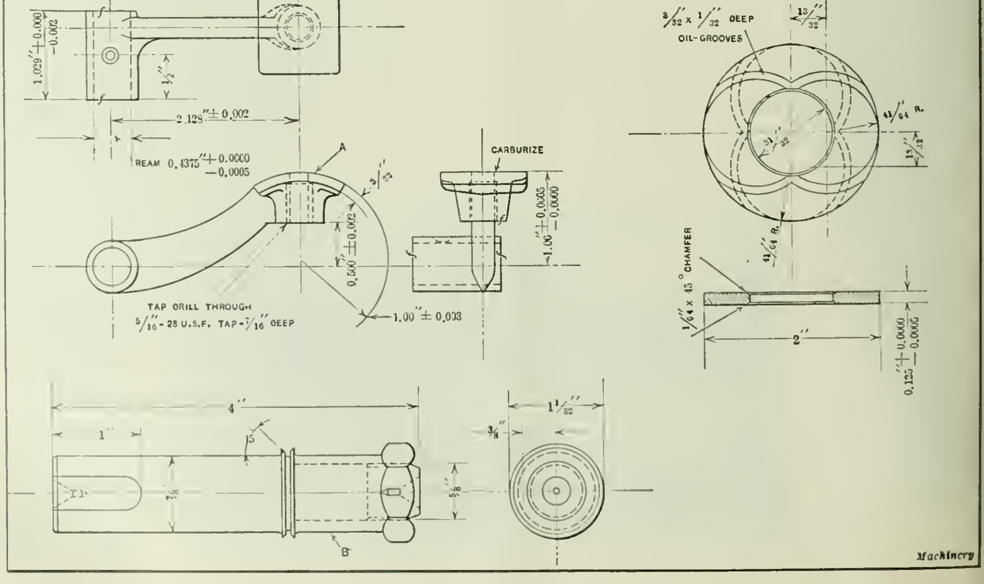

Fig. 3. (Upper Left View) Valve Follower; (Upper Right View) Bronze Washer; (Lower View) Special Arbor for straddle-facing Washers

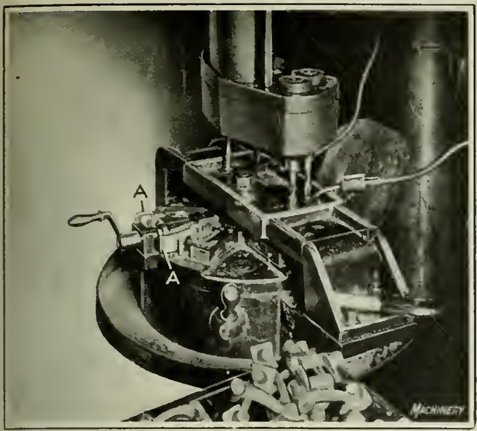

Fig. 4. Drilling Machine equipped with Multiple Head and Indexing Fixture for drilling and reaming Valve Followers

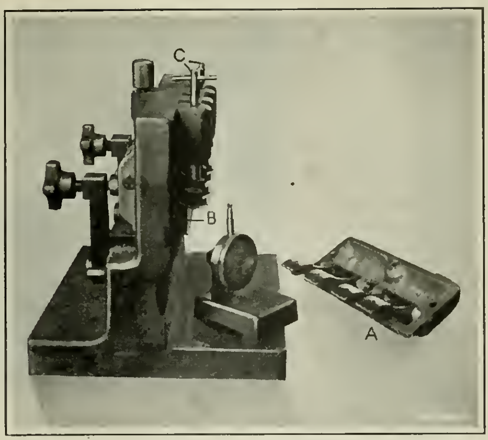

Fig. 5. Inspector's Gage and Test Blocks employed for gaging the Ground Cheek of Valve Followers

slotted driver A to which the crank-arm is attached in such a way that it can be adjusted to vary the arc of oscillation of the fixture. The body B has two projections on each side, in which a steel stud C is secured; the stud extends at both sides of the projection so that two followers may be carried on each stud. The end view shows the work W in broken outline in the position which the opposing followers occupy relative to the face of the grinding wheel when the loaded fixture is set up.

The head end of the fixture body has a cast ear D, so that when the fixture is placed between centers, a stud E will engage a slot in the ear to drive the fixture. Upon tightening a thumb-screw, the crank-arm transmits a rocking motion to the fixture. The work is seated against steel buttons carried in the body, and is held in this position by flat springs F which engage each pair of forgings close to the cheek. In loading the fixture, the operator simply snaps these springs over the work. The body of the fixture has steel female centers inserted at each end.

For the roughing operation a 36-L Norton wheel is used, and for finishing a 38-46 grade J wheel. A grinding wheel speed of 2500 revolutions per minute is employed which is equal to approximately 6000 feet surface speed per minute, and a feed of 0.0005 inch per oscillation. It may be mentioned incidentally that the same equipment is used for grinding the forgings to remove the copper-plating from the cheeks before the forgings are carburized on these surfaces.

Valve Follower Assembly

The camshaft housing valve follower cover in which the follower forgings are assembled is an aluminum casting. The central hole A, Fig. 2, which carries the stud for the followers must be accurately line-reamed and must have a uniform diameter in all four bearings within a tolerance of 0.0005 inch. This 7/16-inch hole is line-reamed on a Prentice lathe carrying a special long line-reamer with a universal-jointed driver which is held in the lathe chuck. The set-up of this job is illustrated in Fig. 7, which also shows the fixture used to hold the work while the holes are being reamed.

The work rests on four hardened steel buttons located so as to coincide with the centers of bosses cast on the inside of the aluminum covers. It is held back against two ground blocks at the rear of the fixture by means of a floating clamp A which seats evenly on the unfinished surface of the casting when the knob B is tightened. The cover of the fixture also has an equalizing clamp C carrying a hardened and ground button at each end, engaging the flat surfaces B (see Fig. 2), at each end of the casting. The fixture itself is clamped in

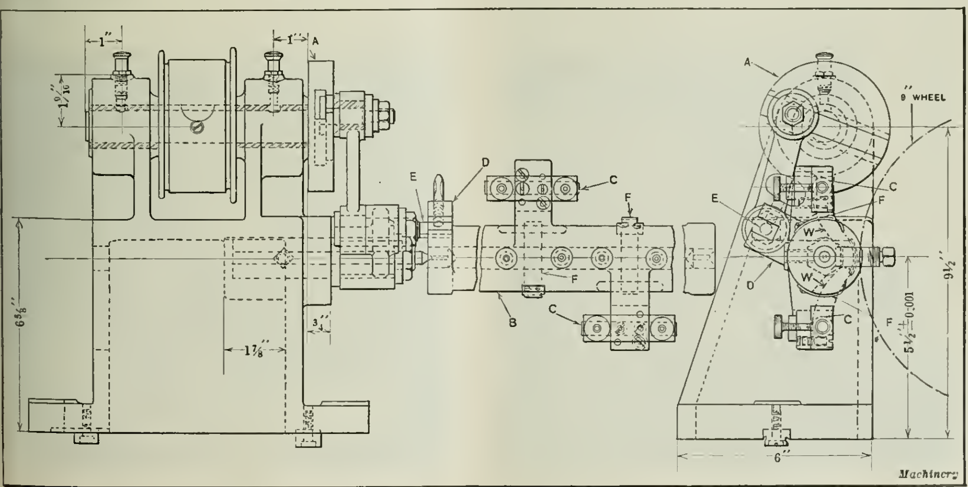

Fig. 6. Assembled View of the Special Head and Grinding Fixture employed on the Machine shown in Fig. 1

a milling vise which, in turn, is clamped to the bed of the lathe. The reamer operates at 180 revolutions per minute, and the feed is 0.005 inch per revolution of the spindle.

The gaging equipment for inspecting the ground cheeks of the assembled followers relative to the finished face of the aluminum cover, as well as the alignment, is illustrated in Fig. 5, which shows the assembled unit clamped to the upright part of the fixture on one side, with the followers extending through and resting on a hardened steel parallel *B*, which is set into the opposite side of the fixture. Four spring pins *C* hold the followers against the parallel, while a test block with a dial indicator is employed to gage the accuracy of the ground surfaces on the followers.

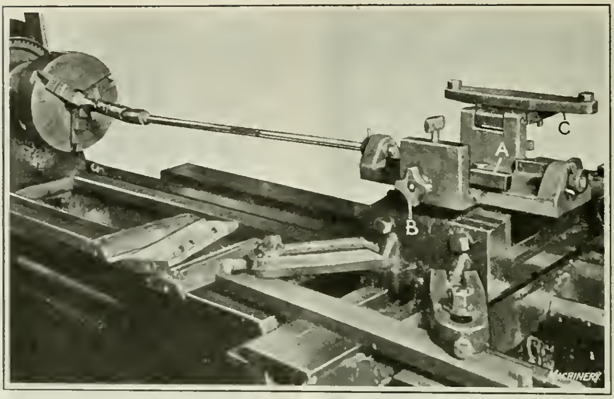

Fig. 7. Lathe set up for line-reaming Valve Follower Covers

Camshaft Drive Pinion Floating Washer

The camshaft drive pinion floating washer, shown at the right in Fig. 3, is machined from a cast bronze cylinder from which nineteen washers are made. The cutting apart of these bronze washers is illustrated in Fig. 8, which is a view of a Lodge & Shipley lathe looking toward the faceplate, and showing the multiple tooling set-up which is employed in this operation. The parting tools are set evenly in a special tool-block by means of a backing plate which is adjusted by the two screws shown at *A*. The casting is grooved to a depth which will bring the diameter within the grooves to 0.985 inch. This is slightly greater than the reamed diameter of the axial hole in the casting so that the washers can be readily broken apart. For grooving, a work speed of 50 feet per minute is used, with a hand feed.

It will be seen from Fig. 3 that there are circular oil-grooves 1/32 inch deep in both sides of this bronze washer. The machine and fixture used for cutting these grooves is illustrated in Fig. 9. The difficulty of holding these thin flat pieces so they would not become distorted made necessary the provision of special means for performing the oil-grooving operation. A heavy fixture is used for holding the washers during the milling of the grooves; to the base of this fixture is attached an upright bracket, which furnishes a rigid bearing for the cutter-arbor. This arbor has a driving lug which fits into a slot in the end of the hollow end-mill used to cut the grooves. One of these mills is shown on the table of the drilling machine. The mill can enter the arbor bearing when the machine spindle is raised, thus giving ready access to the work when loading and unloading the fixture.

The upper part of the fixture which carries the work may be slid transversely so as to bring the center of the spindle 13/32 inch either side of the center to agree with the location of the grooves in the work, as shown in Fig. 3. This movement of the fixture is effected by hand, the weight being sufficient to make the use of a locking device unnecessary. The cam-lever shown at the side of the fixture raises a center post to bind the work from underneath against flanges extending on each side, under which the work is located. This eliminates all possibility of distortion, and holds the washers perfectly flat during the grooving operation. A similar grooving operation is performed on both sides of the work using the same equipment. A Henry & Wright drilling machine is used for this work. It has been found advantageous, owing to the toughness of the material from which these washers are made, to heat them to between 650 and 700 degrees F. before any further machine work is performed. Formerly this was not done, and some difficulty was experienced in finish-facing the washers to within the required limits.

The washers are straddle-faced to a thickness of 0.128 or 0.129 inch, using diamond facing tools, and are then ground to the finished thickness indicated in Fig. 3, where it will be seen that a tolerance of 0.0005 inch is allowed. Considerable difficulty was experienced at first in holding the washers

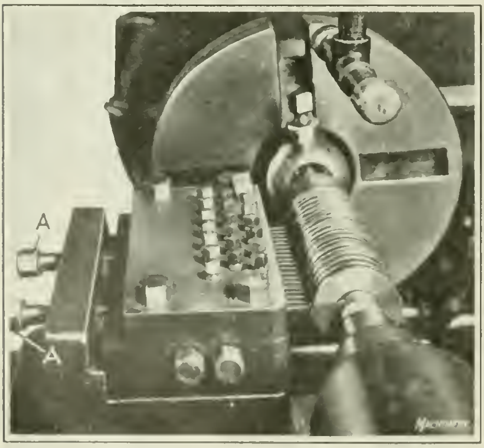

Fig. 8. Lathe with Multiple Tool-block, set up for cutting Bronze Washers from a Casting

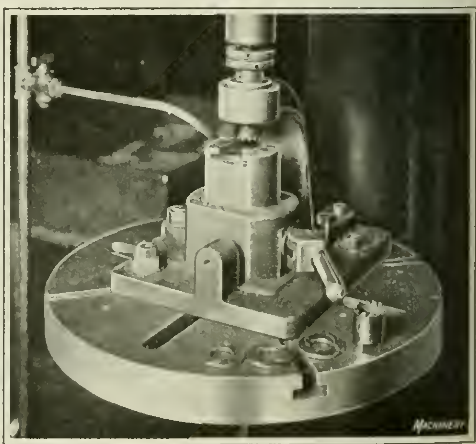

Fig. 9. Drilling Machine and Fixture used in cutting Oil-grooves in Bronze Washers

while straddle-facing them to thickness. For this reason, it was found desirable to chamfer both sides of the central hole, and to use a hardened tool-steel arbor, such as shown in the lower part of Fig. 3, to hold the work. This arbor has a 45-degree center and a sleeve *B* with a similar angular end, so that the washers can be mounted squarely between the shoulder on the arbor and the sleeve by means of the chamfered hole. A diamond tool is especially suitable for machining bronze, particularly where the work must be held within close limits. A hand-feed is employed and a work speed of 80 feet per minute.

The concluding installment of this article, which will appear in May MACHINERY, will describe operations on the camshaft drive shaft bearing retainer, the motor fan, and the intermediate and fan shafts.

SET-UP INSTRUCTIONS FOR BROWN & SHARPE AUTOMATICS

By SAMUEL R. GERBER
S. R. Gerber Co., Industrial Engineers, New York City

The importance of adhering strictly to detailed instructions for setting up automatic screw machines can readily be seen. If the set-up man does not see to it that he has all the necessary tools for the job before he starts setting up a machine, he may find himself well on the way before he discovers that a tool is missing. The set-up man can avoid this difficulty by adhering strictly to the rule of returning all tools to the tool-crib immediately after taking a job off the machine. If all tools, cams, and accessories are placed in a box and returned to the tool-crib where they are kept until they are needed again, there will be no need to search for tools the next time the job is started. It should be the duty of the man in the tool-crib to inspect the tools carefully before he puts them away. If he finds any tool that needs repairing, it should be attended to before the tools are put away on the shelves; if he finds any that are worn out or broken, he should immediately put in a requisition for replacements, so that they will be on hand when needed again.

It is also of vital importance that the set-up man set the machine to operate at the correct feeds and speeds. For this purpose he should be furnished with an instruction card which contains all the necessary information. Without such information the feeds and speeds and lay-out depend entirely on the memory of the set-up man. If the feeds, speeds, and job lay-out are noted on a card at the time when the machine is operating satisfactorily considerable trouble will be obviated on future set-ups.

List of Setting-up Operations

The following list of operations for setting up Brown & Sharpe automatic screw machines and the detailed explanation of these operations, if strictly adhered to, will, no doubt, greatly reduce the lost time in the department and consequently reduce costs, which, after all is the ultimate aim.

1. Obtain tools, instruction card, and drawing from tool-crib. Check all tools with tool list to make sure that none are missing. If any are missing, report to the man in charge of the crib and if he cannot furnish the required tool immediately, return all tools to him and start another job.

2. Tear down old job and return tools to crib. Remove gears, cams, and tools; clean and place in box. First remove and clean chuck. Then remove feed-finger from feed-tube and substitute new one. Finally, return tools to crib.

3. Put in chuck and feed-finger. Use pin-wrench for tightening up chuck-head.

4. Put on cams and gears and shift belts. Follow carefully the directions on set-up card and see that the belts are set to give proper speeds.

5. Grind tools. It is important to provide proper rake and clearance angles.

6. Place tools in turret and cross-slides and set them properly. Follow instructions furnished on set-up card, measuring the distance from the turret for all turret tools and setting cross-slide tools in proper relative positions.

7. Set trip-dogs. To set trip-dogs for turret tools, turn the handwheel until the cam-roll is on the high point of the cam lobe; then move the turret trip-dog in position under the trip-lever. Turn the handwheel until the cam-roll is on the high point of the next cam lobe and set the trip-dog as before. Continue this until all trip-dogs for the turret are set. To set the trip-dog for the chuck, turn the handwheel until the cam-roll just reaches the top of the stop-lobe on the cam; then move the trip-dog to position under the trip-lever. To set the trip-dog for the spindle, turn the handwheel until the cam-roll is on the high point of the cam lobe just preceding the cam lobe for threading; then move the trip-dog to position under the trip-lever. The second spindle trip-dog should be set where the cam-roll reaches the "dwell" of the cam lobe for threading. When both overhead and machine speeds are changed, avoid tripping simultaneously.

8. Put stock in chuck and adjust. The jaws should be adjusted so that the chuck can be locked with a snap by means of the hand-lever.

9. Make final adjustments. Adjust tools to bring part to fit gage. Set gage-stop first to obtain the proper length of piece. Feed stock to the stop, mark with the cut-off tool, measure the distance between the end of stock and the cut-off mark, checking this distance by means of the length gage. Finally adjust the feed length. The following precautions are necessary in making final adjustments: (A) Set the forming and cutting-off tools accurately before setting the turret tools; (B) test the thread body diameter before running on the threading die; (C) test length of piece before drilling or threading; and (D) test the diameter of holes before reaming.

10. Report to foreman. The foreman should always pass on the quality of the work before it proceeds further.

Importance of Following a Predetermined Sequence in Setting up the Machine

The order of operations in the list given is of the utmost importance for the successful setting up of the job in minimum time. For instance, the third step "Put in chuck and feed-finger" must be done before the sixth step "Place tools in turret and cross-slides, etc.," and the fifth step "Grind tools" must surely be done before the tools are set in place. Nevertheless, it is surprising how frequently these operations are done in the reverse order, which means repeating certain steps.

The seventh step "Set trip-dogs" must be done before the eighth step "Put stock in chuck and adjust." If the stock is put in the chuck before the trip-dogs are set, as is usually the case, it invariably follows that either a drill or the cut-off breaks. This means that the set-up man must remove the stock and proceed as he should have in the first place.

After the trip-dogs are set and the stock supplied, the set-up man may proceed to make the required piece, which can generally be done with few additional adjustments. It may require time and patience to train a set-up man to follow instructions in setting up an automatic screw machine, but any machine shop foreman will readily agree that it is worth while to train the set-up man, especially if he realizes that he can save time in the department by employing some such simple instruction methods.

* * *

Individual motor drive in the textile industry has been applied successfully for the first time to the revolving flat cotton card, an installation having been made at the plant of the Mason Tire & Rubber Co., of Kent, Ohio. Push-button control is employed, which provides for easy starting of the cylinders and spindles and permits adjusting the speed to suit conditions. The drive is equipped with a reversing motor switch.

Selling Machine Tools by Demonstration

By a Machine Tool Sales Manager

EXPERIENCED salesmen state that there are two classes of minds—those most easily impressed by what they see, and those most easily influenced by what they hear. Machine tool salesmen will probably agree that their customers respond more quickly to what they see than to what they hear; but still it is necessary both to explain and to demonstrate. The salesman has a fund of information about the machines he sells. This is his sales talk—his talking points for the ear of the prospect. In addition, he has something to show, to be conveyed through the eye. This is commonly called the demonstration.

The Use of Catalogues, Blueprints, and Photographs

In the simplest form of demonstration, the salesman uses catalogues, photographs, and blueprints. He seldom goes very far with his talking points without resorting to catalogues and other trade literature. He appeals simultaneously both to the ear and to the eye of the prospect.

It is the ambition of salesmen in some lines to become such fluent talkers that their prospects will listen to them spellbound, developing an eagerness to buy all that is offered for sale. It is doubtful if any machine tool salesman ever reached that goal, and if he did, it would not be of great value; for machine tool selling is an unemotional matter-of-fact business, and it is questionable if the most accomplished spellbinders from other fields of selling would have any great success with machine tools. Nevertheless, there is great value in being able to set forth selling arguments logically and forcefully; but an even greater appeal can be made through the eye, and more sales have been made by men who can clearly demonstrate the value of what they have to sell than by those who merely talk about the good features.

Some salesmen do not make the most of catalogues as a selling aid. Any machine tool manufacturer can tell of letter after letter received from possible customers, asking questions about points that are illustrated and explained in the catalogue, even though the salesman has called upon them recently. The salesman has overlooked some good demonstration material. Many salesmen also receive blueprints and photographs from the manufacturer, and submit them to their prospects without first becoming familiar with the recommendations made. They neglect to take advantage of the possibility of demonstrating to the prospect in terms of the prospect's problems.

The Importance of Complete Explanations of Methods

The neglect to fully explain lay-outs, drawings, and blueprints works an injustice not only to the manufacturer but also to the prospect. Recently an automobile manufacturer sent out blueprints to several machine tool builders. He received a number of proposals, and finally purchased a machine from Black & White. A bid had also been made on equipment by Smith Co. whose sales manager later happened to visit the automobile plant and saw Black & White's machine on the job. The production was much less than Smith had quoted. He asked why the other machine had been chosen. The buyer frankly told him that Smith's proposition had not been thoroughly studied. "It was really an oversight," he admitted, but added "Your salesman was also to blame. Your method of handling the job is somewhat unusual, and I did not understand at the time. The blueprints were left with me without explanation, and in the rush I did not study them thoroughly. Black & White's proposition, on the other hand, was presented to me so clearly that it seemed to me at the time to be the best we could hope to do. Now that we have this equipment, we cannot afford to take it out."

In this case the salesman lost out possibly because he did not himself fully understand the manufacturer's production plans, and left the blueprints for the buyer to study instead of using them as a means to demonstrate the superiority of his machine and method. No doubt he told the buyer repeatedly what the machine would do, but neglected to explain *how* it was done.

Demonstration of Machines

The use of catalogues and blueprints is not as effective as a demonstration of the machine itself. In some cases it is almost impossible to sell without an actual demonstration of a machine in operation. But there are great difficulties connected with demonstrations of machine tools.

An example of the physical demonstration of a difficult subject was recently met with in the practice of a bronze bearing manufacturer whose claims of superiority are based on the physical construction of his metal. This manufacturer had only a limited success when he depended upon printed or verbal statements. Then he supplied his salesmen with a microscope and fractures of his and other bearing bronzes. By thus demonstrating his metal in comparison with other materials, he not only increased his business but also received the benefit of publicity through his prospective customers telling their friends about the unique demonstration.

The practice of taking prospects to visit installations in nearby shops in order to demonstrate machine tools is very effective, but there are several objections to be noted. Frequently new machines are being introduced, and in that case other installations are not always available or conveniently reached. Sometimes a machine in use does not show up in as satisfactory a way as regards finish. The particular job on the machine at the time may not demonstrate it at its best, and it is always somewhat of an imposition on even a good friend to disturb his shop with visitors and temporarily hold up production; last, and most important, the salesman depends upon someone else to play what is usually the last card in his hand.

Demonstrations in Show-rooms

The show-room of a machinery house is seldom put to its maximum use. As a display place of machine tools it accomplishes only one of its possibilities. It augments the catalogue demonstration by showing the tool itself, so that the buyer can note its proportions and finish, and can move a lever or two or a handwheel here and there; but it would be still more effective if the machine were actually running. In European machine tool sales-rooms it is the usual practice to have one machine of every type under belt, and the salesmen are trained so that they can step up to the machines and operate them in a way that brings out the various features. This practice is worthy of thought on the part of those who would derive the maximum value from their show-room floor space.

Let us take a leaf from the book of the seller of phonographs. The chances of selling a phonograph by means of a catalogue are remote. The chances of selling by a mere display of the cabinet are small. But the playing of a record on the machine exhibits the service that the salesman really tries to sell. It is service that is sold in machine tools just as much as in phonographs.

In making a first-class demonstration of any article, it is highly important that the demonstration be in line with the normal use of the product. A salesman for the manufacturer of small tools used to carry with him a milling cutter as a sample of the firm's product. It is impossible to make a quick demonstration of the normal use of a milling cutter, but this salesman thought that he could demonstrate the abuse that his cutter would stand by throwing it on the floor. All went well with his demonstration until once when the cutter came in contact with a concrete floor. After he had exclaimed "Just see the abuse our cutters will stand," he sent the cutter to meet the hard concrete. The cutter broke into several pieces.

The writer has often heard machine tool salesmen argue that an exhibit that is not under belt at a convention is a waste of space; yet only a small percentage of the visitors at a convention are buyers, and under the excitement of the convention they are least susceptible to impressions. On the other hand, a running exhibit on a machinery dealers' floor is a perpetual exhibit to which only interested parties come, and they can concentrate upon the one item of the machine that they wish to buy.

The Introduction of New Machinery and Tools

There is every indication that many improvements in machinery and tools will be introduced by machine tool builders in the near future. Totally new and different tools will be brought out, but even in the mechanical field the buyers are notoriously slow in taking up new ideas. They are invariably skeptical, and equipment for machine shops is the object of more careful scrutiny than many other classes of products. The buyers of machine tools will not seek new equipment. The machine tool salesman must seek the buyer. There is still plenty of room for improvement in the demonstration and methods of selling machine tools. It is those that give most careful thought to effective demonstration who will enjoy the greatest success in selling.

FORM TOOL FOR GRIDLEY AUTOMATICS

By JOE V. ROMIG

In turning formed work on Gridley four-spindle automatics, it is customary to rough-turn with one tool and finish-form with another. A double-deck type of tool-holder such as the one shown at *A*, Fig. 1, is used on the rear or forming slide. The forming and sizing tool *F* and its holder *B*, shown mounted on the double-deck holder *A*, were devel-

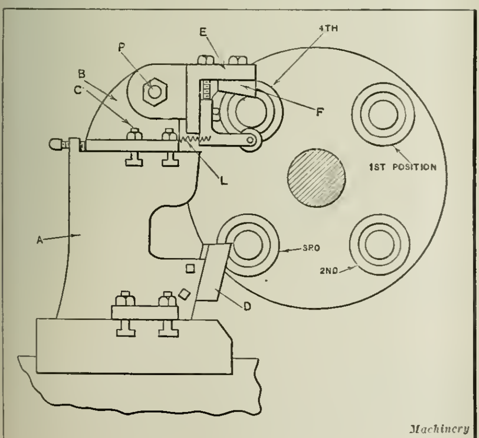

Fig. 1. Double-deck Tool-holder used on Gridley Automatics

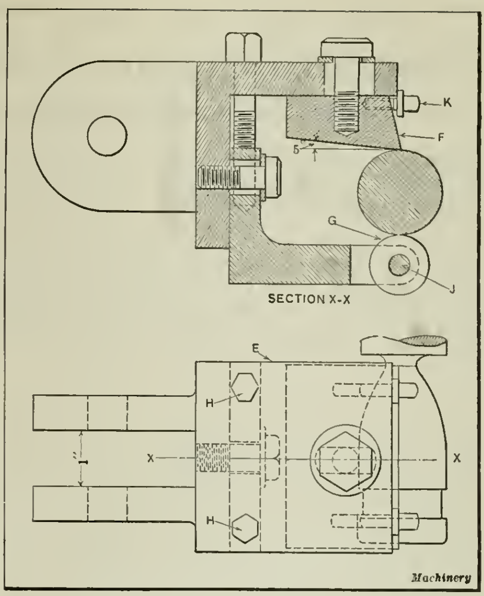

Fig. 2. Forming Tool used in Holder shown in Fig. 1

oped for use on work requiring a fine finish and a high degree of accuracy. The holder *B* is of inverted T-shape, and is clamped to the top face of holder *A* by bolts *C*. Slots are provided for these bolts which permit the tool to be adjusted so that it will be properly aligned with the lower tool *D*.

On the vertical section of holder *B* is pivoted the tool-carrying head *E*, which is also shown in Fig. 2. This tool-head is made of an accurately machined casting. The tools used in this holder are made with a bottom clearance of from 5 to 8 degrees and a lip angle which varies from 0 to 7 degrees according to the hardness of the material to be machined. It will be noted that the tool *F* shown in the illustration has a bottom clearance angle of 5 degrees. This tool passes over the top of the work, the latter being held to size by means of the roller *G*. This roller is mounted on an adjustable slide and is clamped to the inner face of the holder *E* as shown. Two elevating screws *H* are used to adjust and hold the roller square with the tool. On work having more than one diameter it is necessary that the roller be built up of two pieces of different diameters, each roller running loosely on the roller-pin *J*.

On tapered work also two rollers must be used, as any slippage on the work would mar the finished surface. By pivoting the whole head as shown, a self-adjustable feature is introduced, which works satisfactorily. The pivoted bolt *P*, Fig. 1, should be drawn up tight enough to hold the head erect by the friction of the clamping faces. The tool *F* is drilled and tapped on its front face for the two small screws *K*, which are used to adjust and hold the tool square with its holder as indicated in Fig. 2. A newly sharpened tool sometimes has a tendency to chatter, but this can be overcome by drawing a fine-grained oilstone across the edge.

Besides turning and forming the work accurately to size, the tool also has a burnishing action, which produces a very fine finish. The writer has found it advisable to insert a spring *L*, Fig. 1, between the base and the swinging head. This spring is made just strong enough to lift the head slightly. This will bring the roller into engagement with the work and permit the tool to be drawn downward as the slide feeds inward, thus resulting in a clean shearing cut. From 0.005 to 0.010 inch is sufficient allowance for a finishing cut. This tool operates equally well on straight, curved, or tapered work. It was first used in making one-pounder shells.

Standardization of Jig and Fixture Design

THE use of standardized parts in the design of jigs and fixtures is intended primarily to avoid unnecessary repetitions in the designing department and to reduce the cost of designing jigs and fixtures as well as the time required for making them. When certain features or details adapted to standardization have been found to be satisfactory, the advantage of using duplicate designs whenever practicable is evident, since such uniformity in the construction of details not only reduces the costs but also insures the continued use of parts that have been tested out in actual practice.

How Many Parts Should be Standardized?

The number or variety of parts which may be standardized to advantage in connection with jig and fixture design varies in different plants, and depends in a general way upon the uniformity of the work. Where there is great diversity in shapes and sizes of the parts requiring jigs or fixtures, standardization is largely confined to such details as handles, bushings, stop-pins, adjusting screws, clamping straps, latches, eyebolts, binder levers, and certain other small parts of a minor nature. If too many parts are standardized, especially large parts which necessarily control to some extent the design of a jig or fixture, there is sometimes a tendency to sacrifice the design or arrangement in order to utilize a standard part. In such cases, the standard is a detriment rather than an advantage.

In connection with the standardization of parts either for jigs, fixtures, or gaging devices, it is advisable to utilize as far as possible all universally adopted standards and commercial parts, such as machine screws, cap-screws, washers, taper pins, or other parts which may be much cheaper to buy than to make in relatively small lots.

Standardization of the Larger Parts

In determining whether or not it will pay to standardize the larger and more important details, such as plates, bases, indexing devices, clamping mechanisms, etc., the probable extent to which such parts or details can be utilized is naturally the factor to consider. In this connection past experience in whatever plant the jigs and fixtures are intended for serves as a reliable guide in determining to what extent certain parts are likely to be used, and also the advisability of having in stock parts made up in advance. These stock parts, which should be kept on hand in amounts depending upon the probable number required under ordinary conditions, frequently make it possible to design and construct jigs and fixtures in a relatively short time.

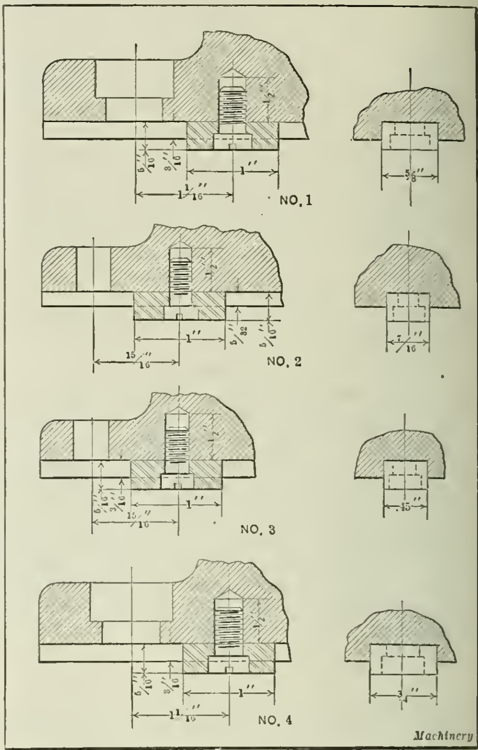

Fig. 2. Four Sizes of Standard Fixture Keys

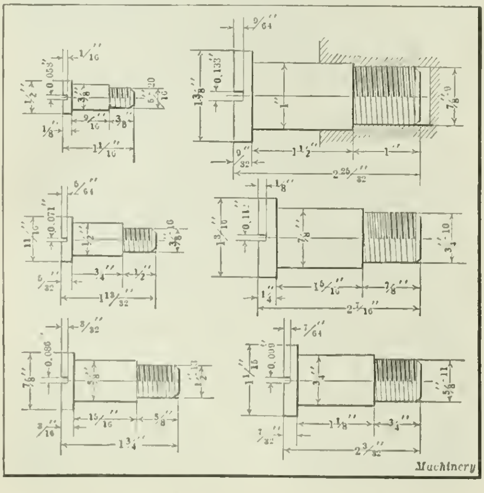

Fig. 1. Six Sizes of Standard Shoulder Screws

In the designing department of the Pratt & Whitney Co., Hartford, Conn., the parts for jigs, fixtures, and gaging devices have been standardized as far as practicable, although in jig and fixture work, standardization is confined chiefly to the minor details, owing to the extremely wide range of work handled in the various departments and the necessity of designing jigs and fixtures which differ greatly, not only in size but also in arrangement. The following examples do not cover all the standardized parts, but they illustrate in a general way the kinds of parts that can be standardized to advantage. The dimensions are given whenever there is a range of sizes, for the convenience of those desiring to adopt similar standards.

Shoulder Screws

Fig. 1 illustrates six sizes of shoulder screws with body diameters varying from 3/8 to 1 inch. These screws are used as pivots for latches and certain kinds of clamping blocks or plates which require a swinging movement, as when inserting or removing work, but still remain permanently attached to the body of the jig or fixture. The section lines around the largest screw illustrated indicate how they are fitted in place. It will be noted that the body of the screw enters a counterbored recess for some distance, thus giving the screw a rigid support against lateral thrusts. These screws are made of cold-rolled steel, casehardened. The heads should have a free fit when they enter counterbored recesses.

Fixture Keys—Standard Knobs

Four sizes of standard fixture keys are illustrated in Fig. 2. These are used for aligning a jig or fixture body with the machine by engaging a slot in the machine table. A tongue is sometimes formed directly on the body of the fixture by planing, but a removable key is generally considered preferable. These keys are all of the same thickness and length, but the widths vary.

†Binder handles with hole or tap at pin angle.

Two forms of knobs are illustrated in connection with Table 1. The upper section of the table covers two sizes of cast-iron knobs which are keyed to the shaft. The steel knobs listed in the lower section are made in four different sizes, and are secured to the shaft by a taper cross-pin.

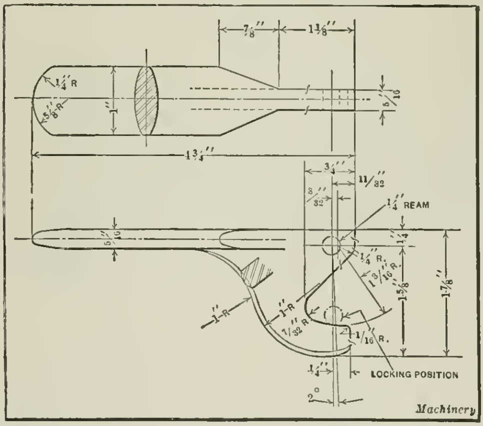

Fig. 3. Drill Jig Clamping Handle of the Cam or Eccentric Type

Shoulder Drill Bushings

Drill bushings of the shoulder type with holes varying from 1/16 to 1 inch are covered by Table 2. These flanged or shoulder bushings are preferred by many tool designers whenever it is practicable to use them. The flange prevents any endwise movement of the bushing, such as might be caused by the action of the cutting tool. If this flange must be flush with the surface of the jig or fixture, it is let into a counterbored recess. These bushings are made of tool steel, hardened and ground.

Binder or Clamping Handles—Cranks

Table 3 applies to binder handles, having (1) plain holes with cross-pins, (2) tapped holes, and (3) either plain or tapped holes located at an angle to the handle. The left-hand half of the table gives the general dimensions, and the right-hand half covers the diameters of plain holes, the

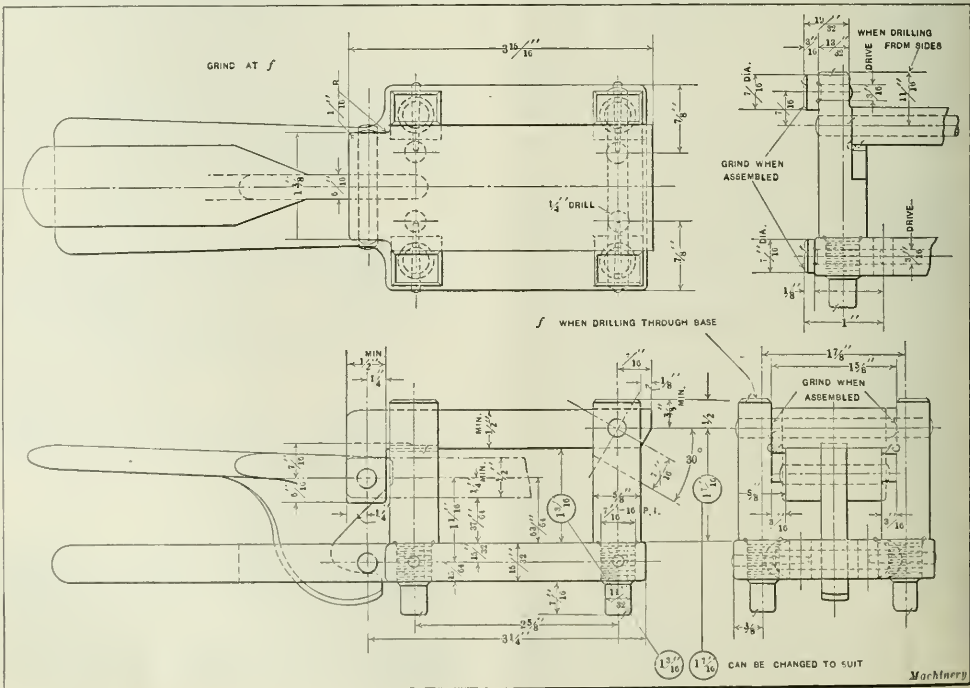

Fig. 4. Drill Jig equipped with a Cam-handle and a Standard Base

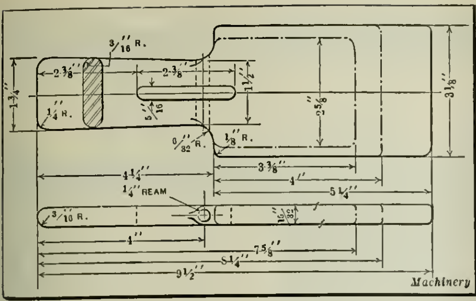

Fig. 5. Standard Bases for Drill Jigs

taper pin drill numbers, the diameters of tapped holes, and the corresponding threads per inch.

Dimensions for different sizes of cranks of the type used for turning adjusting screws, etc., are given in Table 4, which also includes the dimensions of the squares on the screw or shaft. Dimensions for the handles used in connection with these cranks are given in Table 5, which includes additional sizes.

Cam-handles and Drill Jig Bases

A clamping handle of the cam or eccentric type, which has been extensively used, is illustrated in Fig. 3. This is made from a tool-steel forging, and the cam end, which engages a clamping pin, is hardened and tempered. The style of base used in conjunction with this cam-handle is shown in Fig. 5, which gives the dimensions of three standard sizes. The base is made of machine steel, and the sides are ground as indicated by the finish marks. Fig. 4 shows a drill jig equipped with a cam-handle and a standard base. This is the smallest jig of the series, there being medium and large sizes which make use of the medium and large sized bases shown in Fig. 5.

Binder and Centering Plugs

Sometimes it is practicable to standardize an entire unit, consisting of several assembled parts. Such a case is shown in Fig. 6, which illustrates the binder and centering plug for a fixture used for holding rifle bolts. The clamping action is derived from a helical cam surface A on the binder sleeve, which engages a block B attached to the body of the fixture. When the handle at the end of the binder sleeve is swung to the open position C, the projecting end of stop-screw D seen above the binder sleeve is opposite a longitudinal slot E, thus permitting the sleeve to be moved back far enough to insert or remove the work. The latter is held and centered by a plug at one end and a bushing at the other. The same style of binder, modified as regards center and plugs or minor details, is applied to various fixtures.

STANDARDIZATION WORK IN JAPAN AND NORWAY

Standardization work in Japan has recently been given a great impetus by the organization of the Japanese Engineering Standards Committee. The main function of this committee is to serve as a bureau for solving problems involving engineering standardization. The committee consists of seventy members, and the Minister of the Department of Agriculture and Commerce serves in the capacity of president. The details of the work of standardization are handled by seven secretaries who are engineers of the government departments of Agriculture and Commerce, Communications, Railways, Military Engineers and Naval Engineers. The work is being pushed with vigor, investigations already being under way on metals, woods, bricks, screws, electric wires, and electric motors. In Norway a national standardization committee has been organized by the Federation of Norwegian Industries. One of the first projects which is to be taken up by the new committee, after the necessary work on organizational problems, is the standardization of ship machinery and ship details.

MILLING SHIFTER FORK TRUNNIONS

By A. H. SCHWAB

In the production of automobile shifter forks, such as shown in Fig. 2, it is necessary to turn the trunnions or bosses *A* and *B* to a diameter of 19/32 inch. The milling machine attachment shown in Fig. 1 was designed for use in performing this operation. This fixture is provided with two hollow-mills *C* and *D*. The axis of the short hollow spindle *F* on which the high-speed milling cutters are mounted is at right angles with the main spindle, and parallel with the milling machine table. Thus, while held in the fixture illustrated in Fig. 3, the work can be fed first to the right for milling the boss or trunnion *B*, and then to the left for milling trunnion *A*.

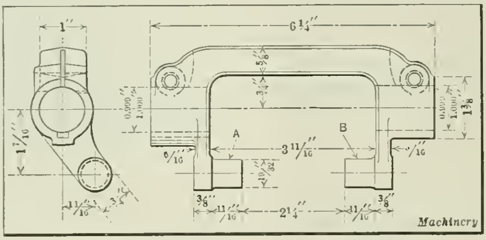

Fig. 2. Automobile Shifter Fork

Referring to Fig. 1, *G* is a cast-iron ring which is bolted to the milling machine. The worm *H* and the worm-wheel *J* are held in a steel housing *E* that is bolted to ring *G*, a recess being cut in the latter part to receive the flange of housing *E*. The housing is bored out to receive the milling machine arbor and is provided with bushings which support the worm and take the thrust. The ball bearings in which hollow spindle *F* is mounted are held in place by cap *K* and the threaded side plates *M* and *N*. Worm-wheel *J* is bored out to enable it to pass over the ball bearing races in order to facilitate assembling. Bushing *L* is made in two pieces so that it fits the recess cut in spindle *F*. Cap *K* is held in alignment by two sets of keys located at right angles to each other.

The hollow-mills *C* and *D* have bayonet slots milled on one side to permit rapid attachment to, or removal from, the spindle. These milling cutters run at 200 revolutions per minute. The fixture shown in Fig. 3 for holding the work is of simple construction and requires very little explanation. The work is placed in this fixture, and locating mandrels *P* and *Q* are pushed into place to support the work as shown. The wing-nuts are then tightened on hook-bolts *R* and *S*, thus clamping the trunnion-carrying arms of the work against set-screws *T*. Screws *U* and *V* are brought into contact with the work to support it against the thrust of the cut.

* * *

The United States Geological Survey estimates that our reserves of petroleum approximate 9,150,000,000 barrels, which is said to be enough to last only twenty years.

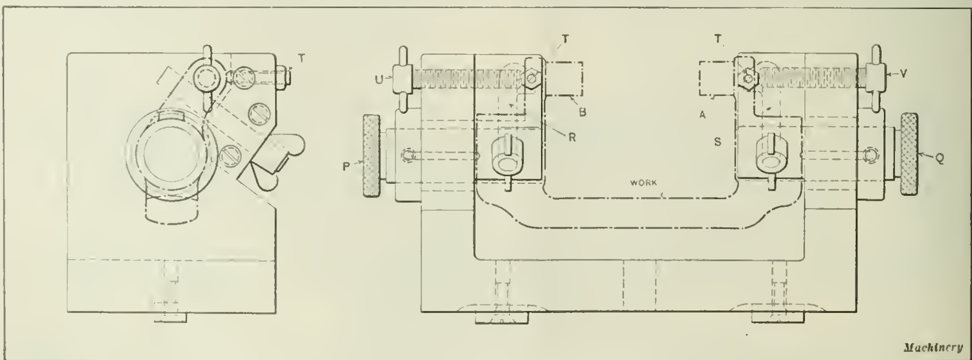

Fig. 3. Fixture for holding Shifter Fork shown in Fig. 2 while milling

The Design of Pull Broaches

Depth of Cut—Pitch—Length—Shape of Teeth—Methods of Attaching Broaches to Machines

By J. LABENSKY and PALMER HUTCHINSON

THERE are few shops that make a practice of manufacturing their own broaching tools, even the larger users of broaching machines having, as a rule, taken the making of broaches away from their own tool-rooms and turned it over to one of the concerns that make a business of manufacturing these tools. This fact is somewhat surprising when one considers that broaches can seldom be purchased from stock like drills, reamers, taps, and dies, but must be made up individually after an order has been placed. This practice may be attributed to the fact that many tool draftsmen are not familiar with the principles governing broach design.

Details in the design of the more widely used styles of broaches have been compiled as empirical data by all the better known broach manufacturers, and although the necessity constantly arises for the design of special tools for which there are no such data, broach usage has progressed far enough for the designer to be able to combine experience gained in making the more common broaches with mechanical common sense, and lay out special broaches that will in nine cases out of ten work successfully when coupled to the draw-head of a machine.

Depth of Cut per Tooth

The first consideration in designing a broach is the amount of stock to be removed from the work by each cutting tooth of the tool. This varies with the material to be cut, the type of broach, and, in some cases, with the length of work, power of machine, and size of broach. When the term "depth of cut," is used in reference to round broaches, it means the total increase in the diameter of a tooth; when referring to spline broaches, the total increase in the diameter of a circular series of teeth; to square, hexagonal, and rectangular broaches, the increase in the measurement across the corners of the teeth; and to keyway cutter-bars, the increase in the height of each tooth. The depths of cut which have proved satisfactory for general cases are given in the following:

ROUND REAMER BROACHES

For steel	0.001 to 0.0015 inch
For brass	0.002 to 0.003 inch
For cast iron	0.002 to 0.003 inch
For babbitt	0.003 to 0.005 inch

SPLINE BROACHES

Ten-spline	0.003 to 0.004 inch
Six-spline	0.003 to 0.005 inch
Four-spline	0.004 to 0.006 inch
Two-spline	0.005 to 0.006 inch
One-spline	0.002 to 0.003 inch

SQUARE, HEXAGONAL, AND RECTANGULAR BROACHES

For steel	0.0035 to 0.004 inch
For cast iron	0.0045 to 0.006 inch

KEYWAY CUTTER-BARS

For steel	0.003 inch
For cast iron	0.004 inch

Pitch of Broach Teeth

The second consideration in the design of a broach, and one of great importance in that the successful cutting action of the tool depends in a degree upon it, and because many of the other broach dimensions are derived from it, is the pitch. Pitch, in its relation to broaches, is defined as the distance between successive teeth, and this distance is controlled by several factors. The pitch determines in part the length of the broach, and so should be made as fine as possible if maximum production is to be attained, because with the modern adjustable-stroke broaching machine, production varies inversely with the length of the cutting tool.

There are limitations, however, to the fineness of the pitch. In the first place, the pitch must be coarse enough to allow ample chip room between the teeth. It will be obvious in this connection that the depth of cut per tooth governs the pitch somewhat. Theoretically, a round broach designed to ream babbitt would have a greater distance between its teeth than a round broach designed to ream steel, because the babbitt-cutting tool would be made to remove a heavier chip than the steel-cutting tool. In practice, this statement would hardly hold, but it is a fact that an ordinary broach has only sufficient room between its teeth to carry off the chips from one cutting stroke. It is for this reason primarily that broach makers emphasize the necessity of brushing the chips from a broach after every stroke of the machine. A few chips left on the tool combined with those of the succeeding cut may tear the work or break the tool. Generally, however, if the other factors that control the pitch are considered, the matter of chip room will take care of itself.

There must always be two, and there should preferably be three, cutting teeth in the work at a time; otherwise, the part being broached will drop down between the teeth. This difficulty may be eliminated, and often is when several thin pieces are stacked for broaching at one stroke, by affixing a support to the faceplate of the machine, which will hold the work rigidly in place. While the number of teeth in the work should never be less than two, there should not be an excessive number cutting at one time. If this is the case, the stress on the tool will be beyond the breakage point or the driving nut of the machine will become heated. Although the amount of pull available at the draw-head of a broaching machine may be readily measured or calculated, there are no adequate data or formulas for determining the power needed to pull the countless sizes and types of broaching tools through the various materials that are broached—from fiber to nickel steel.

From the foregoing it may appear that a draftsman, in deciding on the pitch of a broach, faces a somewhat complicated problem, but such is not the case. Practice has proved

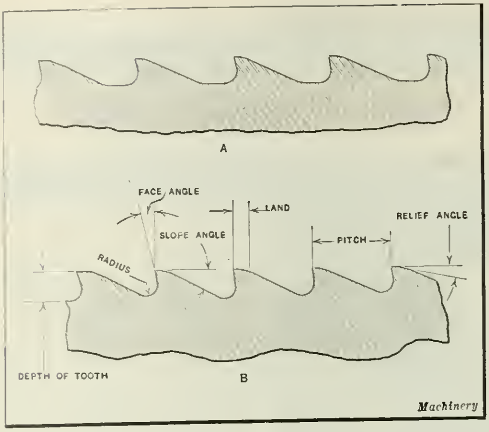

Fig. 1. (A) Flatted Spaces between Broach Teeth; (B) Nomenclature of Broach Teeth

that if the number of broach teeth in the work at a time is somewhere between three and six, all of the considerations relative to pitch are satisfied and the tool will function properly. The broach designer need merely divide the length of the work that the prospective tool is to cut, by a constant in order to determine the pitch, which is calculated to the nearest 1/16 inch. This constant is the number of teeth that should be in the work at one time, and is as follows for several types of broaches: Square broaches, from 3 to 5; spline broaches, from 3 to 6; keyway cutter-bars, from 3 to 6; round broaches, 3; and special-shaped broaches, 3.

Few commercial broaches are made with the pitch over 1¼ inches, and by far the greater part of the work for which broaches are used is less than 10 inches in length. When the work is over 4 inches long, the designer adopts a plan which permits him to keep the pitch 1¼ inches or under in the majority of cases. Teeth 1 inch or more apart are rugged enough to permit the back to be machined away considerably without weakening them to the breaking point; hence the bottoms of spaces between broach teeth of 1-inch pitch and over are usually flatted as shown at *A*, Fig. 1, to give the necessary additional chip room for long work.

Length of Broaches

After the depth of cut per tooth has been determined, the total amount of material to be removed by a broach is divided by this decimal to ascertain the number of cutting teeth required. This number of teeth multiplied by the pitch gives the length of the active portion of the broach or the distance that the tool must taper. By adding to this dimension the distance between three or four straight teeth, the length of a pilot to be provided at the finishing end of the broach, and the length of a shank which must project through the work and the faceplate of the machine to the draw-head, the over-all length of the tool is found. This length is often greater than the stroke of the machine or greater than it is practical to use for a tool of the diameter in question. In such cases, a set of broaches must be used; two, three, four, and five broaches are often necessary to machine a single piece of work, while a set of forty-eight broaches was made during the war to machine the dovetail slots in the recoil cylinders of the U. S. Army 4.7-inch guns. Simple formulas for determining the length of the more common types of broaches in accordance with general practice will be given in the following. In these formulas,

L = length of broach;
S = constant for length of shank (5½ to 6 inches);
W = length of work;
P = pitch of teeth;
T = number of cutting teeth;
B = allowance for sizing teeth on reamer broaches for steel (4 inches); and
F = allowance for pilot on finishing end (¾ to 1 inch).

Round broaches for reaming babbitt or bronze are most often designed with a guiding tooth following each pair of cutting teeth as shown at *A*, Fig. 2. When this is done one of the guiding teeth must always enter the work before the two preceding cutting teeth have left and must not leave the work before the following cutting teeth have entered. Each guiding tooth is made 0.0005 inch less in diameter than the cutting tooth ahead in order to compress the metal and keep the broach from drifting. The reason for making the diameter of the guiding tooth less in diameter than the preceding cutting tooth is because the diameter of the hole becomes less after the cutting tooth passes by, due to the expansion of the metal. The width of the guiding teeth is normally equal to the pitch. The teeth have rounded shoulders instead of keen cutting points, and are neither relieved nor under-cut. Sometimes the guiding teeth are of button shape. This type of tool carries a row of button teeth as shown at *B*, or a long straight section, at the finishing end for burnishing the work. This arrangement gives a compressed and glossy finish to the broached surface. The formula for finding the length of broaches of the type shown at *A* is as follows:

$$L = S + W + 2PT + 8P$$

while for broaches of the type shown at *B*, the length is

$$L = S + W + 2.25PT + 8P$$

Reamer broaches for steel are frequently made similarly to the broaches for softer metals, but are more often made without guiding teeth. In the latter case it is customary to leave three or four straight teeth of the regular pitch at the end of the tapered section, followed by sixteen teeth of equal diameter ¼ inch apart, as shown at *C*. Since these teeth do not remove metal, their pitch may be made as fine as desired. The formula for the length of such a broach is as follows:

$$L = S + W + PT + 3P + B + F$$

The length of square and spline broaches may be determined by the formula:

$$L = S + W + PT + 3P + F$$

The formula for the length of keyway cutter-bars is:

$$L = S + W + PT + 4P$$

Shape of Broach Teeth

In deciding upon the shape of the broach teeth, the considerations are depth of tooth, width of land, radius at base, and the two main tooth angles, which are the face or cutting angle at which the teeth slope forward from the vertical plane, and the slope angle to which the backs of the teeth

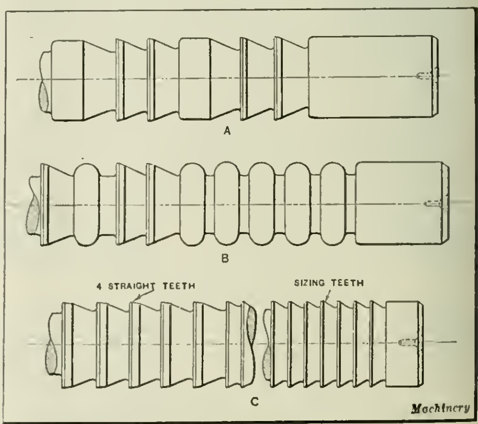

Fig. 2. (A) and (B) Broaches for Soft Metals such as Bronze and Babbitt; (C) Broach for Steel

are ground. This nomenclature will be understood by referring to the diagram at *B*, Fig. 1. The slope is relatively unimportant, as it is developed by connecting the rear of the land with the base of the succeeding tooth before the radius at the base is decided upon. The depth of tooth is usually made from one-third to a maximum of one-half the pitch. On a round broach of 3/4-inch pitch, for example, from 1/4- to 3/8-inch depth of stock would be removed.

The land of broach teeth, as illustrated, is the partially straight and partially angular top of the teeth. It varies in width with the pitch and, on occasions, with the hardness of metal that the broach is to cut. The wider the land, the more times a broach can be sharpened without reducing its size. Consequently, there is a tendency among uninitiated broach users to demand that the tools be made with lands of excessive width; however, if the lands are made too wide for a given pitch they cause the teeth to drag and tear into the work. The following relations between the width of land and pitch have proved satisfactory for general cases:

Pitch, Inches	Width of Land, Inches
1/4	1/32
3/8	1/32 to 1/16
7/16 to 11/16	1/16 to 3/32
11/16 to 1 1/4	1/8

The land is backed off or relieved to an angle of 1 1/2 or 2 degrees for a part of its width, leaving usually from 1/64 to 1/32 inch absolutely flat or parallel to the tool axis.

The arc at the base of broach teeth is by no means a matter to be neglected, either by the designer or by the shop. The shape of this arc must be such as to cause the chip to roll into a compact curl as it is forced down from the cutting point of the tooth. Should the chip strike a flat surface at the base of the tooth, there would be a tendency for it to shatter and be forced out from the space between the teeth. This radius can be determined graphically by simply drawing a smooth curve after the lines defining the face of one tooth and the rake of the preceding tooth have been drawn in. Ordinarily, it will be found that a radius equal to one-half the depth of the tooth gives the desired curve.

The face angle of broach teeth varies with the hardness of the metal to be cut, and determines the cutting keenness of the tool. Teeth on a broach designed for cutting steel usually slope forward from the vertical at an angle of from 8 to 12 degrees, while some slope as much as 14 degrees. For cutting softer metals, such as babbitt or bronze, the face angle is decreased to from 4 to 6 degrees. Broaches for cast iron have the tooth faces ground at an angle of from 6 to 8 degrees in the majority of cases. Efficient broach sharpening demands that the disk wheel of the grinding machine be set to the face angle of the broach teeth and that the sloping surfaces be lightly skimmed with the abrasive, to maintain this face angle throughout the life of the tool.

Methods of Attaching Broaches to Machines

The final consideration in laying out broaching tools is the means of connecting the tool shank to the draw-head of the machine. There are numerous designs of broach shanks;

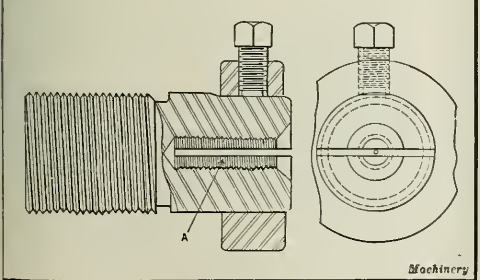

Fig. 3. Pull-bushing intended for Broach with Threaded Shank

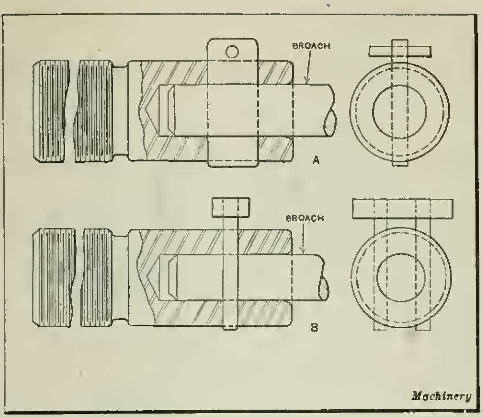

Fig. 4. Types of Pull-bushings employed when Broach must be removed after Each Operation

a common type is the threaded shank, the usefulness of which is limited to keyway cutter-bars or to broaches for machining external surfaces. Broaches of these types do not have to be removed from the machine after each cut. Fig. 3 shows a pull-bushing for a threaded shank broach, the shank being screwed into hole *A*. The large threaded portion of the pull-bushing fits the tapped hole in the draw-head of the machine. Keyway cutter-bars operate in a work-bushing or support. Their shanks are below the outside of the bushing, and so the work may be slipped on the bushing over the projecting end of the bar.

Round, square, hexagonal, spline, and other broaches for machining internal surfaces must be removed from the machine after each cut, and from the standpoint of rapid production it is, of course, impractical to thread the shanks of these classes of tools. Therefore, the shanks of the greater number of broaches in use have a rectangular slot at right angles to their axes. The shanks are inserted in a slotted pull-bushing attached to the draw-head of the machine, and are held in place by a hardened key as shown at *A*, Fig. 4. These shanks must fit snugly in the pull-bushing to prevent the tool from vibrating and possibly breaking under stress.

Many broaches of the sort that must be removed from the machine quickly have two semicircular recesses machined opposite each other on their shanks and at right angles to their axes. These shanks are held in the pull-bushing with a special key, as shown at *B*. This method is particularly applicable when the tools are comparatively light. Occasionally a broach which must be removed quickly is too small in diameter to permit the slotting or milling of recesses or flats on its shank, as in the last of the designs illustrated. In such a case it is the practice to thread the shank to a very fine pitch and grip it by a collapsible pull-bushing consisting of a cam and a split nut, so designed as to release the tool quickly when the cut is completed.

PROGRAM FOR A. S. M. E. SPRING MEETING

A tentative program for the spring meeting of the American Society of Mechanical Engineers to be held at Atlanta, Ga., May 8 to 11, has been issued. On Monday, May 8, a council meeting will be held in the morning, and the regular business meeting will be held in the afternoon. Tuesday morning, May 9, there will be a joint session of the Textile and the Machine Shop Sections, as well as a meeting of the Material Handling Section. A public hearing will also be held by the Power Test Codes Committee. Wednesday, May 10, there will be another joint session of the Textile and Machine Shop Sections, and also a meeting of the Fuel Section. Thursday, May 11, will be devoted to sessions on management, power, and welding.

Forming and Assembling Dies for Roll Cam

By W. B. GREENLEAF

THE dies described in this article are used in making parts for the roll cam shown at *A*, Fig. 1. The term "roll cam" is applied to this assembled unit for the reason that the two ends or caps serve as rollers, while the central member acts as a face cam. The central member *B* consists of a sheet-metal cylinder with a flanged sheet-metal disk *C* pressed over it, which is shaped in a forming die to give the face or cam surface the required contour. The end caps or rollers, one of which is shown at *F*, are pressed on the ends of the cylinder and must be a tight fit on this member. The assembled roll cam is about 1 1/16 inches long, and the roll ends are 25/32 inch in diameter. The cam has a throw of 0.100 inch. The stock from which these pieces are made is 0.017 inch thick.

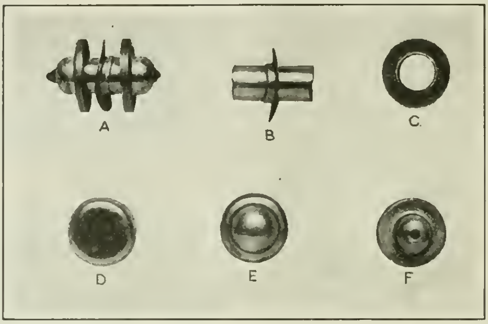

Fig. 1. Sheet-metal Products of Forming and Assembling Dies

Combination Blanking and Forming Die

In Fig. 2 is shown the combination die used to blank and perform the first forming operation on the cap shown at *F*, Fig. 1. The first forming operation is accomplished in two stages. After being blanked by punch *G* the continued downward movement of the press ram causes the blank to be formed over forming punch *H* to the shape indicated at *D*, Fig. 1, the relative positions of punch *G* and pressure-ring *I* being shown in the upper right-hand corner of Fig. 2. Ring *I* is just long enough to release the shell from all pressure between punches *G* and *H* at this stage.

The second stage of the forming operation, which forms the shell to the shape shown at *E*, Fig. 1, is completed at the end of the downward stroke of punch *G*. At this stage of the forming process, punch *G* has depressed pressure-ring *I* until it rests on the thin hardened steel washer *K*, and has forced the forming punch *H* and the heavier hardened steel washer *L* downward against the pressure of springs *M*. This action carries the blank down over the punch *N*, forming it to the shape indicated at *E*, Fig. 1. On the return stroke of the ram the blank is stripped from punch *N* by the forming punch *H* which is forced upward by pins *O*, actuated by springs *M*. Pressure-ring *I*, actuated by spring *J*, and acting through the four pins *P*, strips the blank from forming punch *H*. At the end of the upward stroke, knock-out *Q* comes into action and ejects the formed shell from punch *G*. The shell now has the shape indicated at *R* in Fig. 2 and at *E*, Fig. 1.

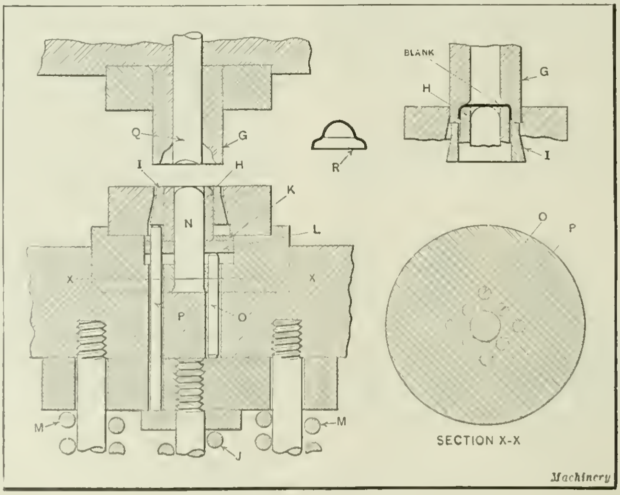

Fig. 2. Combination Blanking and Forming Die for Part F, Fig. 1

Piercing and Second Forming Punch

The piercing and the final forming operation which brings the piece to its finished form, as shown at *F*, Fig. 1, is performed by the die shown in Fig. 3. After being blanked and formed by the die shown in Fig. 2, the piece is placed on the die *T*, Fig. 3. On the downward stroke of the ram, punch *U* surrounds the outer edge of the flange of the work and holds it in the recess in the top of the die while the cap part is redúced to the proper size and the hole is pierced by punch *V*. At the end of the downward stroke sufficient pressure is exerted on the top of the flange to square the corners, flatten out any inequalities in the upper surface, and also flatten out irregularity in the edge caused by the drawing operation.

Blanking, Piercing, and Flanging Die

In Fig. 4 is shown a die for blanking, piercing, and turning up the flange on the cam blank shown at *C*, Fig. 1. The die- and punch-holders *A* and *B* are similar to those used in the dies in Fig. 2. The work is blanked by the tool-steel die *C* and pierced and flanged by die *D*. The tool-steel knock-out pad *E* is actuated by a spring *F*, acting through three pins, one of which is shown at *G*. The point of screw *H* projects into a slot in pad *E*, and thus serves to retain the latter member in the blanking die. *I* is the tool-steel blanking die, and *J* the piercing punch, which is supported in a machine-steel block *K*. The tool-steel knock-out pad *L* is a close sliding fit in punch *I*, and as it is also a close fit over punch *J*, it serves to support and keep the latter member in proper alignment. The two pins *M*, which pass through holes in washer *N*, are actuated by the press knock-out at the end of the upward stroke, thus causing the knock-out pad *L* to strip the work from the punch. From the illustration it will

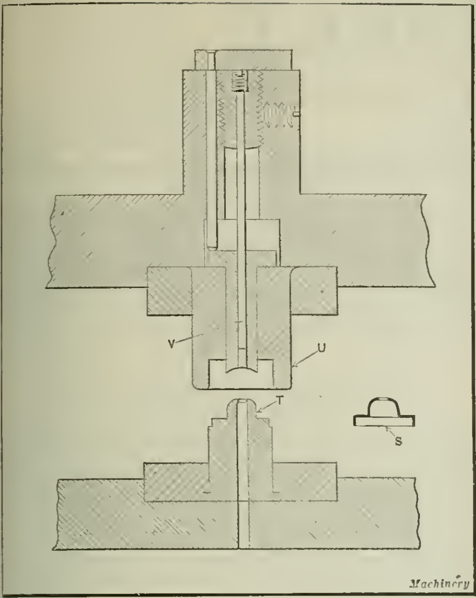

Fig. 3. Die for Piercing and Final Forming Operation

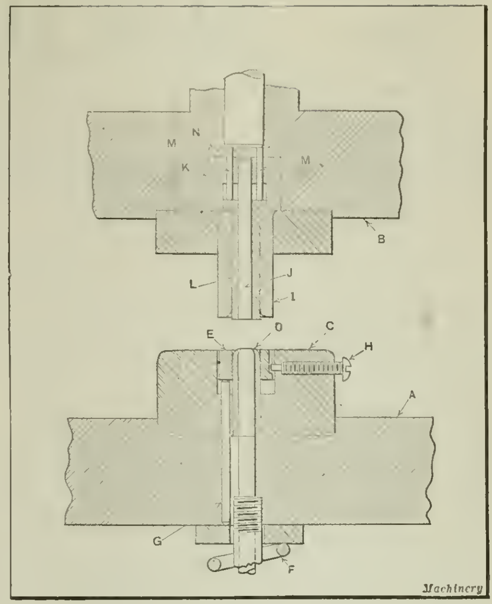

Fig. 4. Die for blanking, piercing, and turning up Flange

be evident that the center hole is pierced first, after which the piece is blanked and a flange formed as the punch continues downward. This die and the two previously described are used in inclined presses so that the pieces drop out at the back.

Assembling Die

In Fig. 5 is shown the die employed to assemble the flange *C*, Fig. 1, on the metal cylinder, and at the same time give the face or cam surface the required contour. In operating this die, the cam-plate is set on die *A* with the flange down and fitting into the recess provided for it. The cylinder is then inserted in die *B*, in which it is a loose fit. The cylinder also fits snugly over the end of punch *C*, which serves to hold it in position. On the downward stroke of the press ram, the cylinder is driven through the cam-plate until it rests in the seat in die *A*. While the piece is held in this position the punch or mandrel *C* passes through the entire length of the cylinder.

The final step in the assembling operation is the bending of the plate into the form of the cam. This bending also contracts the hole so that the flange grips the cylinder with sufficient force to hold it in this position. It should be mentioned here that the end of die *B* is formed to the shape of the cam contour, as is also the mating surface on die *A*, although this is not shown in the illustration.

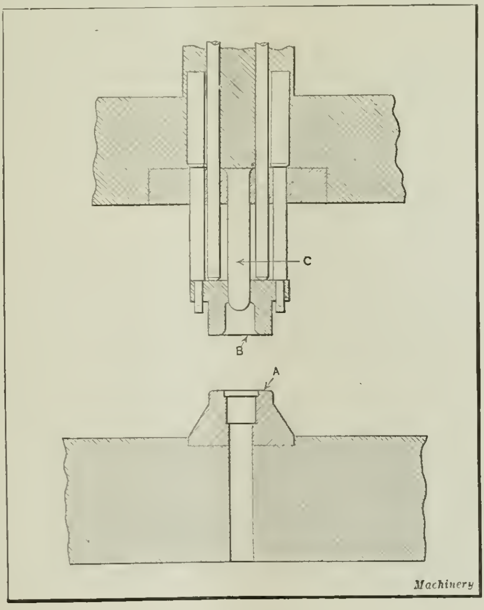

Fig. 5. Assembling and Cam-forming Die

CALITE—A HEAT-RESISTING ALLOY

Calite, an alloy containing iron, chromium, nickel, and aluminum, is the result of experiments conducted by metallurgists of the General Electric Co., for the purpose of finding an alloy that would withstand high temperatures, could be quenched repeatedly, and would be highly resistant to oxidation. Annealing boxes made from calite have been run for 1500 heat-hours without warpage, growth, or failure. The metal runs freely when molten, and any casting which can be made of steel can also be produced from this alloy. Sections as low as 3/16 inch in thickness have been successfully cast. Calite cannot be machined in the cast condition nor cut with an oxy-acetylene torch; hence, it must be finished by grinding.

This new alloy is said to resist oxidation up to about 2375 degrees F., but a working temperature of 2200 degrees is recommended. Calite is practically non-corrosive, samples having been polished and subjected to a spray of saturated sea-salt solution at 100 degrees F. for 200 hours without any effect on the polish. The physical properties are: Melting point, 2780 degrees F.; softening temperature, 2500 degrees F.; specific gravity, 7.03; weight per cubic inch, 0.25 pound; Brinell hardness when annealed, 286; scleroscope hardness when annealed, 40; thermal conductivity, 25 per cent that of iron; and tensile strength, 36,800 pounds per square inch.

NEW TOOLMAKING CENTERS

In June MACHINERY an article reviewed the gradual westward movement of the machine tool industry, which forty years ago was almost entirely located in New England, New York, New Jersey and Pennsylvania. During the interval, the industry so developed in the Middle Western states that at the present time a line drawn north and south through Rochester, N. Y., would divide the machine tool building business almost equally.

In the making of jigs, fixtures, power press dies, gages and small tools, New England also had but little competition until recent years; but many plants of considerable size producing such tools are now located in the Middle West. This is a natural result of manufacturing conditions in the Middle West, where there are many large plants that require special tooling equipment, the manufacture of automobiles being centered in Detroit; and large plants are located throughout Michigan, Ohio, Indiana and Illinois. Within the last ten years several of the cities in these states have become important tool-building centers, particularly Dayton, Columbus and Urbana, Ohio; Detroit and Chicago. Some of the plants in these cities have been very highly developed for the purpose of building special tools, partly because of the exacting requirements of the automobile business and partly because of the demand for tooling equipments and gages for war materials and munitions during the war. Entirely new tool building centers have been developed to supply the demands of the great Middle Western territory, which, during the last two decades, has developed so rapidly in metal-working and manufacturing. Meanwhile, New England tool manufacturers continue to hold their own, the increased industrial activities of recent years providing an outlet for the greater tool building capacity.

* * *

THE CENSUS OF MACHINE TOOLS

February MACHINERY recorded for the first time in the history of the industry the census figures giving the total number of machine tools of various types built in this country, and their value. The Department of Commerce has done the industry a distinct service by compiling these statistics, for such information is of practical value to our manufacturers. The statistics published covered 1919, but in future a similar census will be taken every other year. The Bureau of Census is now collecting figures covering the production in 1921; and, as such information loses value by delay in publication, it is hoped that this material will be available for publication much sooner than were the 1919 figures. Even with all the delay in the publication of those returns, the Bureau established a record for the prompt handling of such material.

Manufacturers should aid the Census Bureau to the utmost extent in collecting data of this kind. All information given to the Bureau is confidential, and only figures showing totals are published. No individual manufacturer's name is disclosed, and in case a manufacturer produces only a single line of machines so different in classification that it could be identified if grouped alone, it will be classed with a broader group of machinery so as to absolutely prevent the identification of any concern's output in the published report.

In addition to figures relating to production and the value of the product, the machine tool census in future will give the number of men employed and the percentage of employment in the industry. These statistics will refer not only to the entire country, but also to each of the most important machine tool manufacturing states. The information which the Census Bureau is endeavoring to supply has been needed greatly by machine tool manufacturers, and they should facilitate the work by making prompt returns on the blanks furnished them by the Bureau, which will thereby be enabled to give out the figures for early publication.

SYSTEMATIZED COST REDUCTION

In a well-known plant recently visited, a systematic effort is being made to improve manufacturing methods and reduce operating costs. A committee of the leading mechanical men is devoting its time during the prevailing depression to a thorough study of methods employed throughout the entire works. This committee takes up one department at a time, beginning with that where the raw material is received, and continuing its study all the way to and including the shipping department. The work is not done in a hurry, and no process or operation is considered too unimportant for careful thought. The department foremen are interviewed and their suggestions carefully noted, and the men operating the various machines are also given an opportunity to offer suggestions for increasing the output or improving its quality.

Much lost motion has been eliminated by improvements in methods, tooling equipment and machines. Sometimes the machinery is rearranged to facilitate the operations. Old machines have been scrapped and new ones to replace them investigated and decided on, even if not ordered.

Before changes are made, the practical points are usually talked over with both the foremen and operators, so as to insure their approval and cooperation. In this way harmonious relations are maintained, and when a new method is put into operation or a new machine installed, all do their best to help make it successful. This practical attempt at systematized cost reduction is not yet completed, but what has been accomplished so far shows that it is possible to reduce costs materially and meet the new level of prices at a profit. This method of reviewing the entire manufacturing process of a plant is easy to carry out under present conditions, and is recommended to manufacturers generally.

* * *

THE DEFINITION OF "DEDENDUM"

In spite of all the efforts to standardize engineering nomenclature, the meaning of many engineering terms is still vague and subject to different interpretations. A technical term without a definite and accepted meaning is likely to cause serious confusion, and an important step in standardization work is to agree on the precise definitions of terms.

In the gearing field the meaning of most of the terms used has been, through common usage, generally established, except the term "dedendum," which is used by some manufacturers and in some books of reference as meaning "the distance from the pitch circle to the root of the tooth," thus including the clearance allowed at the root; whereas others use the term as meaning "the distance from the pitch circle to the clearance circle." In the latter instance the dedendum, in standard-tooth gears, is equal to the addendum.

The American Gear Manufacturers' Association is giving serious consideration to the definition and standardization of terms used in gearing, and doubtless will soon settle what is actually meant by the term "dedendum."

Service of the Tool and Contract Shop

FIFTEEN years ago comparatively few shops were engaged exclusively in the designing and making of special tools, jigs, fixtures, gages, etc., on a contract basis for other manufacturers. Today there are a great many contract shops all over the manufacturing area of the United States, and some have so developed in size and reputation that they stand on a par with the great manufacturing shops. This remarkable development is due to the highly specialized service such shops can render, combined with a wider recognition of the importance of well-designed tool equipment as a means of increasing the efficiency of machine tools.

Toolmaking versus Manufacturing

All large manufacturing plants maintain tool designing departments and tool-rooms for designing and making the tooling equipment required in the regular manufacturing routine and for equipment maintenance; but it is usually found impracticable to maintain a designing force and a toolmaking department extensive enough to adequately meet the requirements for complete tooling equipments to put new products on a manufacturing basis. In cases of that kind it has been found more profitable to call in the tool specialist—the shop that devotes all its time to designing and building special tools, jigs, fixtures, and gages. In so doing the manufacturer utilizes the special experience of men trained in developing manufacturing equipment, men who from year to year handle manufacturing problems in many different industries, and acquire a knowledge of manufacturing problems much wider than can be obtained in any other way.

The Economy of Specialization

The tool and contract shop is simply a logical development of the modern principle of specialization in manufacturing. In the early days many manufacturers built their own machine tools for making machines for other purposes—in fact, some of the well-known machine tool builders in the country started as makers of other products—rifles, sewing machines, textile machinery, etc. In the course of time they found it necessary to develop machine tools for use in building these machines and devices, and ultimately they became known as machine tool builders rather than as makers of their original products. The time has passed, however, for the makers of other lines to undertake the manufacture of their own machine tools. It is far more economical to buy machine tools from those who specialize in them and who thereby have brought the American machine tool industry to the highest standard established anywhere in the world.

In regard to special tools, jigs, and fixtures, we are passing through a transition period. Up to a few years ago it was the common practice of all manufacturers to make most of their own tooling equipment—at least all equipment that could not be obtained directly from the manufacturers of machine tools. Now the tendency is more and more to have tooling equipments built by specialists in this branch, just as machine tools are built by specialists in that field. In New England and in the Middle West we find large shops devoted exclusively to supplying other manufacturers with tools, fixtures, and gaging equipments; and while years ago, when a new enterprise was started, the first thing was to find a corps of tool designers and toolmakers, today all this preliminary work may be handed over to shops especially fitted to do it. Hence, the plant can be equipped right from the start to do manufacturing instead of tool work.

Just as it makes for economy and efficiency to have specialists build machine tools, so it is found that it makes for economy and efficiency to have specialists design and make tooling equipments of all kinds. The next ten years will probably see a still further development along these lines, with a higher degree of specialization and consequently a greater degree of economy and service.

The Influence of the War upon the Tool Shops

The peculiar value of the tool shop became apparent during the war period, when many shops, unable to provide their own tools, were obliged to turn to outside sources for assistance. Hundreds of tool and contract shops were started during this period—a great many more, in fact, than could be profitably employed during normal peace times. Some of these are out of business, but many have survived and will continue. The experience they gained during the war period will prove invaluable to them and to the industries in peace times.

It is safe to say that the remarkable rapidity with which the United States entered into war production was due, in no small measure, to the experience, skill, and ability displayed by the tool and contract shops. Accuracy and refinement in mechanical processes were demanded of them to an extent never before required in interchangeable manufacture, and they measured up to these exacting requirements in a remarkable degree. Some of the accurate measuring and inspection devices now finding increased application in the mechanical industries were developed by the contract shops during this period. Methods of grinding threads, for example, were first placed upon a commercial basis in the making of thread gages in quantities for munitions and ordnance. Some of the very large machine tool plants, in fact, were turned into contract shops for the time being, and their main business consisted in supplying the war industries with the equipment required for manufacturing and inspection.

Standardization in Tooling Equipment

With the general development of the tool and contract service came definite efforts toward standardization in tooling equipments. While this work has not advanced very far yet, there is no doubt that the next few years will see great progress along these lines, which should materially reduce the cost of making jigs and fixtures. The contract shop with thoroughly standardized parts for such tools can produce a manufacturing equipment much cheaper than a tool-room in which each jig and fixture, and each separate part, must be made as a separate unit. The up-to-date contract shop has a great advantage and a real opportunity.

Another line along which standardization has progressed is in the making of interchangeable gage units of various types, so that when a gage unit which is subjected to the greatest wear becomes unsuitable for further use, this unit may be replaced. In the past, gages were generally so designed that when one part was worn, the gage was discarded.

The value of specialization in the tool equipment field cannot be over-estimated. The tool and contract shop has made a definite and highly important place for itself, a place that will become increasingly important with the multiplication of products and of manufacturing processes, and the realization of greater refinement in mechanical procedure. We have a well defined and well developed machine tool industry and a definite small tool industry, and it is confidently expected that within a few years we shall have a large and important tool equipment industry.

GAGING AND ASSORTING PISTON-RINGS

By HARRY LEVENE

In order to gage or measure accurately finished piston-rings of the regular split type, it is necessary to employ special gages and exercise considerable care in performing the gaging operations. A method of measuring piston-rings that has proved especially useful in separating an assortment of rings of the same nominal diameter into their respective over-size lots is described in the following. This method was developed by the Wilkening Mfg. Co., Philadelphia, Pa., and is used in this company's plant with excellent results.

In gaging or measuring a ring, it is first placed in a cylinder or gage of a known internal diameter. The diameter of the gage should be approximately equal to that of the ring. While performing this operation care should be taken to see that the ring lies in a plane perpendicular to the walls of the cylinder. One of the three following conditions will be observed when the ring is properly located in the gage: (1) The ring will fit the cylinder or gage properly; (2) the gap opening will be larger than the normal opening, showing that the ring is under size; and (3) the ends will be in contact or will overlap, showing that the ring is over size.

Ring of Correct Diameter

The normal gap of a ring is that gap *G*, Fig. 1, which exists when the ring is placed in a cylinder of exactly its own diameter. The width of this gap varies with the make of the ring, but 0.002 inch per inch of ring diameter represents an average value. If the measured gap of the ring fulfills this condition, the diameter of the ring is the same as the diameter of the cylinder.

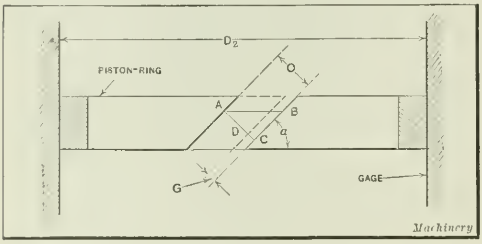

Fig. 1. Under-size Ring in Gage

Under-size Rings

When the opening is greater than the normal gap of the ring, it indicates that the diameter of the ring is less than that of the gage. The amount of the opening, that is, the distance between the ends of the ring, measured on a line at right angles to the angular surfaces of the ring ends, is determined to the nearest thousandth inch by means of a thickness gage. This value *O*, indicated in Fig. 1, the known values of gage diameter, and the angle at which the ring is split, are substituted in the following formula to find the diameter of the ring.

$$D_1 = D_2 - \frac{O - G}{\pi \sin a} \quad (1)$$

in which D_1 = diameter of ring;
D_2 = diameter of gage;
G = normal gap of ring = DC;
O = opening = AC;
a = angle at which ring is split.

Over-size Rings

The third condition—the ends of the ring being in contact or overlapping as shown in Fig. 2—indicates that the diameter of the ring is greater than that of the gage. The amount of this overlap can be measured by means of a thickness gage, and substituting this value *O*, Fig. 2, in the formula

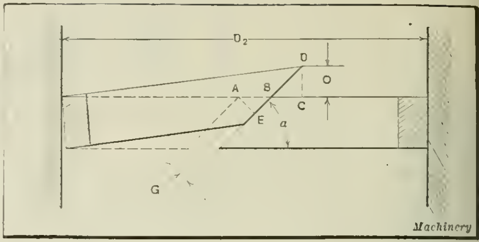

Fig. 2. Over-size Ring in Gage

$$D_1 = D_2 + \frac{G + O \cos a}{\pi \sin a} \quad (2)$$

will give the diameter of the ring. In this formula,
D_1 = diameter of ring;
D_2 = diameter of gage;
G = normal gap = AE;
O = overlap = DC;
a = angle at which ring is split.

The angle at which the ring is split is usually 45 degrees, but it is occasionally made 30 degrees. If the angle is not known, it can, of course, be readily measured. Formula (2) for the third case is not applicable to step-joint rings or to any kind of ring in which the ends cannot slide upon each other. Formula (1), however, can be used for step-joint rings, such as shown in Fig. 3, in which case the angle at which the ring is split is 90 degrees, and the formula thus becomes

$$D_1 = D_2 - \frac{O - G}{\pi} \quad (3)$$

Actually none of these formulas gives absolutely exact results, because they are based on the assumption that the ring will be in contact with the cylinder wall at all points on the circumference, but, nevertheless, they will prove of sufficient accuracy for practical purposes, provided the diameters of the gage and the ring do not differ by more than 0.040 inch.

The separation of an assortment of rings of the same nominal diameter into their respective over-size lots, is easily accomplished by using a gage having a diameter 0.040 inch over size, and employing Formula (1) for rings split on an angle, and Formula (3) for step-joint rings. All the factors in the formulas, except the diameter of the ring and the opening of the gap, remain constant. A table which gives the opening corresponding to each over-size diameter can be made up for this work. A table of this kind will give, without further calculation, the diameters of the over-size rings, and will greatly facilitate the work of separating the rings into different lots so that those of the same diameter will be grouped together.

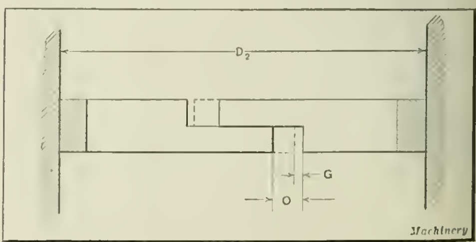

Fig. 3. Under-size Step Ring in Gage

The British Machine Tool Industry

From MACHINERY'S Special Correspondent

London, March 10

THE engineering industry in this country is dependent on the carrying out of several important projects that were delayed by the war. Chief among these is the conversion of many existing sections of railways, not only here but all over Europe, in the Far East, and in South America, from steam to electric power. The General Electric Co., Witton, has recently been awarded an important contract in connection with the extension of the electrified sections of the London Brighton & South Coast Railway, and several other English railways have similar projects that will soon be carried out. The machine tool industry is bound eventually to feel the good effects of these and other long delayed but far-reaching developments; at present, however, few direct results are to be noted.

General Industrial Conditions

During January there was a record output of shipbuilding, the total tonnage launched on the Clyde being 52,000. As very little new work is in hand, such an output brings the worst days nearer. There is some activity in the foundries and sheet-metal industry, aluminum, malleable and cast iron workers being in greater demand than for the last twelve months. Press-tool makers are also in demand.

C. A. Vandervell & Co., Ltd., the well-known manufacturers of electric lighting and starting equipment for automobiles, have undertaken at their Brighton works the manufacture of small tools on a quantity basis. Although they have been occupied with this work for only nine months, they already have a good output of a wide range of these tools, which include plain and spring type inside and outside calipers, spring dividers, toolmakers' parallel clamps, clamp vises, V-blocks, scribing blocks, tap wrenches, and toolmakers' squares.

British Industries Fair

Although the exhibits at the British Industries Fair, now being held in Birmingham and London, are too diverse to be truly representative of any trade, it is significant to note that the number of exhibitors is in excess of previous years and now totals over 500. The general engineering group of exhibits includes machine tools and small tools, hydraulic equipment, sheet-metal working machines, measuring and testing apparatus, heat-treating equipment, foundry, drop-forging and die-casting equipment, and conveying and lifting appliances.

The Machine Tool Trades Association, Inc., reports a successful year, and is able to point to much useful work on behalf of firms who are members of the association. The membership now stands at 142. In a recent ballot on the question of protecting the British machine tool market from being flooded with foreign machines, a motion was carried to the effect that the government should place import duties on all machine tools coming from countries where exchange values had collapsed. The Board of Trade is now giving consideration to these suggestions.

Foreign Trade

In foreign markets, India is the most active machine tool buyer, although of late there has been rather more demand from Australia and Japan. January showed, as compared with the preceding month, a slight increase in imports as well as in exports. The figures for the month were as follows: Imports, 275 tons, valued at £30,538, or £111 per ton. Exports, 1096 tons, valued at £167,021, or £152 per ton. A mean line taken through a graph of the exports of machine tools for last year shows that both in value and in tonnage exports declined at a steady rate, and at the end of the year were only half the figures for the beginning of 1921.

Iron and Steel Trades

The iron and steel trades are slowly reviving. Orders are coming in steadily from home consumers, and some fairly good business has been booked for overseas in the commoner varieties of steel. Crucible steels are also in better demand. It is reported that a further huge surplus stock of high-speed steel has recently been discovered at Constantinople, packed as it left the Sheffield Works some years ago for Russia. This adds to the heavy surplus, said to be sufficient to cover munition-making requirements for twenty years, which was discovered some months ago in the possession of the government. Apart from these stocks, the United States continues to be the best customer for high-grade steels, and there is a moderate demand from India and Japan; home inquiries are also becoming more numerous.

Better feeling prevails in the pig-iron industry, and makers are beginning to reap some benefit from their recent action in cutting prices. A number of important sales are understood to have been put through recently, and from present inquiries it appears that there is a fair amount of business to be placed by home consumers. A notable feature is the export of several thousand tons of pig iron to Germany. In amount the business is comparatively trivial, but this shipment is significant when it is remembered that during the greater part of last year conditions were such that Great Britain, from her former position as an exporter, came to be an importer. Thus the import figures for the three months ended December 1921, were 315,800 tons, as compared with a monthly average of 18,000 tons, during 1912-1913.

Conditions in the semi-finished material field are developing on similar lines. In the majority of cases British manufacturers have nothing to fear from Continental competitors in the overseas markets, and while India and Far Eastern countries are still taking German materials, the bulk of the business is passing into British works.

Developments in Machine Tools

Machines for cutting accurate gears are, perhaps, the outstanding development of recent years in the machine tool industry in this country. The advances are illustrated by statements recently made by leading gear-cutting machine manufacturers: J. Parkinson & Son, Shipley, state that one of their 5A rack type cutter machines will cut 132 feet of finished teeth per hour in cast iron, the gears machined having 156 teeth of 12 diametral pitch and 13/16 inch face. Muir & Co., Manchester, say that they are cutting in one of their rack type cutter machines 180 feet of ½-inch pitch teeth per hour, the cast-iron gears having 44 teeth, 1½ inches wide. On steel quadrants they are cutting 1½-inch pitch teeth, 5 inches wide, at the rate of 50 feet per hour. The Power Plant Co., Ltd., West Drayton, tells of cutting, in an 8½-hour day, 400 cast-iron gears having 44 teeth, 1¼ inches wide, of 6 diametral pitch. The machine was equipped for the purpose with six pinion type cutters operating simultaneously. The Power Plant Co., Ltd., has also aroused considerable interest with a one-tooth pinion meshing with a 63-tooth wheel. The pinion tooth is of the double-helical type and the pitch circle diameters are 0.508 inch and 32.004 inches, respectively. The gear has transmitted 10 horsepower at 1000 revolutions per minute.

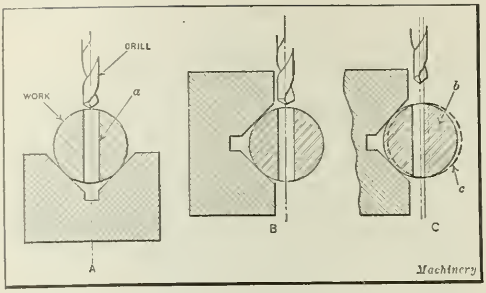

Fig. 1. Effect of Location of V-block on Accuracy of Work

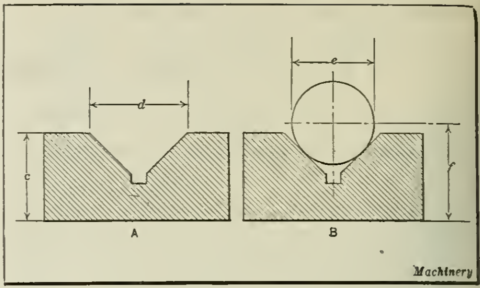

Fig. 2. Methods of dimensioning V-blocks

GENERAL DETAILS OF V-BLOCK DESIGN

By GENE PHELPS

The use of V-blocks in the design of tools often receives too little consideration from the designer. A careful analysis will show that many errors resulting from the incorrect application or design of V-blocks could easily be avoided. It is the purpose of this article to make clear the conditions that govern the use of various types of V-blocks in the shop, and to point out methods of avoiding the mistakes most commonly made by designers and draftsmen in designing V-blocks or in making provision for their use.

The limits of accuracy required on the work must first be considered, since this governs the general design. The view at *A*, Fig. 1, shows a round shaft in the position it occupies while the hole *a* is being drilled. In this view the V-block is shown in a horizontal position while at *B* it is shown tipped up, or in a perpendicular position. If the work is located and drilled as shown at *A*, any variation in its diameter does not affect the center line of the drilled hole, whereas if it is located as shown at *B*, a variation in diameter results in throwing the center of the work out of line with the center line of the drill. In the view at *C*, work *b* is of the correct size, while that indicated by the dotted lines at *c* is a little over-size. It will be apparent that a difference of 0.002 inch in diameter, for instance, will result in throwing the center line of the drilled hole more than 0.001 inch out of line with the center of the work. For strictly interchangeable work, where the accurate location of a hole such as that indicated at *a* is required, the location of the V-block must be given careful consideration.

Dimensioning V-block Drawings

Drawings for V-blocks are often dimensioned incorrectly as shown at *A*, Fig. 2. It is impossible to obtain satisfactory results when this method of dimensioning is employed, especially if the center line of the work is required to be located a given distance above the table on which the V-block is to be placed. The view at *B* shows the proper method of dimensioning a drawing of a V-block required for accurate work. It will be noted that the diameter *e* of the work is given, and that the distance *f* from the base of the block to the center line of the work is also given. This method of dimensioning should invariably be employed if the center of the work, when placed in the V-block, is required to have a definite position relative to some other point.

Grinding V-blocks

The grinding of the sides or angles of a V-block intended for production work is one of the most common mistakes made in the tool-room. At *A*, Fig. 3, is shown a V-block which is ground on the sides *b* and *c*, and provided with a groove *d* to facilitate the grinding and machining operations. A V-block of this type, if intended for production work, is not practical, as it is evident that a round piece of work would bear only on two points. As these bearing points wear very rapidly, the result would be that of constantly lessening the distance between the center of the work and the base or bottom of the block. If the work is not required to be very accurate, this slight wear can, of course, be ignored. At *B* is shown a V-block of similar design to that shown at *A*, but which is lapped at the locating points *f* and *g* instead of having ground sides. The lapping operation produces small lands at *f* and *g* which locate the work very accurately. It is obvious that the location of the work is as accurate with the block shown at *B* as with that shown at *A*, and that the increased bearing surface of the lapped block gives added assurance that it will maintain its accuracy much longer. In making drawings for V-blocks of this kind, the dimension *h* from the base to the center line of the work should be given. In machining the block, proper allowance should, of course, be made for lapping.

The deep relief or groove cut in V-blocks to facilitate machining often causes cracking as shown at *c*, Fig. 4, when the block is hardened. This is especially true of shallow V-blocks of the type shown at *A*. It is evident that the small amount of stock indicated by dimension *b*, together with the sharp corners at the bottom of the groove, make it difficult to harden the block properly without producing cracks. At *B* is shown a V-block in which the neck has been eliminated. It will be noted that the dimension at *c* is considerably increased in this case, which greatly lessens the danger of cracking when hardening. When this type of block is used for production work, it will be found advisable to employ the lapping method of finishing, as indicated at *B* in the illustration Fig. 3.

INDUSTRIAL CONDITIONS IN FRANCE

By MACHINERY'S Special Correspondent

Paris, March 13

French business men are watching with interest the rising value of the franc in relation to the dollar and pound sterling, because it is felt that any considerable increase in the value of the franc would cause a grave reaction on the economic situation. It would be necessary to reduce salaries proportionately, and, furthermore, stocks would depreciate in value. A reduction of ½ per cent on the tax payable on interest received from state bonds is seriously considered. Such a measure would have an excellent effect on trade.

Business in General

There has been no marked improvement in business conditions taken as a whole, although there is considerable activity in the automobile field. The Renault company has taken on 5000 workmen during the last few months. Besides automobiles, this concern also manufactures locomotive parts, Diesel engines, and a few machine tools. The machine tool field continues to be very quiet. The output of the coal mines in the Bassin du Nord region increases daily, and the deficiency caused by Germany's defaulting in the delivery of coke has been made up. The production in the devastated regions during 1921 was about 5,365,000 tons—a considerable increase over the figure for 1920 of 2,450,000 tons. In 1913 the production was 18,660,000 tons.

Effect of New Customs on German Machine Tools

The heavy duties imposed by France on German machine tools lead American and British dealers to look forward to increased sales. The increase in the value of the franc also tends toward that end. The duties imposed on German machine tools cf various weights are as follows, considering the value of the franc as 9 cents:

Weight	Francs per 100 Kilograms	Dollars per 100 Pounds
Over 25,000 kilograms (about 27.5 tons)........	132	5.40
From 5000 to 25,000 kilograms (5.5 to 27.5 tons).	158.4	6.50
From 1000 to 5000 kilograms (1.1 to 5.5 tons)...	211.2	8.60
From 250 to 1000 kilograms (550 pds. to 1.1 tons).	316.8	12.90
250 kilograms and under (550 pounds)..........	660	26.90

The duties imposed on other foreign machine tools are only one-fourth those levied against German products.

Taking a double-head Lincoln-type milling machine of German make, as an example, the method of calculating the final price would be as follows: Price quoted, 4125 francs; customs duty, 2217 francs; importation tax, 45 francs; and customs clearance fee, 26 francs, making a total of 6413 francs (about $580).

According to quotations, the prices of other standard German machine tools, considering the mark worth 5.5 centimes, are approximately as follows: A continuous vertical milling machine weighing 4000 kilograms (about 4.4 tons) costs 22,450 francs (about $2000) or about 5.6 francs per kilogram; a vertical boring mill weighing 8000 kilograms (about 8.8 tons) costs 37,900 francs (about $3400) or 4.73 francs per kilogram; a Landis-type threading machine weighing 1050 kilograms (about 2300 pounds) costs 6090 francs ($550) or 5.8 francs per kilogram; and a lathe weighing 4300 kilograms (4.75 tons) costs about 21,700 francs ($1950) or about 5.05 francs per kilogram.

Prices of American Machine Tools

The prices of high-grade American machines, based on the weight, range between 8 and 10 francs per kilogram (32.6 to 40.8 cents per pound). A vertical milling machine of well-known American make, weighing 1300 kilograms (2870 pounds), is offered for sale at 13,000 francs (about $1170) which amounts to 10 francs per kilogram. A universal milling machine weighing 3200 kilograms (3.5 tons) sells for 31,360 francs ($2820) or 9.8 francs per kilogram. Taking price and quality into consideration, one of the large French dealers handling German and American machines believes that there is little difference from a sales standpoint between the machines received from the two countries. French buyers, however, are still tempted by the lower price of the German machines, this being partly due to the effective work of German salesmen. The price of French machine tools varies from 8 to 10 francs per kilogram, which is the same as for American machines.

MACHINE TOOL INDUSTRY IN SWEDEN

The building of machine tools in Sweden began to be of some importance between the years 1840 and 1850. In the early development of the industry each machine shop made all the machine tools required in the manufacture of its particular product, but after a few years a number of shops began to specialize on certain machines and build them as a commercial product; and machine tools eventually became their principal line.

As far as quantity and variety are concerned, the production of machine tools in Sweden cannot compete with that of the United States, Germany, or England, all of which have enormous domestic markets. The Swedish manufacturers of machine tools have based their production on the home consumption and have not paid much attention to the export market. The natural result is that the manufacture of machine tools in Sweden embraces only the types and sizes which are most in demand by Swedish industrial enterprises. They are those general utility machines which can be produced in considerable quantities even though the area of the market is limited. As a general rule it may be stated that heavy and expensive machines and special-purpose machines of the type of which only one or a few are required in any one factory, are not manufactured in Sweden.

Lathe Production and the Market for Lathes

Lathes form the major part of the machine tools manufactured in Sweden. In 1914, prior to the war, there were at least three Swedish concerns of considerable size engaged in the manufacture of modern types of lathes—the Köping, Munktell, and Lidköping Works. In fact, the Swedish production of standard types of lathes had at that time grown to such proportions as to meet the domestic demand. An export market had also been obtained in the neighboring Scandinavian countries, as well as in Finland, Russia, and some of the other smaller countries. At the Baltic exhibition in Malmö in 1914 the design and quality of workmanship of the Swedish lathes aroused favorable comment by German engineers, and by the German technical press.

The war brought on an enormous demand for lathes and some of the European belligerent countries were unable to supply the manufacturers of war material with the necessary quantity of these machines. This presented an opening for the Swedish machine tool builders, which they were not slow to take advantage of. Not only did the previously established machine tool manufacturers engage in supplying this demand, but many other manufacturers started building lathes, with the result that a large export trade with Russia, England, France, Germany, and Austria was developed. Although most of this export trade was of a temporary nature, it resulted in the older establishments enlarging their plants and improving their methods so that they are now better prepared to compete with those of foreign make than before.

Machine Tools other than Lathes

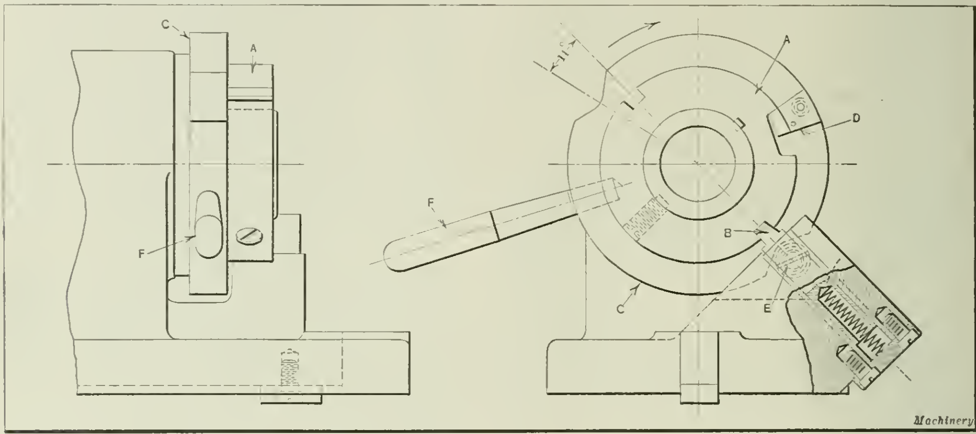
Planers and shapers of standard types are manufactured in Sweden in sufficient numbers to satisfy the domestic demands. Before the war there had been some export trade developed with the neighboring Scandinavian countries. Power presses, drop-hammers, and forging machines of different types are also among the machines produced by the oldest of Swedish machine tool manufacturers. Very few machines of these classes are imported into Sweden. Other kinds of machine tools manufactured in Sweden are drilling machines, milling machines, and boring machines.

INDEXING MECHANISM WITH AUTOMATIC PAWL RELEASE

Many designs of jigs and fixtures require an indexing movement for locating work in different positions relative to the cutting tool. It is common practice to so arrange the indexing device that the locating plunger or pawl must be released with one hand while the work-spindle is turned with the other. The indexing mechanism shown in the accompanying illustration is so arranged that the locating pawl is automatically released and the work-spindle can be rotated from one position to the other by means of a single hand-lever *F*.

This indexing mechanism is arranged for holding the work-spindle in two positions, 180 degrees apart, as governed by the notched locating plate *A*, which is engaged by plunger *B*, the latter being pressed inward against the plate by a spring. Adjacent to the notched locating disk there is a pawl-releasing plate *C*. This plate has two curved recesses, and one of these must be opposite roller *E* on the pawl whenever the latter is in engagement with the locating plate. When plate *C* is turned clockwise, as indicated by the arrow, roller *E* rides up on the periphery of *C*, thus forcing the pawl back out of engagement with the locating notch. As the work-spindle cannot rotate until the pawl is withdrawn, plate *C* is permitted to turn independently about 14 degrees, or far enough to allow roller *E* to be forced backward out of the locating plate.

This independent movement of plate *C* occurs while dog *D* is moving across to the opposite side of a slot formed in plate *A*. The movement of disk *C* relative to the work-spindle also causes the roller recess on the other side to move around 14 degrees, or until it is in alignment with the locating slot on that side; consequently, the pawl is free to engage this slot after the work-spindle has been turned one-half revolution. This indexing mechanism is used by the designing department of the Pratt & Whitney Co., Hartford, Conn., whenever such a device is required for jig and fixture work.



Indexing Mechanism with Automatic Pawl Release

* * *

An international exhibition of foundry equipment and materials will be held in Birmingham, England, June 15 to 24 in connection with the annual convention of the Institution of British Foundrymen. The exhibits will be shown in Bingley Hall, and will embrace every phase of foundry work.

TEN YEARS' EXPORTS OF MACHINE TOOLS TO GREAT BRITAIN

In 1912 Great Britain imported $2,678,995 worth of machine tools and metal-working machinery from the United States; by 1914 her imports of American machines had increased to $3,174,333. Owing to the war demands, the British market rose abnormally during the period 1915 to 1918, reaching a maximum in 1916 when $20,434,934 worth of American machines were imported. This represented an advance of nearly 600 per cent over the 1914 market. Since the war there has been a rapid decline from this high level. During the last two years there has been a growing tendency for Great Britain to increase her exports of machine tools and metal-working machinery, with a corresponding decrease in imports of these machines, the imports of American machine tools and metal-working machinery for 1921 amounting to only $2,698,321.

The statistics show that in 1912 Great Britain consumed 22 per cent, in 1913, 21 per cent, and in 1914, nearly 23 per cent of the total American exports of machine tools and metal-working machinery. Although in 1921 Great Britain consumed only 14 per cent of the total exports, this 14 per cent represented, in dollars, slightly more than the 22 per cent taken in 1912, as the amounts in the table show.

Detailed statistics are not available for the years previous to 1918, but it is interesting to note from the table the changing demands for various kinds of machines during the last four years. In 1918, 1919, and 1920 American machine tools were in much greater demand in Great Britain than other metal-working machinery, but during 1921 the market for the latter rose slightly above the demand for machine tools.

VALUE OF MACHINE TOOLS AND METAL-WORKING MACHINERY EXPORTED TO GREAT BRITAIN, 1912-1921

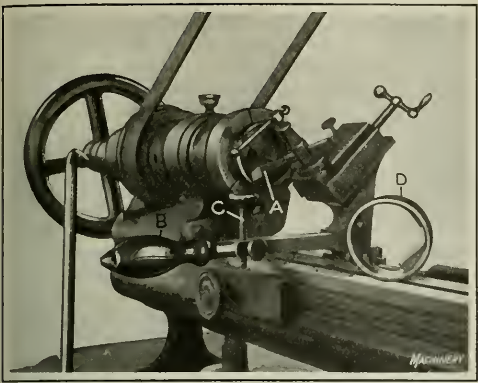

Fig. 1. Set-up employed for threading the Bezel Case of a Dial Gage on a Bench Lathe

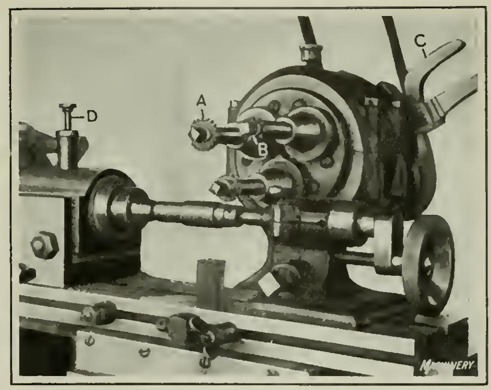

Fig. 2. Milling Machine with Special Cutter-head for machining Gage Train Wheels

Tooling Equipment and Methods Used in Making Dial Gages

Some Interesting Operations Performed in the Stickney & Randall Plant, Waltham, Mass.

By ROBERT MAWSON

THE thickness dial gage manufactured by Stickney & Randall consists of a stand, on the upright part of which there is fitted, by a tongue and groove construction, a vertical bearing for the stem of the table. The table and the stem are integral, and adjustment and location are obtained by means of adjusting screws. Fig. 3 shows the application of the gage for testing the location of a hole in the dial case. This case is fitted to the top part of the casting, which is machined to receive it, and through it extends the gaging spindle *A*, which is operated by the lever shown at the left side of the gage. The registry mechanism for the dial provides for obtaining readings in thousandths of an inch by means of the long hand, and in ten-thousandths of an inch by the short hand.

The first operation to which attention is directed is performed with the set-up shown in Fig. 1 and consists of threading the bezel case. This part is cast from a special hard composition and is held in the chuck of a Stark bench lathe. The threading tool *A* is fed to the correct depth by operating handle *B* which is carried by the lead-screw at the rear of the lathe. The proper depth of thread is obtained by the adjusting screw *C* which, after the adjustment has been obtained, can be locked in the correct position by means of the knurled screw on the side of the arm of the attachment. The case may be clearly seen at *D*, the casting being 2 inches in diameter and containing 32 threads per inch cut internally with the equipment shown.

Fig. 2 shows a Stark bench milling machine equipped for machining the steel train wheels of the dial gage. Twenty-five of these wheels, or gears, are placed on an arbor at a time and the outside diameter is machined to the correct measurement by cutter *A* carried on one of the three spindles of a special index milling head. The second spindle, which is the one shown in position for machining the wheels, is used to rough-cut the teeth, and the third spindle *B* performs the finishing operation on the teeth. In machining brass wheels spindle *B* is not required. For machining the outside of the wheels, both the cutter *A* and the arbor revolve, the speeds and feeds being so arranged that the spiral cut taken will reduce the diameters of the stack of blanks to the size required. After the head has been indexed by operating the lever *C*, the arbor is held stationary by pin *D* in the index-head during the cutting of the teeth. The blanks are machined with 100 teeth and the index-head is operated by a gear and index-pawl at the extreme end of the head.

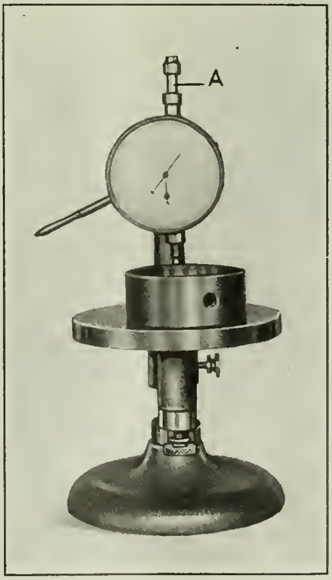

Fig. 3. Gaging the Location of the Spindle Hole in the Dial Case

Use of Jeweling Caliper to Obtain Force Fit

A number of small pinions and the staffs or studs on which they are assembled are shown on the ways of the bench lathe in Fig. 4. It is important that the staffs and pinions of all the gages have the same degree of fit, and to obtain this result a jeweling caliper, commonly used in the watchmaking industry, is employed. The staffs are made on an automatic and there is some slight variation in their diameters, so that some method must be employed to compensate for this variation. The pinion is bored out with the tool carried on the end of the push-spindle *A*. The radial adjustment of this tool to provide the necessary degree of fit is obtained by placing the staff between the jaws of the caliper as shown at *B* and using

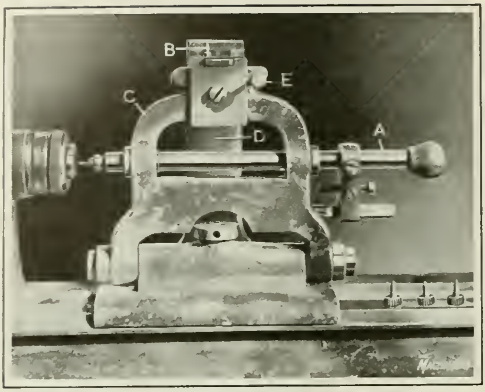

Fig. 4. Jeweling Caliper for obtaining Force Fit between the Pinions and the Staffs

it to gage the amount of metal removed in the boring operation on the pinion, which is later to be assembled on the staff. The pinion is chucked from the outside diameter as shown, and the arm *C*, which fulcrums on a shaft at the base of the tool, is swung forward until its jaw grips the staff. The stationary jaw (which does not show clearly in the illustration) is carried on the column *D*. If it is desired to bore the pinions with a larger hole than is required for a force fit, the necessary adjustment is obtained by the adjusting screw *E*, the point of which is brought up against an ear on the stationary column *D*.

After the arm which carries the spindle has been properly located, the operator pushes the boring tool into the revolving pinion, the spindle being provided with long bearings to maintain the correct alignment. By this method the pinion staff hole is bored slightly smaller than the outside diameter of the shaft or just enough to allow a good drive fit. After the gage has once been set, it requires no readjustment until all the parts have been completed. The length of travel of the spindle is governed by a stop on the spindle near the rear bearing.

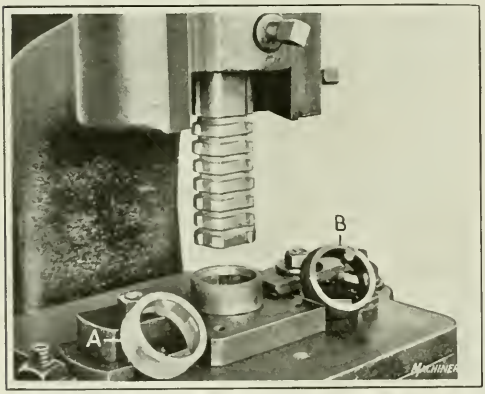

Fig. 5. Broaching the Inside of the Dial Case

Operations on the Dial Case

The broaching of the inside of the case is shown in Fig. 5. This work is done on a screw press—a bench tool commonly used in watchmaking and similar work. The casting is placed on the table of the machine and is located in relation to the cutting edges of the broach by a short pilot. The pilot and the broach are of special shape as required by the irregular contour machined. A casting before and after broaching is shown at *A* and *B*, respectively, and another case partly machined is shown in position under the broach.

The drilling of the bushing holes in the cases is shown in Fig. 6. The bushings that are assembled in these holes furnish the bearings for the gaging spindle or stem *A*, Fig. 3, and these holes must be drilled accurately to bring the center line of the gaging spindle parallel with the face of the case. Previous to this operation the outside of the case is turned and ground to size; it is located in the jig shown by means of adjustable V-blocks and stop-pins at the rear fitting against the lugs on the inside of the case. The V-blocks slide in the jig and may be clamped in the desired position by machine screws. The holes to be drilled are not radial, and so in order to start the drill correctly and prevent it from pushing over to one side when starting, the spotting tool shown at the left is first employed. After a hole has been drilled through from one side, the spotting

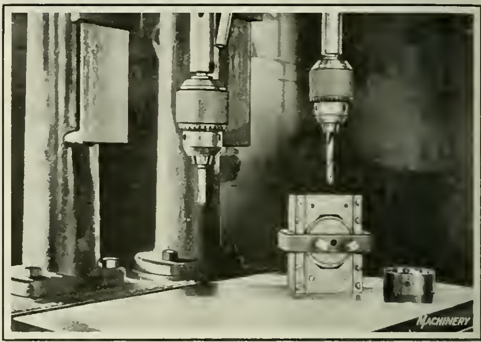

Fig. 6. Drilling the Holes through which the Gage Spindle operates

and drilling operation is repeated on the opposite side by simply reversing the position of the jig on the table.

For inspecting the parallelism of the spindle hole in the case and for checking its location relative to the face, the work is placed on the table of a regular thickness dial gage, as shown in Fig. 3, and the spindle *A* provided with a wide foot to extend into the hole and register its location from the surface of the table. By repeating the operation on the opposite side of the case the parallelism can also be checked. It is important to hold this degree of parallelism to the closest possible limits so that the gage stem will slide smoothly in its bearings.

Drilling Pillar Plates for Train Wheels

A bench type of multiple drilling machine which is used for drilling the train wheel plates of the dial gage is illustrated in Fig. 7. The plates, which are simply plain circular

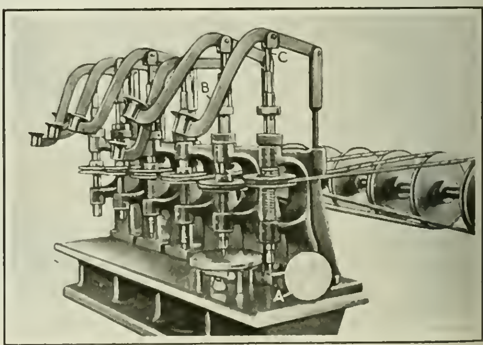

Fig. 7. Bench Type Multiple Drilling Machine on which the Pillar Plates are drilled

disks shown at *A*, are located in a four-legged drill jig, being clamped on the under side by a circular cover-plate which fits the outside of the work. To load this fixture, it is simply necessary to invert it, slip the work under the clamping straps, and tighten the wing-nuts which bind the clamping dogs firmly in place.

The drilling machine has six spindles, driven by twisted rawhide belts from a countershaft at the rear of the machine. The countershaft is adjustably supported so that it may be raised or lowered when changing the tension on the belt. Hand feed is used, the operator simply forcing down lever *B* which hinges in the yoke end of connection *C*, the opposite end of this connection being fitted to the end of the spindle by a loose ball and socket joint. When lever *B* is released

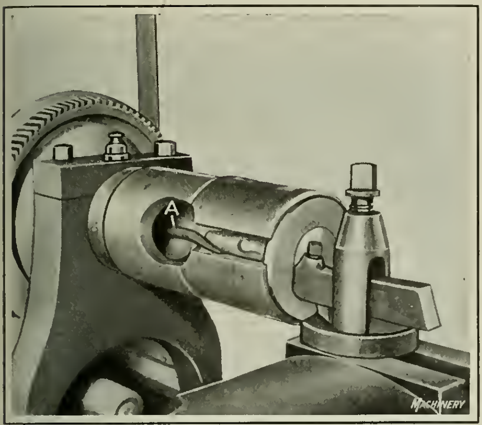

Fig. 8. Equipment used in facing the Base of the Gage Stand

at the completion of the drilling operation, the coil spring interposed between the spindle driving pulley and the lower bearing, returns the spindle and drill to the upper position. Multiple-spindle drilling machines of the bench type, such as this one, are extensively used in the manufacture of various parts of dial gages.

Machining the Gage Stand

The first operation performed in machining the gage stand —facing the base—is shown in Fig. 8. The design of the piece being machined is shown at *A* in Fig. 10. It will be seen that there is a pad on the part of this stand to which the bearing for the table stem is fitted. In facing the base,

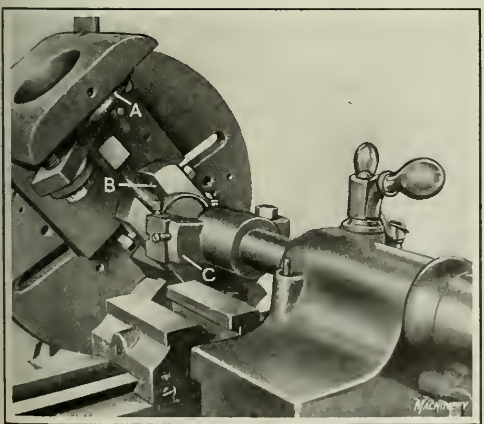

Fig. 9. Lathe Set-up for machining the Stand to receive the Gage Head

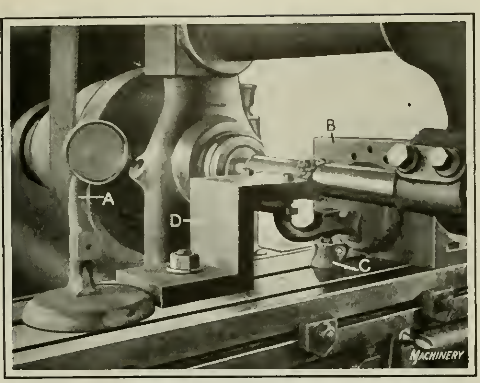

Fig. 10. Milling the Pad to which the Table Stem Bearing is attached

the casting is placed in a cylindrical fixture, seated on the end, as shown in Fig. 8, the upright part extending in and being drawn firmly into position by a hook *A*, which engages the casting back of the dial case cup section; this hook is operated similarly to a draw-in chuck. The nut is screwed up by the operator until the casting is located against the face of the fixture, after which the facing operation is performed in the usual manner.

The stand is then machined to fit the gage head, in the fixture shown in Fig. 9, which is attached to the faceplate of a lathe. The base *A* of the casting is located against a foot on the angle-plate fixture and clamped by means of straps. A slot *B* locates the work properly relative to the center of rotation and also drives it through two screws

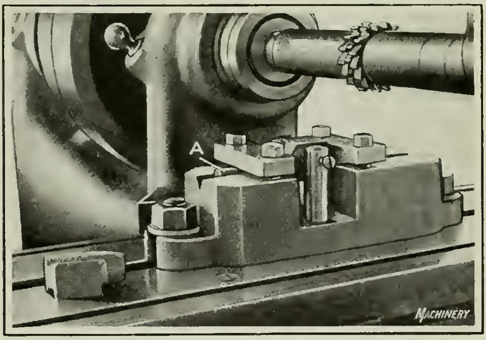

Fig. 11. Equipment used for milling the Surfaces by which the Table Stem Bearing is fitted to the Stand

which bind the work in place. The operation consists of turning the outside and inside surfaces of the circular wall within which the dial indicating mechanism is contained. and the work is performed with a special tool-head *C* in which both the tools required for the operation are carried.

In machining the pad to which the table stem bearing is attached, care must be taken to machine this surface so that when the table is assembled in the bearing, the center line of the stem will be normal to the base of the gage. The pad is machined with a tongue, using a gang of three plain milling cutters. A simple angle-plate fixture *B*, Fig. 10, is employed and a screw-jack *C* for supporting the piece during the operation and preventing distortion caused by the thrust of the cutters. The gage-head end of the casting is clamped to the double angle-plate *D*, both this plate and the one against which the base is attached being located on the machine table by tongues engaging the central table slot. By this set-up the machined surfaces are maintained in correct relationship to each other.

Other Equipment Used in the Manufacture of the Gage

Equal care must be taken when machining the fit for the table stem bearing casting. This casting is shown lying on the table of a milling machine in Fig. 11 before being machined, and located in the fixture after the operation has been completed. Before the work comes to this machine, the stem hole is drilled and reamed in a lathe, no special equipment being employed. The casting is then placed on an arbor *A* which fits the reamed hole and extends beyond at each end, being located on the fixture by a V-groove in which the projecting ends of the arbor rest. The gap in the fixture allows the casting sufficient clearance space, and the chips from the cutters accumulate in this cut-out section instead of in the V-groove. The casting is located in an upright position between two adjusting screws carried in posts at opposite sides of the fixture, and is secured to the fixture by ordinary spring-supported straps. The method of locating and clamping the work should be apparent from the illustration. A gang of three milling cutters is employed to mill the groove corresponding to the tongue on the pad of the gage stand, which was milled with the equipment illustrated in Fig. 10.

Fig. 12 shows the grinding operation performed on the face of the gage table *A*. The turned stem of the casting is held in the fixture *B* by a clamp bolt which tightens the split bearing in which the stem fits. A very simple type of workhead is employed, which is mounted rigidly on the table of the machine and driven by a belt in the regular way. After the work has been secured in the fixture, the table of the machine is fed in and then traversed back and forth across the grinding wheel until the desired results are obtained. This gives the surface of the gage table a smooth finish and assures that it will be exactly at 90 degrees with the center line of the stem and consequently parallel with the base of the stand.

The final inspection of the indicator is made with the device illustrated in Fig. 13. The finished indicator is attached to a disk *A* which has a stem by means of which the disk is locked and adjusted radially in a split bearing *B* in the head of the shaft *F*. This allows for inspecting indicators of various sizes. It will be noticed that the indicator is not shown in the position that it would occupy if it were actually attached to the disk, but is tipped so that the readings on both the indicator and the micrometer thimble *C* may be observed. The micrometer head may be located on shaft *F* by means of a pin lever which binds the split bearing where desired. Final longitudinal adjustments of the micrometer spindle are accomplished by the knurled screw *D*, and the spindle itself may be removed from its bearing for convenience in changing the arm *E* in which it is carried. With the instrument located so that the indicator spindle is in alignment with the micrometer spindle, the micrometer spindle is brought into contact with the end of the indicator spindle, both readings registering zero. As previously mentioned the adjusting screw *D* is used to bring the micrometer reading to the exact zero mark on the micrometer thimble. If the indicator is correct, the readings on the micrometer head and on the gage dial will correspond as the micrometer thimble is turned. Shaft *F* carrying the entire set-up may be revolved in its bearing and located to obtain the best lighting effect for the inspector.

STANDARDIZATION ACTIVITIES

The American Engineering Standards Committee has just completed arrangements by which cooperation with the standardizing bodies in other countries will be made more effective. In order that all standards shall be available to the industries of the various countries, it is planned that each national body will sell the approved standards of the other bodies. The American Engineering Standards Committee, 29 W. 39th St., New York City, has available the publications of the standardizing bodies in Austria, Belgium, Canada, France, Germany, Great Britain, Holland, Sweden, and Switzerland.

The work of standardization in the iron and steel field in the United States has been furthered by the addition of two new member bodies—the American Railway Association (Engineering Division) and the Association of American Steel Manufacturers—to the American Engineering Standards Committee. The Association of American Steel Manufacturers is an organization of forty iron and steel manufacturing companies. Its activities are limited to the standardization of rolling mill practices, and to the standardization and inspection of iron and steel products. The American Railway Association, which represents practically all the steam railways of the country, has four great technical branches, each having its own secretary, the Engineering and the Mechanical Divisions, the Signal, and the Telephone and Telegraph Sections.

* * *

The feasibility of arc-welding alloy steels has been demonstrated by the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. With adequate mechanical treatment and heat-treatment, tensile strengths of 130,000 pounds per square inch have been obtained in the weld. The possibility of forging arc-deposited metal has been clearly demonstrated, as well as the resistance of the forged metal to fatigue stresses; this widens the field of application of the process. Progress has also been made by the company in percussive welding. It has been shown that materials can be quickly and efficiently welded by this method, which cannot be so united by any other known method, and uniform welds can be produced.

REFITTING BEARINGS IN AUTOMOBILE CRANKCASES

A specially designed boring-bar and fixture is used in the shop of the Detroit Cadillac Motor Car Corporation, New York City, for line-boring the bearings of automobile crankshafts. This equipment, which was made especially for Cadillac automobile repair work, has been the means of greatly increasing the accuracy of the job and decreasing the time required to perform it.

When the crankshaft journals of a Cadillac motor have been found to be worn so far under size and out of round that it is impracticable to fit bearings to them, the crankshaft is removed from the case and the three journals are ground to a uniform diameter, depending on the condition of the crankpins. In fitting new bearings to this reground shaft by the old method, a large amount of hand scraping and fitting was required. By the new method, the cases are first fitted with three under-sized bearings supplied by the factory, and these are placed in position in the crankcase after the shaft has been reground, and are then line-bored. A view showing the top of the crankcase with the boring-bar and fixture in place is shown in Fig. 1, and Fig. 2 shows the underneath side of the fixture.

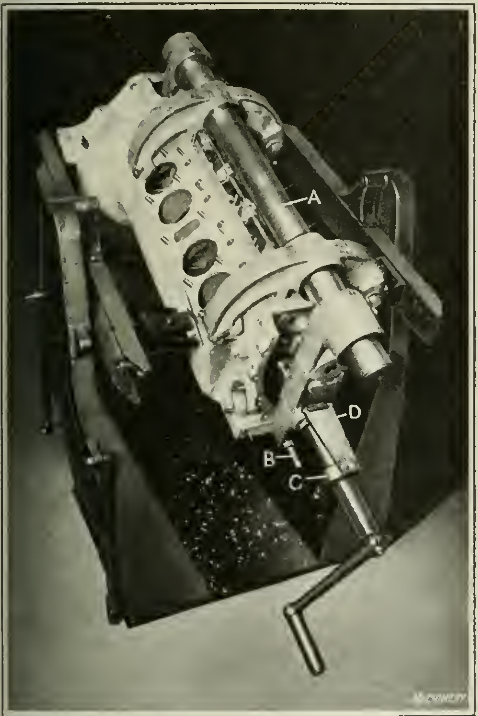

Fig. 1. Boring-bar and Fixture used for refitting Main Bearings of Crankcases

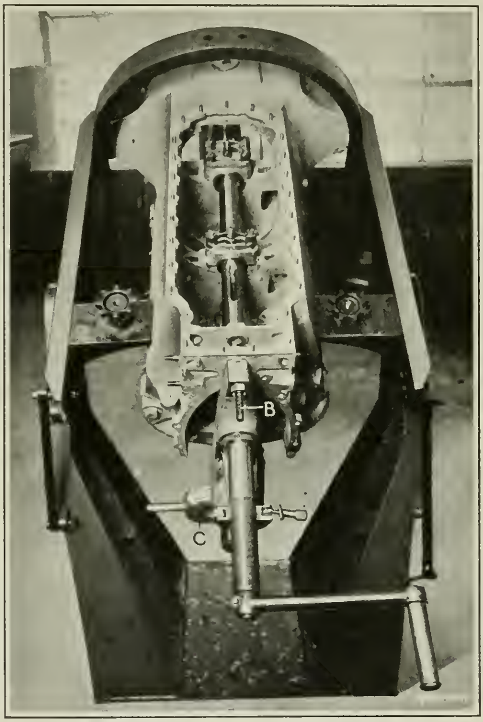

Fig. 2. View of Reverse Side of Crankcase, showing Interior and Bar in Place

This boring-tool consists of a single bar in which three cutters are carried, the cutters being set radially 120 degrees apart. The cutters operate simultaneously, one on each bearing. A rigid fixture is provided for supporting the bar, as shown in Fig. 1. This consists of a heavy steel bar *A*, to which two heavy double-armed castings are fitted, the extending ends of which carry accurately ground pads, which are designed to rest accurately on the crankcase cylinder block faces. As a secondary means of location, a locating pilot *B* is used at the front end of the fixture which is inserted into the oil-pump drive shaft bushing on the casting.

Fig. 2 shows the method of supporting and clamping the case while the bearings are being bored, as well as the method by which the bar is located and the feeding arrangement. Here the feed-nut *C* which is hinged over the threaded boring-bar is shown open for the purpose of illustrating how the nut is closed and clamped on the bar. This nut is carried by an arm *D*, Fig. 1, which may be swung into a vertical position when the tool is not in use; then the hinged member of the nut is closed around the bar as shown. The threaded part of the boring-bar, which constitutes the feed-screw, is of very fine pitch, and the cutters are fed through the bearing by turning the handle at the end of the bar.

The three cutters on the boring-bar are set to bore out under-sized bearings to a diameter 0.002 inch greater than that of the ground crankshaft journals. Great care has been exercised in the manufacture of this boring-bar, and it is stated that even with the bar pulled out so that no support is afforded at its further end, the end will not run out more than 0.0005 inch. The operation of fitting these main bearings, including setting up the bar and its cutters, takes approximately one hour. The former method of fitting these bearings to a reground shaft took about ten hours and could not be done even then with the same degree of accuracy that is possible with this tool.

NATIONAL FOREIGN TRADE CONVENTION

The ninth national foreign trade convention will be held in Philadelphia May 10 to 12. Some of the important topics to be considered at this meeting are the following: Financing foreign trade; the merchant marine; foreign investment; taxation; education for foreign trade; banking facilities; sales promotion; foreign competition; foreign credits; combination for export; foreign advertising; and the stimulation of foreign trade.

Organization of a Large Tool Division

Duties of the Various Members and Units of an Organization Responsible for the Development of Quantity Production Tools

By H. P. LOSELY, Industrial Engineer, Detroit, Mich.

THE manufacture of a new product in a plant in large quantities and with a sufficiently low cost to compete with other manufacturers of the same product necessitates the making of special tools, jigs, and fixtures, the number of which depends, of course, upon the number of component parts of the product and the operations on each part. In addition to this, although special tools are being used in the making of an established product, increased competition occasionally necessitates the redesigning of tooling equipment to permit the product to be more economically or satisfactorily made. The supplying of a large plant with tools of this class obviously involves a tremendous amount of work, and tool superintendents are frequently unable to handle it efficiently, due mainly, to the system under which the tool division operates. In the following, a description is presented of a tool division organization which is based on the experiences of four manufacturing concerns, three of which developed tools for a new product, while the fourth constantly makes tools to suit contract orders.

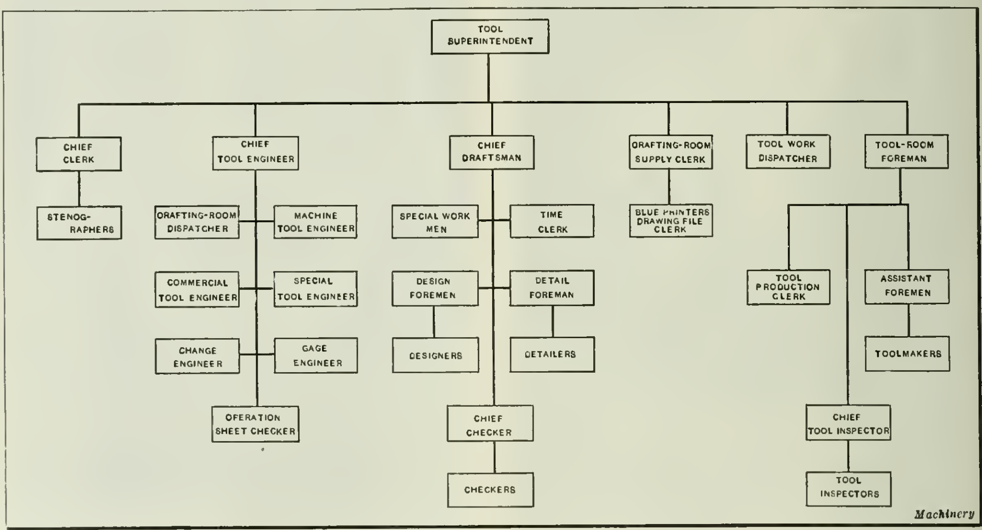

Fig. 1. Organization Chart for a Large Tool Division

Graphic Representation of Tool Division

A chart showing the arrangement of the members and units of the tool division to be described is illustrated in Fig. 1. In this organization it is intended that between one and two hundred men are to be employed on the activities covered; with a smaller organization, some of the functions assigned to several men should be combined and assigned to one. Objections may be raised that there are too many bosses and too much overhead with this scheme. The fact is that in cases where the design foremen attend to all the functions here assigned to separate men, they cannot supervise many designers without neglecting them and often making them wait for work. This causes a waste of time more costly than the employment of a few specialized men to line up all the details of operation. Above all, the lack of centralized responsibility for each division of the work is certain to cause a lack of coordination, which requires a great deal of trouble to straighten out, or if not discovered, results in inefficient plant operation—for instance, excessive or insufficient equipment may be used, or work may not be assigned to the most suitable department.

The main burden of preparatory work falls on the chief tool engineer and his assistants, and their duties will be detailed at length. If their work is properly done and the drafting-room is well directed, the tool-room will get correct orders in the proper sequence. Furthermore, orders will be so distributed that the tool-room can meet the required deliveries. In adapting this plan to the needs of any particular plant, the chief point to bear in mind is that it is only a means of supplying the manufacturing departments with real tool service, that is, supplying them with the right tools at the right time. The duties of the men and units connected with the actual making of tools will not be described, because they will be evident from the titles.

Functions of the Tool Superintendent

The tool division is responsible for all activities relative to a tool up to the delivery of the inspected tool to the production department. This centralizes final responsibility for tools in the tool superintendent, and it is part of his problem to maintain harmony between the tool designing and tool making sections of the division as well as among their individual members. It cannot be too strongly emphasized that the tool superintendent should be a broadgage executive. It is an old rule that an executive must be thoroughly acquainted with the technical part of his work, but still more he must be able to handle his men, consider the needs of his co-executives, and so dispose his forces as to get maximum results from minimum efforts. The tool superintendent then, must be thoroughly familiar with general machine shop practice, and know what can and what cannot be done in the way of machining and processing, but his main duties are to coordinate the activities of his department and foresee the needs of other departments affected by his work. His problem is not one of ordering new equipment and designing tools, but is essentially determining in which direction he can most economically provide good tool service.

If a million dollar plant lies idle while waiting for the completion of tools when there are orders on hand which should be yielding a profit of $1000 a day, it is the duty of the tool superintendent to plan so as to cut down the idle time to a minimum, balancing the extra expense of overtime work against the reduction of loss on idle time. If deliveries of products are being retarded because one or two parts cannot be manufactured fast enough, the tool superintendent should see that he is properly informed, then determine whether extra tools are needed, and, if so, what

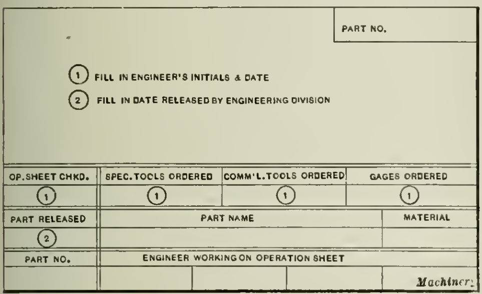

Fig. 2. Card used for keeping Track of Jobs while making up the Operation Sheets

would be a reasonable amount of money to spend on them. While such problems in their origin may be the concern of the production manager, their final solution devolves upon the tool superintendent, and the more his viewpoint is that of the broad business man rather than a purely technical one, the better will be his decisions. It is for this reason that, in the organization outlined, all technical duties are delegated to subordinates.

At the beginning of any tooling process, the tool superintendent should spend enough time on his organization and system to have it well lined up. A feverish start with the idea of turning out a great number of drawings and orders in a short time usually proves costly. At the same time forethought for the continuity of the personnel is necessary; to have key men leave the organization when a job is half complete may prove very disconcerting. It should be a point of honor with the key men not to leave work in an unfinished condition, and there should be a distinct understanding to that effect. If a bonus can be arranged for completion of a job within a definite time, it will be an additional advantage. Just how far to go with such a bonus system, of course, depends upon circumstances.

One of the first things to do on a job is to get an estimate of the amount of work to be done. The nature of the work precludes obtaining an accurate estimate; nevertheless past experience should be a good guide. For instance, the tooling of a complete high-class automobile involves designing some 10,000 special tools at an average of 30 hours drafting work, or a total of 300,000 hours. If an analysis of this description is made at the outset, the most economical size of tool division can be rapidly decided upon, and a plan mapped out for the distribution of work. In determining the outline of this plan, consultation with the financial, sales, and production departments is necessary, and as soon as the organization is settled upon, the tool superintendent should exert every effort to insure the fulfillment of the schedules agreed upon.

Duties of Chief Tool Engineer and Drafting-room Dispatcher

Chief Tool Engineer—The chief tool engineer determines the general lay-out of operations on a part, and is responsible for the correctness of all operation sheets, all designs issued for special tools, and the completeness of orders issued for commercial tools. In other words, he must see that everything issued by the office is technically correct. It is evident that the person holding this position must be a man with a good technical knowledge and wide experience. In an organization of any size, he will find it necessary to delegate a considerable portion of his work to assistants as outlined on the chart, and should, therefore, be a good leader. The position of chief tool engineer is second only in importance to that of tool superintendent, and no pains should be spared in getting it filled properly.

Drafting-room Dispatcher—The function of the drafting-room dispatcher is to so distribute work to the tool engineering and designing sections that tool orders, both special

Fig. 3. Card used for keeping Record of Amount of Work assigned to a Machine

and commercial, are sent out in the best possible sequence. The main qualifications for this position are a knowledge of tools and tool design; an appreciation of the relative importance of parts, both as to the amount of preparatory work involved and whether or not the parts can be made with improvised tools in case of emergency; steady habits; an ability to systematize work; and persistence in following up orders.

Dispatching Work through the Engineering Section

In dispatching work through the tool engineering section, it is first necessary to consider whether any particular work needs urgent attention. For instance, the machine tool engineer may report a shortage of machines for a certain class of work. It might then be advisable to have the operation sheets made out for parts requiring the use of such machines, before dispatching anything else, in order that the machine tool engineer will have definite information on which to base requests for additional equipment. Of equal importance is the dispatching of complicated parts requiring many operations and expensive tooling. Whether work should be dispatched first to the machine tool engineer or to the special tool engineer depends upon the relative time necessary to get the machines or special tools. It is well to remember that when an operation sheet has once been made out by the tool engineers, several draftsmen can work simultaneously on the various tool designs and the making of tools can be distributed among different shops, so that a great deal can be accomplished in three months. On the other hand, if there is a shortage of equipment, and deliv-

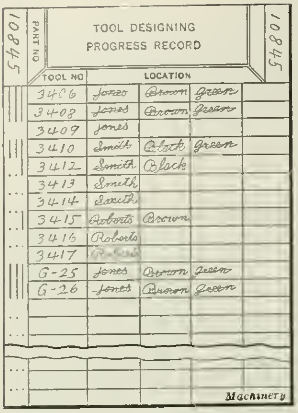

Fig. 4. Tool Designing Progress Record

eries of new machines will take six months or more, it will be more important to find out exactly what additional equipment must be purchased so that it can be ordered in ample time.

The dispatcher must have a complete list of the parts for which tools are to be made, and this list must be kept up to date. This is taken care of by routing all engineering release notices of parts over the desk of the dispatcher, the latter marking the release date on the form shown in Fig. 2, which will be discussed later. Occasionally parts are provisionally released, in order to make preliminary studies of tooling. These notices follow the same route as regular release cards, but they are specially marked. In order that the dispatcher and tool engineers may have ready access to the drawings of parts, it is advisable to keep an open file of all part prints for the use of the chief tool engineer's staff.

It is assumed that there are at least fifty jobs being handled in the tool design department at a time. The best way of following up these jobs is to list them on visible index cards somewhat similar to the one illustrated in Fig. 2. These cards are used for keeping track of jobs while the operation sheets are being worked out. As the jobs are assigned to the various engineers, the cards are marked accordingly. It is thus possible to tell at a glance how the engineering stands. When making out the card, the dispatcher should look into the probabilities of the part, and estimate roughly how much and what class of tooling work there will be. He must keep in mind the two main factors—getting work out on time, and keeping everybody supplied with work—and dispatch accordingly.

Dispatching Work through the Designing Section

If a plant is doing contract work, to get effective results, it should have a manufacturing schedule, and this schedule, if made in detail, should specify the date of each operation on a part, and thus automatically determine the priority sequence of tool orders. The dispatcher must then make every effort to have tools out on time to enable the manufacturing department to keep up with the schedule. However, in the majority of cases, it is a question of either supplying tools to permit the quantity production of a new article or to change existing manufacturing methods, and in such instances the priority question becomes more difficult to solve. The usual procedure is for the production manager to decide which tools he wants first; unfortunately this method is often unsatisfactory, primarily because no comparison of various requirements is made, the requests being usually based on the vociferousness of the different foremen's claims, or on what the production manager happens to see.

One method having good features is to insist on an estimate of savings to be accomplished by the use of any new tools ordered, as against present tools or no special tools, in the case of new production. Where a tool in new production is absolutely necessary on account of interchangeability, it may be marked "must" on the request. It will then be evident to the dispatcher that a tool which will save $3 a day is more important than one which will save only $1. Tools marked "must" will, of course, have the preference, as they are absolutely necessary. If, in addition, an estimate is marked on the order of the amount of time required for the designing and making of the tool, the dispatcher will have a chance to dispatch work so that the tools will be finished about in the correct sequence.

In Fig. 4 is shown a visible index card for recording the progress of tool designing. All tools for each part are listed by number on this card as soon as the order is issued. As the work is given out, the name of the man or company receiving it is noted under "Location." When the design is approved, the first vertical line to the left of the tool number is drawn; when the detail drawings are completed, the second line is filled in, and when the drawings are all checked and sent to he blueprinted, the third and last line is filled in. A horizontal line is drawn under the vertical lines when all the tools required for the part have been listed. This line is necessary, because the individual tool numbers are not visible without withdrawing the card from the index. The file thus shows graphically, at a glance, how the work stands on any part. This card is filed in a horizontal position, rather than in the vertical position shown in the illustration.

Duties of the Tool Engineers and Operation Sheet Checker

Machine Tool Engineer—The function of the machine tool engineer is to determine on which machine any given job shall be done. In doing this he must consider the following factors: The most suitable machine; other demands for the same machine; the available equipment; the capacity of the available equipment; and the advisability of using the equipment over-time or purchasing additional equipment to suit. A card should be kept for each machine, showing the size and location of the machine and having space for listing all work assigned to the machine and the estimated time required for each operation. While an elaborate card may be out of place, at least a plain 3- by 5-inch card should be used. If the manufacture of one general product only, is being planned, a cumulative total of the time the machine will be in use, can be carried, either per operation, as shown in Fig. 3, or, if a definite schedule is decided on, for the total average daily production. If a varied class of products is made, the problem will be complicated by the fact that the schedule on one or all of the products may be changed independently of others. If there are not too many products, a solution may be found by using a larger card such as illustrated in Fig. 5, carrying a separate column for each product and adding the time per unit of each product separately. Pencil figures may be used for a compilation of the total machine load according to the individual schedules in force. In this manner, any overload on a given piece of equipment will be quickly revealed. In such cases the machine tool engineer should consult with the chief tool engineer to find out whether the overload can be avoided. If not, steps can be immediately taken to run the equipment over-time, purchase new equipment, or have some of the work done at an outside plant.

Fig. 6. Sheet showing the Complete Sequence of Operations on a Part

This feature of protecting the manufacturing schedule from unintentional overloading of the equipment will often pay many times over for the work spent on compilation. Cases have been known where a delivery promised in two months could not have been completed in a year with standing equipment; the management of any concern will naturally appreciate prompt information about such conditions while there is a chance to remedy them and make the promised delivery. In planning the duties of the machine tool engineer, the production planning department should be consulted. It may be found that the latter requires and keeps records which will fulfill the needs of the tool designing section either without change or with slight amplification. If such is the case, arrangements can be made for the cooperation of the tool engineers and the planning department, and this function of the machine tool engineer can be eliminated.

Special Tool Engineer—The function of the special tool engineer is to work out the details of each machining operation. He receives from the drafting-room dispatcher the operation sheet shown in Fig. 6, on which is given the operation lay-out already decided upon by the chief tool engineer. From this sheet and the part drawing, the special tool engineer decides what machine will be best suited to each operation and what sort of jigs and fixtures will give the most economical results. When commercial tools can be used he should specify them. He should make rough sketches of the fixtures desired, and when the lay-out is clearly in mind, he should consult with the foremen of all the departments concerned and get their viewpoints, which should be valuable.

The man in the shop responsible for actual results should always have a chance to express himself before the means by which he is to get the results, are decided upon. To shut oneself up in an office and design something for shop use, whether a tool, a machine or just a form, and then thrust it on the shop without introduction, is the best way to make shop men suspicious of office conceptions and eager to condemn them. Once a tool lay-out is settled upon, detail operation sheets of the sort illustrated in Fig. 7, are made out and orders issued for each tool required. It will happen occasionally, of course, that the tool designers will find modifications necessary, and so final distribution of operation sheets should be withheld until all designs are approved.

Gage Engineer—The gage engineer has the same function on inspection operations as the special tool engineer on machining operations. His method of procedure is therefore very similar, except that he consults with the inspection department instead of with the manufacturing foremen.

Commercial Tool Engineer—The function of the commercial tool engineer is to issue all orders for small commercial tools required. The detail operation sheet in Fig. 7 provides the basis for these orders. Occasionally substitutions will have to be made on account of deliveries or stock-room standards, and for this reason the commercial tool engineer should be familiar with the general run of tools used. In this connection, it is well to arrange for chucks to be assigned to certain machines and considered as part of those machines, rather than to consider them as commercial tools listed on operation sheets. The writer has still a vivid recollection of helping to straighten out a badly tangled situation caused by considering chucks as commercial tools and not paying any further attention to the subject on the operation sheets. The result was that when the commercial tool engineer began to order chucks, there were duplications on some machines and shortages on others. The loss in time of men working to clear the situation amounted alone to several hundred dollars, not to mention delayed production. By arranging for equipping certain machines with chucks, listing these, and assigning parts requiring chucks to the proper machines, not only will confusion be avoided, but also the investment in tools will be reduced to the minimum.

Change Engineer—Changes in tools may be required because their design has been found faulty or requires modification, or because the part may be changed, so that the tools need to be adapted. Where the design is faulty, the trouble should be brought to the attention of the change engineer by the production foreman. These men should go over the matter carefully and decide on remedial measures to be taken. The change engineer should then issue an order to the chief draftsman, stating in some detail just what changes are to be made. In the majority of cases, the order can be so issued that the draftsman can make the changes on the drawing without necessitating a trip into the shop. On the other hand, if a vague order is issued, the draftsman usually goes over all the ground again, wasting his own time and that of the men in the shop who resent having to explain things over again.

When a part is to be changed, if the engineering department is functioning properly, the change engineer receives a notice of the change, which also states whether the part as redesigned can be used to replace any old parts that may be out

in service. If so, the tool may be changed without any complications ensuing; the engineer can get out the new blueprint of the part and issue any necessary order for changing the tool. If, however, old parts are out in service and the new part cannot be used for replacements, care must be taken to change the tool in such a way that replacement parts can still be manufactured, and if that is impossible, a new tool must be made.

Operation Sheet Checker—The usual procedure of making out operation sheets is to first develop a rough lay-out of operations; from this the special tool engineer makes rough copies of the detail operation sheets on which he bases his special tool orders and from which the commercial tool engineer issues orders for small tools. Changes will frequently be made on these sheets as the work progresses, and this fact makes it desirable that the entire batch of sheets on each part be checked as soon as all orders are issued. Carbon paper backing should be used in typing the operation lay-out and detail operation sheets so that good blueprints can be made from the originals. The checker should then take the complete set of sheets on the part and check (1) the technical correctness of operation sequence, that is, see that the part can be made as planned; (2) the provision of all necessary tools and operation sheets; and (3) order files to see that all orders have actually been issued. When the sheets have been found correct, necessary blueprints can be made and distributed to those requiring them.

General Notes on Tool Engineering Section

The fewer men that can be used to cover the activities of the tool engineering section, the better will be the results, as references to other men will be less needed. In a small organization one good man should be able to attend to all tool orders—special, commercial, gages and changes. Distribution of other activities will depend upon the qualification of the men available. Only in large organizations should there be more than one man on each sub-activity shown on the chart in Fig. 1.

Duties of Men in the Tool Designing Section

Chief Draftsman—Under the plan of organization here mapped out, the chief draftsman has little to do with the details of designing; the main outline of a tool required is decided by the special tool engineer and the shop foreman who is to use it, and the details are worked out by the designer with the advice of the design foreman. The function of the chief draftsman is mainly a disciplinary one; certain rules of conduct must be enforced, and established standards of office practice maintained. For the chief draftsman to develop both efficiency and harmony in a large office will entail his possessing considerable tact, firmness, and ability to judge the competency of his men and guide and direct them. Needless to say he should have practical experience and be a good tool draftsman himself so that he will be able to judge both the quality and quantity of work turned out by the individual men.

The chief draftsman may either have the drafting-room dispatcher distribute work to the foremen or have the dispatcher mark the tool orders with priority numbers and distribute them himself according to priority. Where a great many designs are being worked on at a time it is necessary to keep a check on the whereabouts of each one. The card shown in Fig. 8 can be used for this purpose, the name of the man working on the drawing being entered each time the drawing is given out, and the cards filed numerically. In order that the chief draftsman may know what each man accomplishes, he may either make the rounds every day to each board, having the foremen accompany him, or he may have the completed drawings passed over his desk. In either case it is highly desirable that some method be developed to rate the value of each man. While this presents considerable difficulties, it can be done provided common sense is applied in the use of the ratings. The features to be considered are correctness, legibility, and improvements suggested; amount of work produced; habits and character; and general value to the company through knowledge of the business and possibility of developing to hold a responsible position.

Records could be kept separately of each item, and with a proportion of relative values of each, a composite figure built up which would give a fair rating for each man. However, the general experience in efficiency work is that if a quantity measurement of work performed is made and quality inspection rigidly enforced, the quantity measurement alone will suffice; this is because the quality defects produced on unchecked work are usually due to lack of attention, and as soon as an incentive to concentration is offered, quality improves as well as quantity. Owing to the unstandardizable nature of drafting work, accurate estimates are impossible, and it would therefore be incorrect to use these ratings as bases for any of the bonus methods used on regular production. On the other hand, if cumulative totals are kept of actual time worked and total estimated time plus allowances for improvements and changes accepted, these figures over a certain period of time should serve as an excellent guide in making wage rate adjustments. However, no allowances should be made for time consumed in correcting errors of the draftsmen. Unless the company has a special department of standards, the chief draftsman should make up standard practice instructions for designers and checkers and keep these up to date. He should also see that all machine data are accessible.

Fig. 9. Form on which a Record is kept of Tool Drawings sent to the Blueprint Room

Time Clerk—If a record is required of the cost of each tool, it will be necessary for the men to turn in tickets showing the time they worked on each tool. In this case a time clerk should be provided to check up the time tickets. It should be remembered, however, that the tool cost is influenced by so many casual factors that any attempt at extreme accuracy of cost finding is out of place; time to the nearest half-hour should be close enough for work of this kind. The men should be instructed accordingly so that they do not spend too much time in making out the tickets. Anyone using the cost records should understand that only approximate tool costs are given. The time clerk should keep on file a card for each man on the department payroll, record of the working time of the man being kept on the card. The time clerk will probably have ample time to prepare reports required by the chief clerk and fill out drawing records for the chief draftsman.

Designers, Detailers, and Checkers, and their Foremen—While there is no question but that the checkers should be separate from the draftsmen and under the supervision of a checker foreman, there are cases where it is advisable to have the detailers under the same direct supervision as the designers. However, if the force is a relatively large one, it will be preferable to have a separate detail foreman in charge of the men doing detail work. This will enable the flow of the work to be more evenly distributed. The detail foreman should be chosen for his ability to instruct and develop men rather than for having wide experience, while the design foremen should be widely experienced men with the ability to foresee difficulties and give designers good technical assistance.

Drafting-room Supply Clerk—The function of the drafting-room supply clerk is to provide draftsmen with all materials, drawings, blueprints, and auxiliary data, and keep records of those to whom such things are given. After long experience in attempting to keep up a large number of standard books, the writer has come to the conclusion that the best way to handle standard sheets is to keep several copies of each sheet, preferably mounted on pasteboard or at least printed on linen, in the supply room in a special file. The index to this file should be posted in an accessible place. Then any man requiring a data sheet can look up the number, draw it out against a receipt, and when through with it, return it to the file. A selection of sheets commonly required may be made and firmly bound together (not in a loose-leaf binder), and every man supplied and charged with a numbered copy. Unless every man is given a copy, it will be difficult to hold anyone responsible for one lost.

Blueprinters and Drawing File Clerk—Orders for the making of blueprints can be made on simple requisition blanks put up in pads. As each drawing is checked, the chief checker should fill out one of these requisitions as authority to print the necessary amount of blueprints, and no tool prints should be made without this authority. Any other blueprints required should be authorized by the chief draftsman; this will serve as a check on indiscriminate printing. As each set of drawings comes to the blueprint room a card, such as shown in Fig. 9 should be made out by the drawing file clerk and filed. This card should be generally accessible; it will prove a time-saver to have the assembly sheet number marked on the card. Standard filing cabinets should be installed to fit the drawing sizes used, and each sheet filed in a drawer of its own size. Drawing sizes and filing methods were discussed in an article entitled "Standard Blanks for Tool Drawings," which appeared on page 786 in April, 1921, MACHINERY.

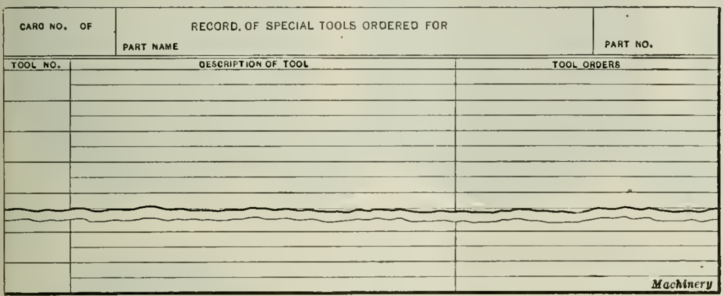

Fig. 10. Record of Special Tools ordered to facilitate the machining of a Part

Work of the Chief Clerk and Tool Work Dispatcher

Chief Clerk—The function of the chief clerk is to see that all clerical work is done promptly and correctly, that record files are properly maintained, and that necessary reports are brought to the attention of the tool superintendent. Copies of all orders issued should be on file and separate sections maintained for incomplete design orders, complete design orders, incomplete shop orders, and complete shop orders. This file is the control point for issuing shop orders, and any special handling desired for the orders can be attended to by placing "ticklers" in this file. It is also necessary to provide a record of all tool orders issued on each part. The card shown in Fig. 10 was designed for this purpose. It will be noticed that provision is made for a full description of the tool, and under "Tool Orders" the symbol and number of tools ordered are to be recorded. The symbol is the designation added to the tool number for indicating what kind of order was issued. Thus on tool No. 582-J-2, if a second repeat order was issued, making the third request for this tool, the order number would read 582-J-2-3.

Regular correspondence files should be kept, and if letters are handed out to men in the drafting-room, receipts should be exacted for them, and these placed in the regular folders until the letters are returned. It is desirable that progress reports be rendered to the tool superintendent by the chief clerk, covering the conditions of the drafting-room and tool-room and the progress of the whole job. The report should show the estimated amount of work in hours and number of designs immediately ahead of the designers, detailers, and checkers, the number of men engaged on each of these activities, the number of men on staff activities, that is, tool engineers, and the number of absentees. The report should also show the total number of tools being manufactured by the tool-room and outside tool concerns, the number of men in the tool-room and the estimated hours of work ahead of them. Since it is assumed that a schedule has been made, it is important to follow up closely the total progress, and it is equally important to check up the accuracy of the estimates. Hence, the chief clerk should furnish a daily report of tools made and corrections of estimates.

Tool Work Dispatcher—The function of the tool work dispatcher is to distribute the orders for tools, after the design is completed, in such a manner as to permit the desired deliveries with the utmost possible economy. Since it is usually the duty of this man to approve bills and pass on estimates, it is evident that the main qualifications for the position are an intimate acquaintance with toolmaking practices, a knowledge of reasonable time charges, and reliability. Since the tool work dispatcher must keep posted on what work the different shops can do, he should have a file showing the equipment of each shop; this will assist him to distribute work economically.

The follow-up file of the tool work dispatcher may consist of cards similar to the one shown in Fig. 4. These will enable him to keep track of the location of all tools on each part and the progress made on each tool. The first vertical line may indicate that castings or forgings are finished, the second, that all parts are finished, and the third, that the tool is completed and has been checked. If the company's tool-room has sufficient capacity to make all, or nearly all the required tools, the duties of the tool work dispatcher should be delegated to the tool-room foreman, who can have a production clerk attend to the follow-up of tools and see that orders are given preference according to the priority numbers marked by the drafting-room dispatcher.

Hand- and Machine-Lapped Surfaces as Seen Through a Microscope

THE manufacture of precision gages, such as gage-blocks and plug gages, requires, first, some method of producing gaging surfaces that are true enough to meet practical requirements, and second, some precise method of checking the gage dimensions. If a gage has a flat surface, the truth of this surface is in proportion to the "effective area" or the amount of "high land" which lies in the same plane. A cylindrical gage is true in proportion to the area coinciding with a true cylindrical surface of given diameter. The term "effective area," therefore, refers to the area of that part of the surface which would make contact with a perfect plane in the case of a flat gage, and with a perfect cylinder when the gage is cylindrical. It is important to note that the finished surface, whether flat or cylindrical, may be highly polished and appear true to the naked eye, when in reality it has a relatively small effective area. Such a surface, if highly magnified, is shown to be a mass of ridges and grooves, which may have considerable polish and yet not form a true surface.

It is evident that a surface having a large percentage of effective area is not only better for precision gaging purposes, but that it also offers much greater resistance to wear, because there is a larger area of contact surface, and for a given amount of metal removed there is less reduction in diameter. In precision gages or the finest grades of work in machine manufacture, the variations between good surfaces and poor ones depend upon differences which are extremely small and yet very important, and in order to carefully study these differences a microscope is employed.

Several interesting examples of photomicrographs made by the Pratt & Whitney Co., Hartford, Conn., in connection with a study of the characteristics of different surfaces, as obtained by various methods, are shown by the accompanying illustrations. Each of these photomicrographs represents a small part of a cylindrical surface, and the different views are so arranged on the page that the imaginary axis of the cylinder is in a horizontal position in each instance. The original views were magnified 280 times, but these halftone reproductions have been reduced so that they show a magnification of about 220. All these views are to the same scale and they have been supplemented by cross-sectional diagrams, Fig. 6, which illustrate the relative depths and numbers of the grooves. These diagrams are conventional representations of an average count of scratches over considerable area of the various blocks. In all photomicrographs of lapped surfaces, the preliminary grinding marks have been removed by lapping. The scratches are due entirely to the lapping abrasive.

Fig. 1. Exceptionally Good Ground Surface

Fig. 2. Hand-lapped Plug Gage

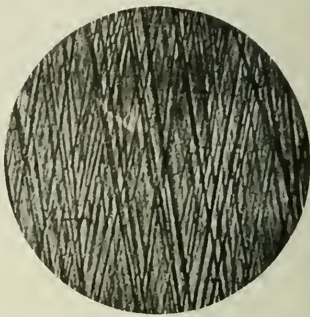

Fig. 3. Better Example of Hand-lapping

These photomicrographs show examples of ground, hand-lapped, and machine-lapped cylindrical surfaces magnified about 220 times. Each engraving is located with the axis of the cylindrical surface illustrated, in a horizontal position. Figs. 4 and 5 illustrate what has been accomplished in producing exceedingly accurate cylindrical surfaces by a mechanical lapping process which is a modification of that used for flat surfaces.

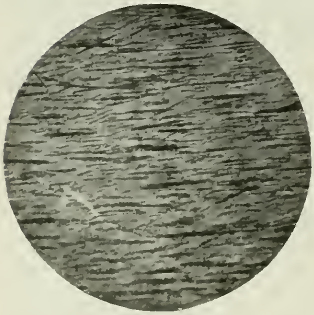

Fig. 4. Machine-lapped Plug Gage

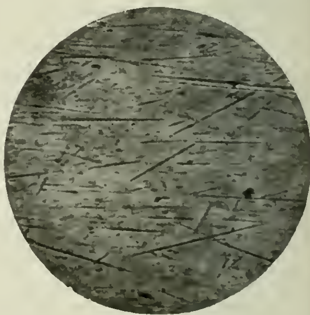

Fig. 5. Exceptionally Fine Machine-lapping

Results Obtained by Hand-lapping

Fig. 1 shows the surface of a commercial plug gage which has been ground but not lapped. This is an example of an exceptionally good ground surface. Fig. 2 shows the surface of a hand-lapped commercial plug gage, but this does not represent good lapping practice. Another example of hand-lapping is shown in Fig. 3. This is a Pratt & Whitney master plug gage. A comparison of this hand-lapped surface with the one illustrated in Fig. 2 shows that the former is much more uniform, and has a much larger effective or highland area.

Results Obtained by Machine-lapping

Figs. 4 and 5 illustrate what can be accomplished by machine-lapping, assuming that it is done in the right way. A first-class finish for a precision plug gage is represented by Fig. 4. While its surface has been machine-lapped, no attempt has been made to give it the extreme degree of finish or polish represented by Fig. 5. Both of these surfaces, however, are practically the same, so far as wearing qualities and usefulness are concerned, but to produce a finish like that shown in Fig. 5 requires probably eight times as long as to secure the surface shown in Fig. 4. For this reason, one is regarded as a commercial finish for precision gage work, whereas the other is more in the nature of a "stunt." It should be remembered that the commercial finish represented by Fig. 4 is a very fine and highly polished surface, and that it is only by extreme magnification that the minute scratches on the surface are revealed.

It will be noted that the scratches seen in Figs. 4 and 5 are short, and either parallel with the axis of the plug or slightly inclined. On the contrary, scratches on the hand-lapped gages extend diagonally around the work, due to the use of a ring lap which is given a traversing movement. The finer surfaces on the machine-lapped plugs are obtained by performing a lapping operation between two flat cast-iron plates having very true surfaces and operating in such a way that the plugs receive a combination of rolling and sliding action. These lapping machines are similar in principle to the ones used for lapping the flat surfaces of precision gage-blocks, which were described in April, 1920, MACHINERY, beginning on page 702 of the article entitled "How Precision Gage-blocks are Made." However, the lapping of true cylinders between flat plates requires an interesting modification of the process utilized for flat surfaces. The "Trilock" reversible plug gages made by the Pratt & Whitney Co., are finished by this modified process, which has also been applied to other commercial products, such, for example, as automobile piston wrist-pins.

In developing this process, the original aim was to produce a cheaper quality of working plug gage by eliminating the expensive hand-lapping operation. It was soon found possible to produce much more accurate results than by hand-lapping and at a fraction of the cost, assuming that the machine-lapped process is applied to the production of duplicate pieces on a quantity basis. This mechanically derived lapping action is not merely one of polishing, but as the photomicrographs indicate, it generates a surface that is practically perfect. A number of these cylindrical gages or other parts are lapped simultaneously, and by systematically and repeatedly transposing them and averaging the errors, the entire lot is finished to a true cylindrical form to within, say, 0.00001 inch or less. Some essential features of this process are covered by patent applications now pending, so that this ingenious method of machine-lapping cylindrical parts cannot be fully described at the present time.

RELATION BETWEEN OUTPUT AND COSTS

By JOHN D. RIGGS

At this time when everybody is making an effort to reduce manufacturing costs it is important to understand fully the relation between rate of production and final cost. When the rate of production on a certain article is increased, it is frequently assumed that there has been a corresponding decrease in the cost. A careful analysis of the elements of cost would often show, however, that there are large factors that are independent of the time consumed; for example, the material used is sometimes a large factor in the cost.

Not all innovations are improvements in regard to cost reduction. As an example, imagine the results if the machines in a mill for making wire nails were run at double the ordinary speed without making any other changes in these machines. Production might be doubled forthwith, but the number of machines which an operator could handle would be cut in half. Furthermore, the maintenance cost would probably be quadrupled, and the useful life of the machines might be reduced to about one-fourth. As a result, the cost of nails per keg would certainly not be materially reduced.

Another example is the case of a plow works which, after having grown from a small beginning to a plant employing over 3000 men, decided to rearrange its share department. The making of a plowshare involves about seven operations, apart from the final polishing and painting. These operations were all performed at a satisfactory rate, except the fifth one. A diagonal and beveled end had been trimmed on a grinder after several attempts at shearing it had failed. The superintendent finally ordered a machine for trimming these ends, and in due time a shearing machine, arranged with an automatic hold-down and adjustable stops, so as to accommodate about twenty-five of the thirty-seven varieties was produced and installed. This shear did in about two seconds what had taken one minute on the grinding machine; it was also a cheaper machine. The superintendent was delighted, but the owner and manager did not enthuse. To him a reduction of one cent in the cost of a plowshare which sells at retail for about $4, was not of the greatest importance.

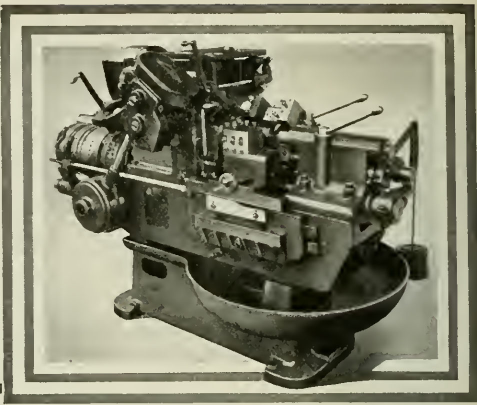
Of the two men looking at the same device one saw an increase in production of from twenty to thirty times the past records, while the other saw a reduction of about ½ of 1 per cent in the production cost of the article, or ¼ of 1 per cent of its retail selling price, coupled with the cost of a new machine.

* * *

The Patent Office relief bill, which has been before Congress almost continuously for the last three years, has been passed by both the House and the Senate. The bill provides for increasing the salaries of the principal examiners from $2700 to $3900 a year, and the pay of the assistant examiners has been raised by $150 to $900 a year. The Commissioner's salary has been increased from $5000 to $6000 a year.

Tooling Equipment for Automobile Hubs and Pistons

By RALPH E. FLANDERS,
Manager, Jones & Lamson Machine Co., Springfield, Vt.



THE front wheel hubs of automobiles are usually malleable castings and can be machined rapidly and accurately without severe cutting strains resulting, if they are properly annealed. The set-up of a double-spindle production lathe for machining the ball-race seats of front hubs is illustrated in Fig. 1. The work is first held in an air-operated chuck in the rear spindle and the inside of the large end is bored, the outside rough-turned, and the end faced and chamfered. The cross-slide is then shifted to bring the sizing reamer and finish-turning tool into position.

After the part is machined by these tools, it is changed to the front spindle and the end just finished is drawn against a hardened adapter by means of an air-operated draw-bar having a T-head that engages ribs cast in the interior of the hub for this purpose. This example illustrates the service that the designer of parts to be machined can render the tool designer if they keep in touch with each other. Without these ribs the part would be difficult to hold. The operation on the small end of the hub is similar to that on the large end.

The usual procedure is to have the bolt holes in the flange drilled or punched next, and then to have the outer bearing races pressed into place. After these operations, the hub is sent to a Fay automatic lathe in which it is supported on taper plugs mounted on the main and tail spindles, as shown in Fig. 2. The tail-spindle is mounted on ball bearings and revolves with the work. With the hub thus accurately mounted on its bearing races, true running of the part when it is completed is assured.

To perform the roughing step in the shortest possible time, both the facing and the long turning cuts of this operation are divided between two tools, which are first fed at an angle relative to the work, as shown by the arrows in the illustration, until they have reached the desired depth. The work is driven by a dowel engaging a bolt hole in the flange. The finishing operation, the tooling equipment for which is shown in Fig. 3, is similar to the roughing operation. In this case, however, the cuts are not divided between two tools, and extra tools are provided for rounding corners and for necking. The output of one roughing or finishing machine and one operator is seventy-five hubs per hour, provided the castings are well annealed.

Operations on Rear Hub Forgings

A typical rear hub made from a steel forging is machined in a double-spindle flat turret lathe with the tooling equipment shown in Fig. 4. The tools are all fed end on, and their arrangement is self-explanatory. While this hub is only occasionally made of malleable iron, it should be possible in such cases to machine it on a double-spindle production lathe similar to that used for the front hub, provided the hole is first drilled in a heavy-duty drilling machine. Fig. 5 shows the manner in which the hub is rough-turned and rough-faced in a Fay automatic lathe, the work being mounted on a taper arbor and driven by a dowel engaging one of the bolt holes in the flange which is drilled prior to this operation. The turning and facing cuts are each divided between two tools, as in the case illustrated in Fig. 2. The finishing operation on the part is illustrated in Fig. 6. Tooling equipment for a hub of a similar type is illustrated in Fig. 11.

A stamped hub flange is machined in a Hartness automatic equipped with the tooling shown in Fig. 7. The operation is simple; the upper tool-holder carries a rough-boring tool which operates while the holder is being fed toward the work, and a finish-boring tool which operates while the holder is being withdrawn, both cuts being short. The facing cut is a long one, and is divided between two tools in the lower holder, one facing from the outside toward the center and the other facing from the center to the periphery. It would, of course, be possible to both rough- and finish-face the part in this operation if that should be necessary.

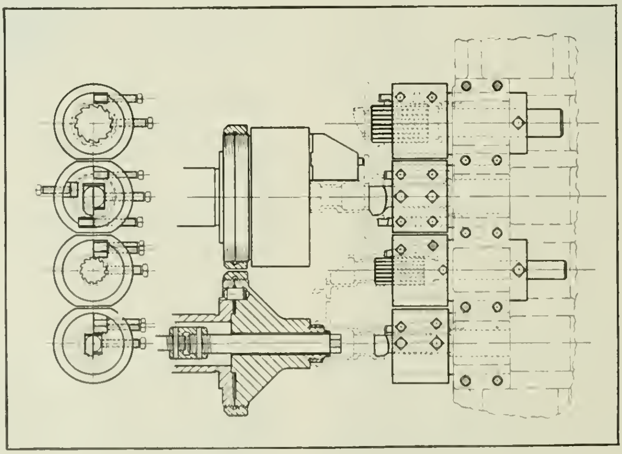


Fig. 1. Set-up of Double-spindle Production Lathe for machining the Ball-race Seats of Automobile Front Hubs

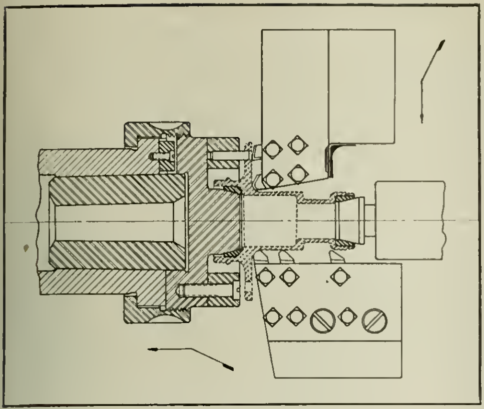

Fig. 2. Hub supported by the Ball Races for the Rough-facing and Rough-turning Steps

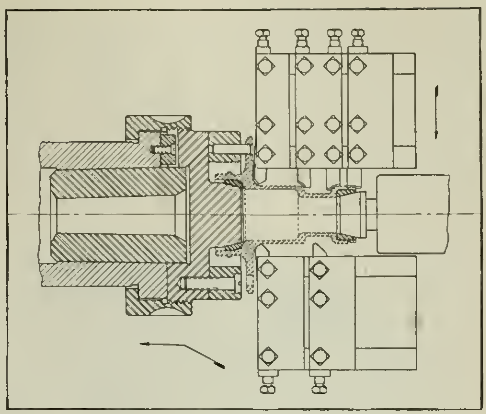

Fig. 3. Finishing Operation in which the Work is supported in the Same Manner as in Fig. 2

Finishing Aluminum Pistons

The machining of aluminum pistons made from die-cast blanks is simple and, owing to the fact that the pistons come from the permanent molds with walls of uniform thickness, no special precautions are required in chucking. In the first operation, which is performed in a Fay automatic lathe, the tool set-up shown in Fig. 8 is employed. The tools in the rear holder rough-bore and rough-face the skirt, while those in the front holder finish-bore, finish-face, and chamfer this end. Meanwhile, a high-speed center-drill driven through the spindle of the machine is advanced to center the boss on the closed end, which is gripped by the chuck jaws. Steps in the jaws locate the piston longitudinally. It should be observed that the skirt is projected far enough beyond the jaws to be free from clamping strain. Only a light pressure of the jaws is required to hold the work in place. This operation is performed so fast that one man can run only one machine, and the output is largely determined by the dexterity of the operator in loading and unloading the work.

The second operation is also performed in a Fay automatic lathe. The piston is held against an

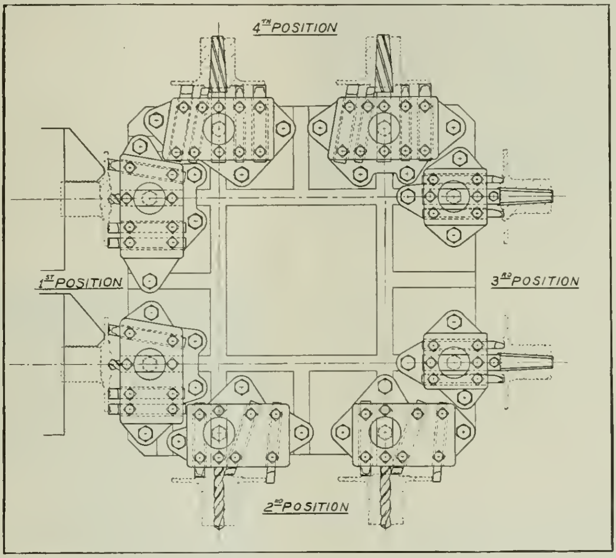

Fig. 4. Tooling Equipment used on a Double-spindle Flat Turret Lathe for machining an Automobile Rear Hub

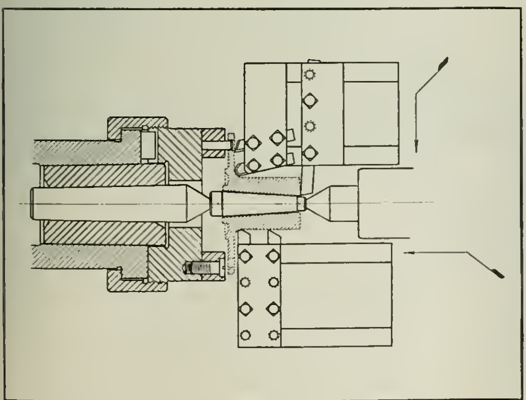

Fig. 5. Rough-turning and rough-facing the Rear Hub in a Fay Automatic Lathe while mounted on a Taper Arbor

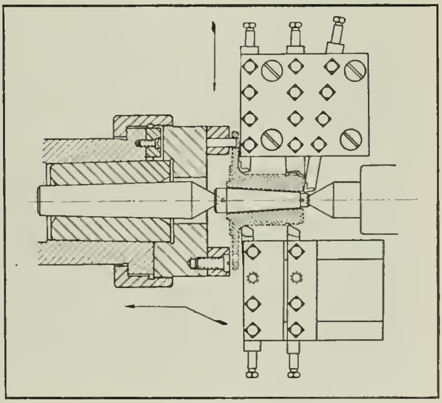

Fig. 6. Finishing Operation on the Rear Hub which is also performed in a Fay Automatic Lathe

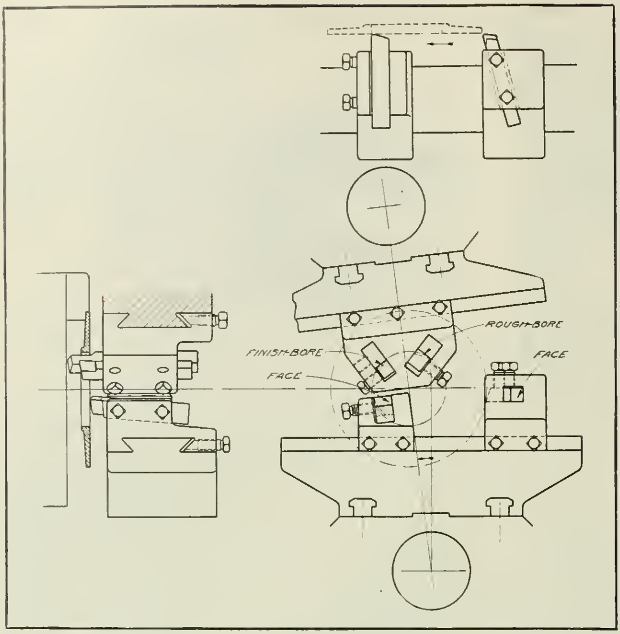

Fig. 7. Tooling Equipment for boring and facing a Stamped Hub Flange in a Hartness Automatic

adapter on the spindle by a ball-bearing tail-center, as shown in Fig. 9, and is driven by a floating fork that engages the wrist-pin bosses. The rear holder is fed radially so that the tools can face the closed end and rough out the grooves. Meanwhile the front holder goes through the somewhat complicated movement shown by the arrow. The turning tool first feeds to depth and then turns the length of the piston, after which the tool-holder feeds in radially once more to bring the tools into position to finish the grooves. The back arm, in the meantime, returns to its original position during which movement the facing tool takes a finishing cut over the closed end.

Only one cut is taken across the outside cylindrical surface, because this surface is ground later. By supporting the work with the tail-center shown, end play of the spindle is taken up and grooves are produced whose side surfaces are planes that match the ground sides of the rings. This obviates a finish-grooving operation in an engine lathe, such as is frequently necessary with first-class work. The machine provided with this tooling is shown in operation in Fig. 10. The operation is extremely rapid, the speed of the work being between 500 and 600 feet per minute, and the production per hour one hundred pistons. One man can run only one machine. The tools can be used several days without requiring resharpening.

Equipment for Machining Cast-iron Pistons

The machining of cast-iron pistons will be described somewhat in detail, as the sequence of operations is the result of a long study and the experience of many makers. This is an excellent example of the interdependence of various operations. The castings are first annealed; this makes them easier to machine, but the primary purpose is to retain the accuracy of the different surfaces after the scale has been removed. Pistons should be made with a good sized boss on the closed end so that a deep center can be provided for supporting the work on the various machines. High production is obtained by taking heavy cuts, and so a small center will not be satisfactory. In the first operation, the piston is placed on a mandrel and centered true with the rough core in an operation on a drilling machine. The inside of the piston head locates on the top of the mandrel, and a stop-collar is used on the machine spindle.

The second operation is performed in a Fay automatic lathe equipped with the tooling shown in Fig. 13. A revolving ball-bearing center holds the head of the piston against an internal mandrel, insuring an even thickness of wall at the head. The plugs of the mandrel are expanded by air pressure and center the piston true with the core at the open end. This arrangement, together with the true center, insures an even wall thickness throughout. A balanced driving member engages the wrist-pin bosses. The tools in the back holder rough-face the open and closed ends and rough-groove the work. Meanwhile the tools carried by the front carriage rough-turn the piston, a sufficient number of tools being provided to turn the entire length of the work in the short time required for facing the closed end. The latter step establishes the cutting time for the whole operation. The production rate of this machine on 3¾-inch diameter pistons is from forty-five to fifty per hour. By having an operator run two machines, from ninety to one hundred pistons can be turned out per hour.

Third and Fourth Operations on the Piston

The wrist-pin holes are rough-drilled in the third operation by using a fixture in which the work is located by the outside cylindrical surface and the finished end, and angularly by means of the internal bosses. This operation completes the removal of scale and the bulk of the material. A little time for seasoning should be allowed at this point.

The fourth operation consists of machining the skirt in another Fay automatic lathe with the tooling shown in Fig. 14. Since the outside cylindrical surface was turned true

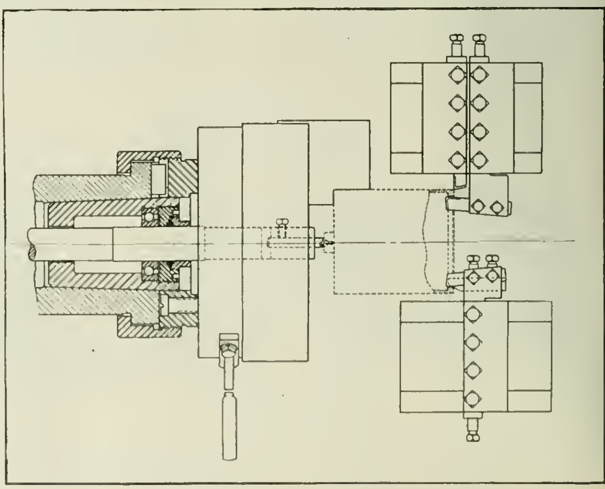

Fig. 8. Roughing and finishing Skirt of Aluminum Piston and centering Closed End

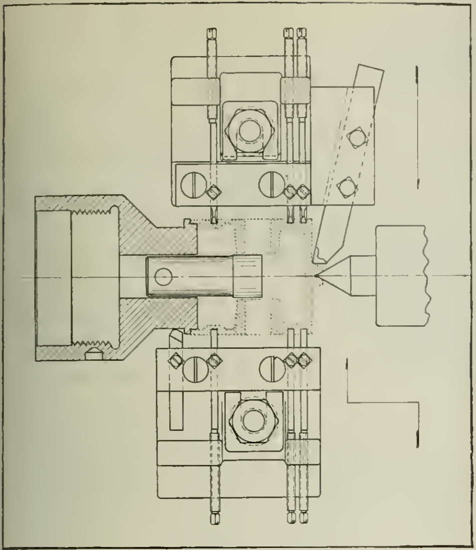

Fig. 9. Turning, facing, and grooving the Aluminum Piston

with the core in the second operation, this surface is utilized in holding the part for finishing the skirt. The piston should project far enough from the jaws to be free from distortion resulting from the gripping of the jaws. The tool in the rear holder rough-bores the work while the front tools finish-bore and chamfer it. The boring is kept within limits of plus or

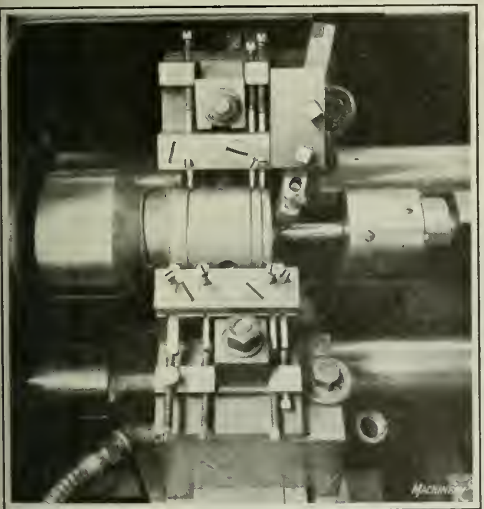

Fig. 10. Machine provided with the Tooling Equipment illustrated in Fig. 9

minus 0.001 inch so that the skirt will be a good fit on the fixtures used later in finish-turning, grinding, and other operations. The possible production in the fourth operation is from 150 to 180 parts per hour, depending upon the rapidity with which the operator can change the work. He can run only one machine at a time in this step.

Finishing Operations—Turning, Grooving, and Facing

In the fifth operation, the piston is finish-turned, finish-grooved, and finish-faced in a Fay automatic lathe provided with the equipment shown in Fig. 16. Here the open end is centered on a hardened seat of the spindle fixture, while the closed end is supported on a ball bearing center, the same as in the case illustrated in Fig. 13, and a balanced drive is used on the wrist-pin bosses. The construction of the center is shown in Fig. 16. A central air-operated plunger strips the work from the fixture when it fits too tightly, and a lever type of tailstock is used for pressing the work on the fixture. The tooling arrangement is nearly identical with that used in the second operation. The outside cylindrical

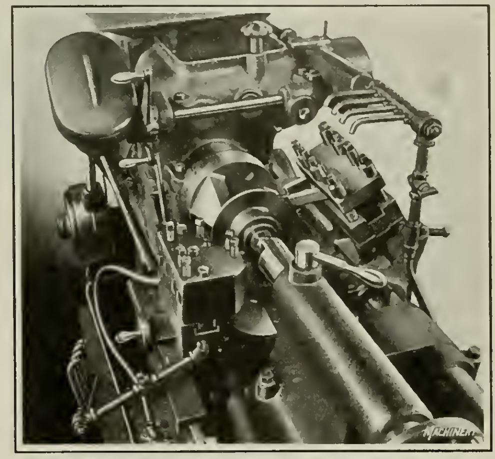

Fig. 11. Another Tooling Equipment for machining a Rear Hub in a Fay Automatic Lathe

surface of the piston is finish-turned for grinding, while the open and closed ends are finish-faced and the grooves finish-turned to the final dimensions.

An intermediate cut is taken on the grooves by tools in a supplementary holder provided beneath the work, as shown in Fig. 15. Thus, the finishing tools of the grooves have little to do and retain their size for a long time. This removes one of the chief annoyances of piston manufacture, which is the holding of the ring grooves to the small tolerance demanded. Advantage is also taken of the pressure of

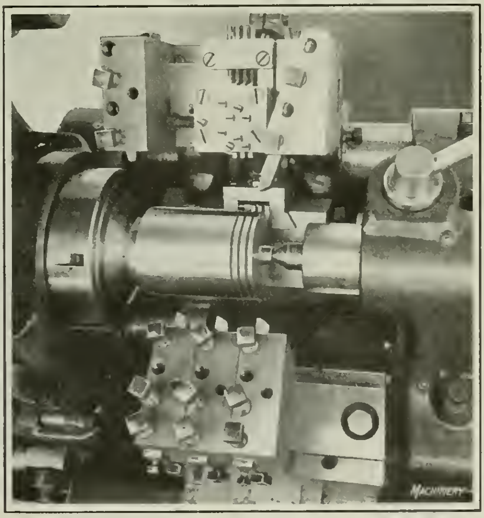

Fig. 12. Close-up View of a Machine engaged in finishing a Cast-iron Piston

the tail-center to eliminate end play of the spindle, and so the grooves in the piston are machined with true faces.

The machine used for this operation is shown in the heading illustration, and a close-up view of the tooling is shown in Fig. 12. The turning tools are automatically relieved on the return movement to prevent scoring the work. The production in roughing and finishing the piston is about the same—from forty-five to fifty pieces per hour, per machine, for a 3¾-inch diameter piston, or ninety to one hundred pistons per hour on two machines run by one operator. The speed used in finishing is higher than that used in roughing, but a finer feed is employed.

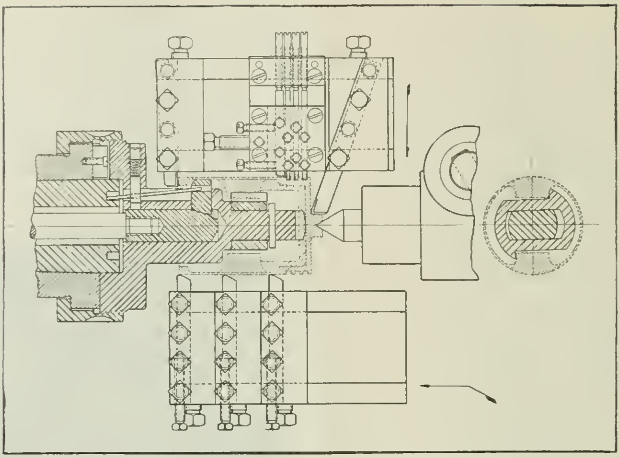

Fig. 13. Tooling used for taking Roughing Cuts on a Cast-iron Piston. Special Attention is called to the Means of supporting the Work

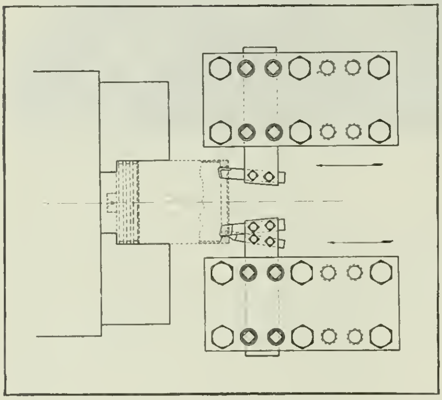

Fig. 14. Rough- and finish-boring and chamfering the Skirt of the Piston

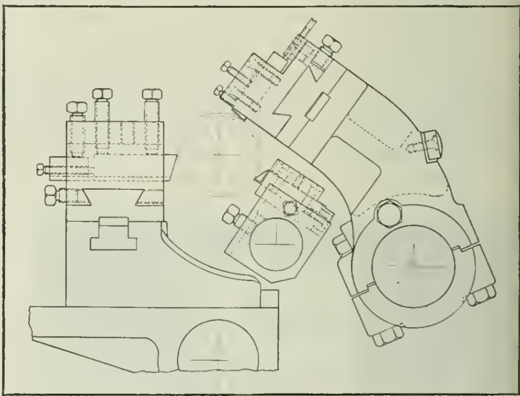

Fig. 15. Illustration showing the Intermediate Holder of the Tooling in Fig. 16

Final Operations on the Piston

The remaining operations on the cast-iron piston are as follows: In the sixth operation, the portions of the piston opposite the wrist-pin holes are relieved. In the seventh operation, the wrist-pin holes are finish-bored and reamed. In the eighth operation, the oil-holes, etc., are drilled. In the ninth operation, the chamfer of the skirt is ground to eliminate distortion (this operation is often omitted). In the tenth operation, the outside cylindrical surface of the piston is finish-ground, being located by the chamfer of the skirt, while the closed end is supported by a dead center. In the eleventh operation, the center boss on the closed end is removed on a hand milling machine. In the last operation, the closed end is disk-ground. Further refinements with a somewhat decreased production are required for the very thin-walled cast-iron pistons found in some engines of recent design.

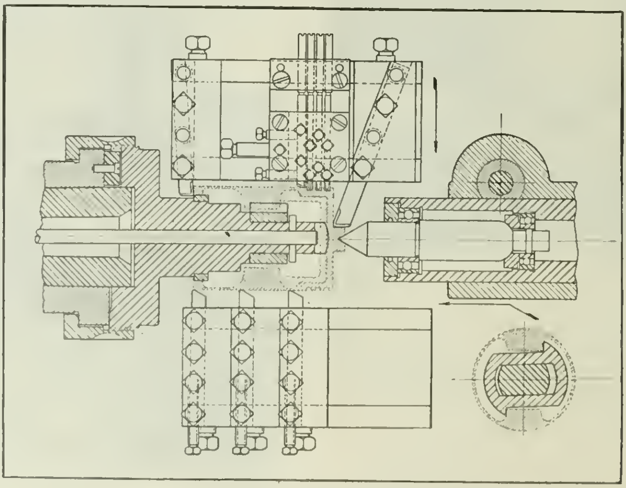

Fig. 16. Finish-turning, grooving and facing the Piston with Tooling Similar to that shown in Fig. 13

* * *

It is estimated, according to a statement that was published in a recent number of *Review of Industry*, that the world's production of iron and steel in 1921 aggregated 64,623,000 gross tons, as compared with 118,093,000 in 1920 and 98,464,000 in 1919.

Use of Machines Operating with a Planing or Shaping Action and Forming Gear Teeth by Generating and Formed-cutter Processes

Third Article of a Series on the Use of Different Types of Gear-cutting Machines for Cutting Various Classes of Gearing

THE gear-cutting machines referred to in previous articles in this series form spur gear teeth either by using a cutter which reproduces its shape, or by using a cutting tool that is guided by a templet or master former. Tooth curves produced by these two general types of machines are the result of what might be called a copying process. When cutting spur gears by using a generating type of machine, the gear teeth are formed as the result of certain relative motions between gear blauk and cutter, instead of simply reproducing the shape of a formed cutter or controlling templet. This particular article is confined to machines which operate with a planing or shaping action, and the first ones dealt with are generating types. A very common type of spur gear generator forms the teeth by milling with a revolving cutter or hob, and the next article of this series will deal with the use of machines of this kind.

Principle of Generating Process of Forming Gear Teeth

When a series of formed cutters is used for cutting spur gears, it is evident that the curvature of any cutter of a set can only be absolutely correct for a given number of teeth. Theoretically, there should be a different cutter for every number of teeth of a given pitch, but in practice this is not necessary. While the error in shape for other tooth numbers within a limited range may be negligible for ordinary requirements, nevertheless it was considered desirable in the development of gear-cutting processes to utilize a method, especially for certain classes of work, that gives the required curvature even though the number of teeth varies. This may be accomplished by a generating method, but the use of a generating type of machine does not always result in greater accuracy than the use of well-made formed cutters, since much depends in either case upon the condition of both machine and cutter and other factors of a mechanical nature. However, a generating process has the inherent advantage of being theoretically correct and of enabling a cutter of a given pitch to cut gears having different numbers of teeth to the correct shape, except for purely mechanical errors such as occur in varying degrees with any method.

In order to illustrate the principle of the generating process of gear-cutting, assume that a finished gear having teeth of correct form is revolved while in contact with a blank, which for purposes of illustration is assumed to be made of some soft, plastic material. The nature of this rolling action would be to generate teeth on the plastic blank. Thus, the teeth on the finished gear, as they roll into contact with the blank, form teeth having the curvature required for meshing properly with the generating teeth. This is a simple illustratiou of the principle of the generating process. Now, if this tooth forming or generating gear were hardened, and its teeth given suitable clearance, the cutter thus formed could be used to generate teeth in a cast-iron or steel blank, provided the cutter had a reciprocating action parallel to the axis of the blank, while both cutter and blank slowly revolved together, the same as two gears in mesh. This method of using a gear-shaped cutter is employed on a type of machine which will be dealt with later.

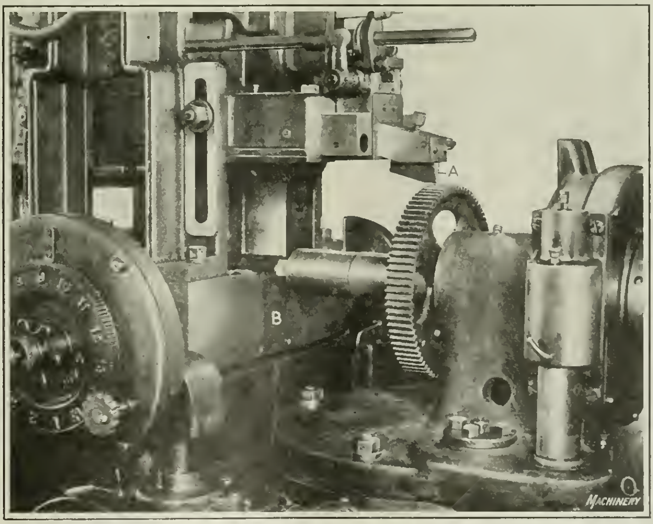

Fig. 1. Gear Planing Machine which generates the Teeth as the Tool, representing a Rack Tooth, feeds laterally

Another method of generating gear teeth is to give the gear blank a rolling movement relative to a rack-shaped cutter. It is possible to employ either a gear-shaped or a rack-shaped cutter for the following reason. A rack can be designed, for any system of interchangeable gearing, which will mesh correctly with a range of gear sizes of the same pitch. Moreover, all gears that will mesh properly with the rack will also mesh with one another. Generating processes of cutting gears are based on this interchangeable feature, which also accounts for the fact that one cutter may be used for cutting various sizes of gears of the same pitch. The cutter represents either a rack or a gear of the interchangeable series, and it cuts or generates teeth as the uncut gear blank and cutter are given movements, relative to each other, similar to a finished gear running in mesh either with a rack or with another gear, depending upon the type of cutter that is used.

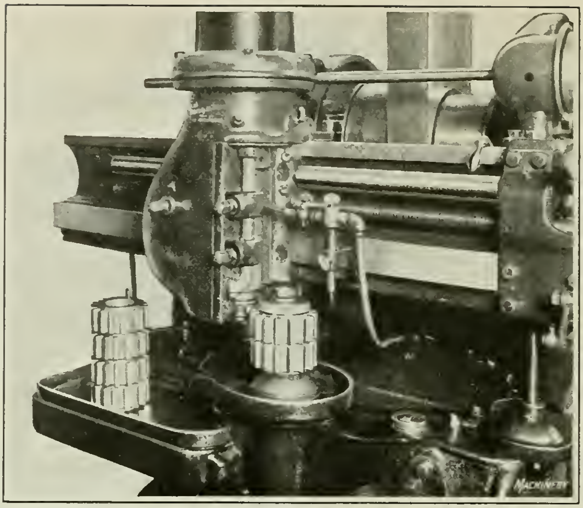

Fig. 2. Gear Shaper which generates the Teeth as the Reciprocating Cutter and Work slowly rotate like Two Gears in Mesh

Relation of the Rack to Gear-cutting Processes

Several types of gear-cutting machines that form gear teeth by generating methods use cutting tools which are shaped like the teeth of a rack, at least so far as the cutting edges are concerned. For instance, one type of spur gear shaper or planer uses a tool that is like a single rack tooth; another type of planer uses a tool having several teeth and resembling a short rack section; then there is the gear-hobbing machine that uses a rotating hob having rack-shaped teeth. The common types of machines for cutting bevel gears by a generating process use tools having cutting edges which represent the sides of crown gear teeth, the relation between a crown gear and a bevel gear being similar to that of a rack and a spur gear.

In order to understand different generating processes and why rack-shaped tools are often used, it is essential to know how the rack tooth form is derived and how it is related to the tooth curves of mating gears. The most important fact about a rack for the involute system of gearing which is now in general use, especially regarding its relation to gear-cutting processes, is that the sides of the teeth are straight. (In actual practice, the perfectly straight tooth form frequently is not used, as, for example, when it is altered somewhat to prevent interference with a pinion or when a rack is milled by using a cutter that is applicable either to racks or spur gears of large radius. This modification of the rack tooth form, however, need not be considered at present, since it pertains more particularly to rack cutting.) Another important fact about a rack tooth is that each side of a given tooth inclines from a plane perpendicular to the pitch line of the rack an amount equal to the pressure angle of the gearing (usually 14½ degrees, but often 20 degrees). Just why the sides of involute rack teeth are straight and why their inclination is the same as the pressure angle will be apparent when the development of tooth curves for involute gearing is understood. By studying the principles underlying these tooth curves, and particularly the relation between a rack and its mating gear, a clearer understanding of the generating processes of gear-cutting will be obtained.

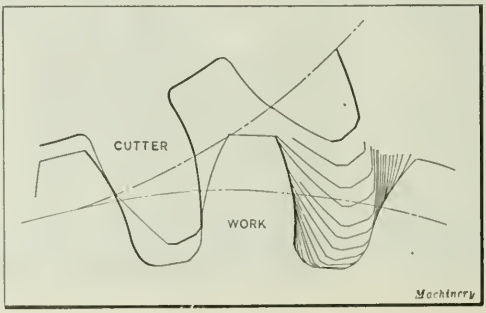

Fig. 3. Diagram illustrating Action of Gear Shaper shown in Fig. 2

The fact that an involute rack tooth is straight-sided is of considerable practical value, as applied to the making of cutters for different types of machines which form gear teeth by a generating method. It is evident that there is a decided advantage in having either a straight-sided tool or a straight side as a basis to work from. For example, if a gear-cutter is in the form either of a single rack tooth or of a short rack section, the work of making an accurate cutter is much simpler than it would be if the cutter teeth had to be given some special curvature. Similarly, if the cutter, instead of representing a rack tooth, is in the form of a gear (like the cutters used on Fellows gear shapers) the practical advantage of the straight-sided rack tooth is obtained, because the teeth of these cutters are ground to correct curvature by rolling the cutter in contact with the straight side of a grinding wheel. The grinding wheel, in this case, represents the rack tooth, and the curvature of the cutter is the result of a generating process.

Cutting Spur Gears on Machine of Generating Planer Type Using Single Rack-tooth Cutter

The first gear-cutting machine of the generating type to be considered is the Bilgram machine, which is shown in Fig. 1 cutting a spur gear. This machine is made by the Bilgram Machine Works, Philadelphia, Pa. The cutting tool *A* represents a single rack tooth, and it is attached to the end of a crank-driven slide which has a reciprocating motion like the ram of a shaper. It is evident that this tool, shaped like a rack tooth, would generate a tooth space of correct shape provided it were slowly traversed laterally between successive cutting strokes, assuming that the gear also received a rotary motion such as would be derived from a rack moving laterally at the same rate as the tool. However, if the machine operated in this manner, it would form only one tooth at a time, and it would be necessary to return the tool and repeat the lateral traversing movement for cutting each tooth space. This is avoided and all the teeth are formed while the tool is slowly traversed from one side of the blank to the other, by giving the gear blank an indexing movement after the completion of each cutting stroke.

Lateral Traversing and Indexing Movements

During each return stroke the tool is lifted automatically to clear the gear, by a suitable mechanism, and the gear blank is indexed; consequently, the tool passes through a succeeding tooth space each time it moves forward. Since the tool is slowly feeding in a lateral direction as though it were a rack in mesh with the gear being cut, the indexing movements exceed the circular pitch of the gear, just enough to com-

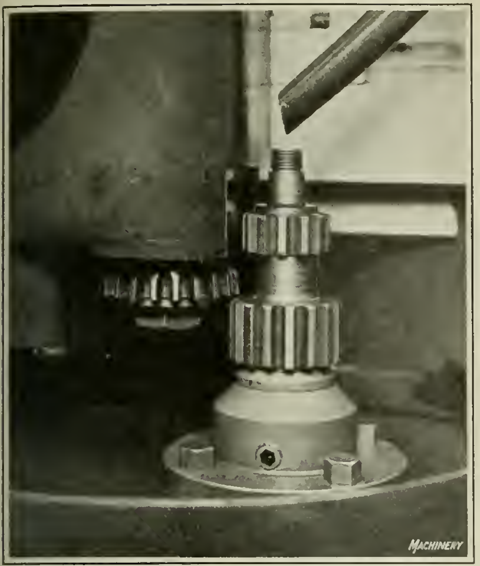

Fig. 4. Gear Shaper which is arranged for cutting on the Push or Downward Stroke of the Cutter

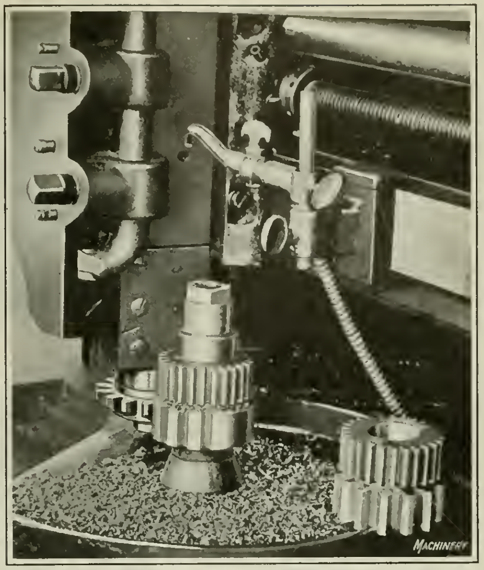

Fig. 5. A One-piece Double Gear cut by using the Pull Stroke for the Lower Section and the Push Stroke for the Upper Section

pensate for the lateral motion of the cutting tool. In other words, the gear blank is not only indexed relative to the pitch, but receives an additional rotary motion so that the tool and gear being cut act just as though a finished gear were rotating slowly in mesh with a rack, one tooth of which is represented by the tool. These rolling and traversing movements are controlled by change-gears selected according to the pitch. The lateral motion of the tool is obtained by the movement of slide *B* upon which the shaper mechanism is mounted. A cutter for a given diametral pitch is suitable for all numbers of teeth, which is true of any machine of the molding-generating type. Incidentally, the same machine can be used for cutting spiral gears, in which case the head carrying the work-spindle is adjusted about a vertical axis to conform to the helix angle of the gear to be cut.

Cutting Spur Gears on a Gear Shaper

When the teeth of spur gears are cut by a generating process on a machine which operates with a planing or shaping action, a gear shaper of the type shown in Fig. 2 is used in most shops. This gear shaper, made by the Fellows Gear Shaper Co., Springfield, Vt., is shown cutting two spur gears at the same time. The cutter has tooth outlines conforming to a gear of the same pitch as the ones being cut. This cutter is reciprocated vertically, and in starting to cut a gear it is first fed in to depth; then one gear tooth after another is formed as cutter and work slowly rotate together just as though two finished gears were in mesh. The action is illustrated by the diagram, Fig. 3. Successive positions of one cutter tooth are indicated by the succession of outlines. The feeding movement per stroke of the cutter will, however, be much less than the amounts shown by these outlines. As the tooth curves on this cutter are ground by a generating process after the cutter is hardened, very accurate gear teeth can be produced by this method.

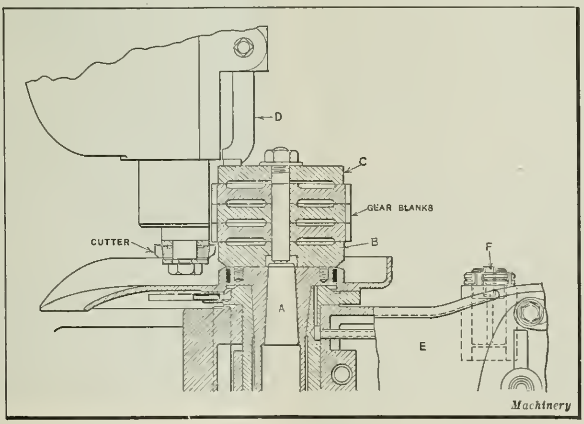

Fig. 6. Typical Method of holding Stack of Three Spur Gears

The gear teeth can be finished in one revolution of the gear blank, although a light finishing cut is often taken. In cutting transmission gears for automobiles, it is common practice to take a roughing cut followed by a light finishing cut. The machine may be arranged to take these two cuts automatically, but when gears are required on a large scale, it is generally considered preferable to use certain machines for roughing and others for finishing.

The rotation of the gear blank and cutter at the correct relative speeds is controlled by means of change-gears. When a machine has been properly adjusted for cutting gears of given pitch and number of teeth, all movements after starting the machine are controlled automatically. The gear blank is withdrawn from the cutter upon the return stroke to prevent dragging, the work-arbor being held by an apron actuated by a relieving mechanism. A cutter of given pitch may be used for any number of teeth of the same pitch, within the range of the machine, since this is a generating process.

Cutting during Upward or Downward Strokes

The cutter is ordinarily attached to the end of the ram with the cutting face upward or so as to cut on the pull or upward stroke. The machine in Fig. 2 is arranged so as to cut in this way. Sometimes there is not enough clearance to permit holding the cutter in

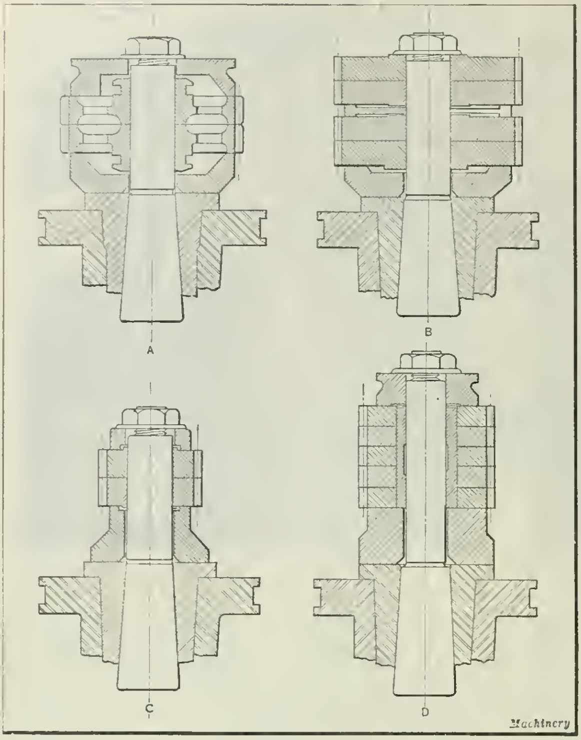

Fig. 7. Different Methods of locating and holding Spur Gears

this way, and then its position is reversed. For instance, this is done when cutting internal gears or whenever there is a shoulder or other part located close to the lower ends of the teeth. Fig. 4 shows a machine cutting a gear with the cutter reversed because of the small amount of clearance at the lower ends of the teeth.

The example shown in Fig. 5 illustrates how the gear shaper can be used to advantage when there is little clearance between two gears formed of one solid piece. In this particular instance, the manufacturing cost was greatly reduced by making the gear in this way. One side of this double gear is 10 diametral pitch, and the other side 5 diametral pitch. This double gear was intended for a cylinder boring machine, the object being to eliminate chatter. The teeth on one side are staggered relative to those on the other in order to split up the tooth action and secure smoother operation. The 10-pitch side of the gear was cut with the shaper operating on the push stroke, whereas the 5-pitch side was cut by means of the pull stroke. The illustration shows the machine cutting the lower side and operating with the pull stroke.

Methods of Holding Gears for Cutting

The simplest method of holding ordinary spur gears of the transmission type is shown in Fig. 2. The gears are mounted on a faceplate resting on the work-spindle, and they are located centrally by an arbor which also provides means for clamping. A similar arrangement is illustrated by the diagram Fig. 6, which shows a stack of three gears. The work-arbor *A* has a reverse taper, and is drawn up tight into the work-spindle when the nut at the top of the arbor is screwed down on the upper clamping plate. The gear blanks, together with the faceplate *B* and the upper plate *C*, are thus clamped rigidly against the end of the work-spindle.

Whenever practicable, the rigid work support *D* is used to take the direct thrust of the cut, assuming that the cutting is during the upward stroke. On apron *E*, which carries the work-spindle, there is a roller *F* for supporting a large faceplate, internal gears, or special fixtures for holding internal gears. Another roller held by a special bracket attached to the apron is used when it is necessary to locate the roller closer to the work-spindle, as when gears or fixtures of smaller diameters must be supported. The design of clamping plates or fixtures for holding either external or internal gearing is, of course, varied more or less to suit the shape and size of the work. A few examples illustrating different methods of holding and clamping will be described to show, in a general way, certain typical as well as more or less special applications.

Holding Gears Having Extended Hubs

Diagram *A*, Fig. 7, shows an approved method of holding sliding transmission gears having extended hubs. The two plates between which the gears are clamped are cupped out to provide clearance spaces for these extended hubs, and to permit the plates to bear directly against the gear rims. In this way, the gears are clamped just inside the root circle where support is needed, and as the lower plate rests directly on the flange of the work-spindle, the pair of gears is held rigidly.

Diagram *B* shows a method of holding gears having hubs which project slightly on one side only. In this instance four gears are placed on the arbor, and between each pair there is a spacing washer which clears the hubs but supports the gears close to the outside of the blank. The faceplate, resting on the work-spindle, is cupped out slightly to clear the lower gear blank hub. Diagram *C* shows an arrangement for two gears.

Arbor Bushings and Special Fixtures

Different sizes of bushings, adapters, or special fixtures are often used in conjunction with the central arbor, and some-

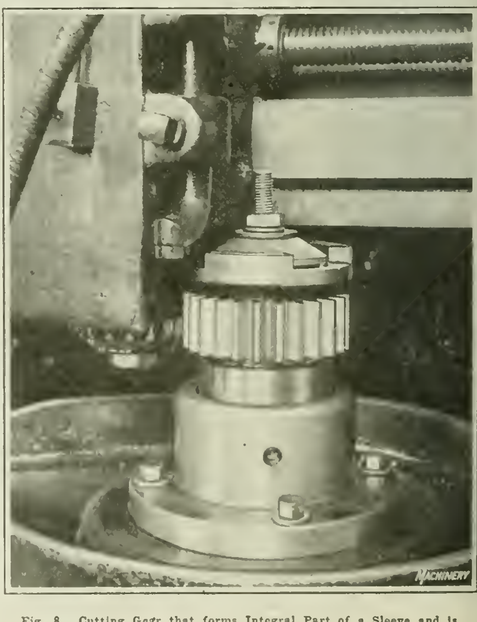

Fig. 8. Cutting Gear that forms Integral Part of a Sleeve and is Close to a Shoulder

times the latter is dispensed with, as, for example, when a gear has a long shank which must extend down into the work-spindle. Diagram *D*, Fig. 7, shows an approved method of holding a stack of gears when the holes are large enough to require a bushing on the arbor.

A type of gear which is rather difficult to hold is shown in Fig. 8. This gear is formed integral with a rather long sleeve, and it is also close to a shoulder, but the gear-cutting operation is readily performed on the gear shaper. The lower end of the sleeve is held in a centering bushing in the machine spindle, and the upper part in an adjustable fixture. Before clamping this fixture, it is centered by placing a dial indicator in contact with the bearing surface of the work. The latter is clamped down in the fixture by means of a bolt passing through the work-spindle. A slotted washer is used so that the work can be removed readily as soon as the nut is released.

Fixtures for Crankshafts with Integral Gears Located Close to Web or Shoulder

An example of work illustrating the application of the gear shaper to the cutting of gears having a small clearance space at one end is shown in Fig. 9. This gear is formed integral with a crankshaft. The lower end of this crankshaft is inserted in an adjustable fixture that is clamped on top of the work-spindle. The push stroke is used, and the crankshaft is stiffened by placing between the webs a small jack formed of a bolt and nut. Each crankshaft is located in the same position by means of a stop which comes into contact with the crankpin.

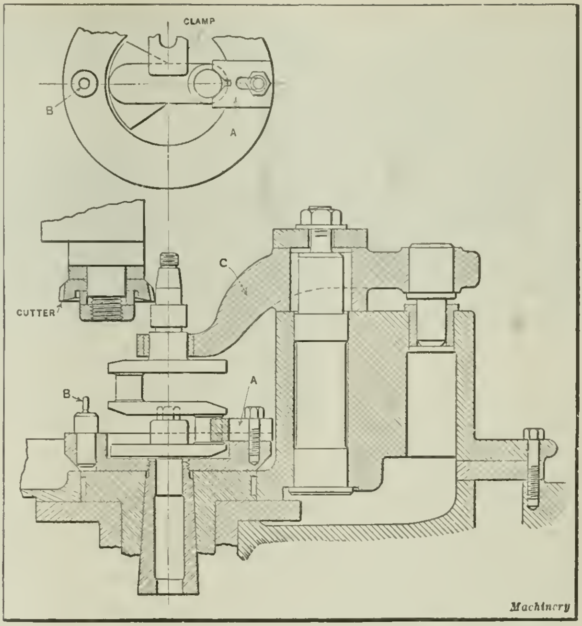

Fig. 10. Method of holding Crankshaft while cutting Gear Near Upper End

A more elaborate method of holding a crankshaft for a similar gear-cutting operation is shown in Fig. 10. The work is centered by a special hollow arbor held in the spindle by a faceplate. This faceplate carries a V-shaped locating stop *A*, and also a cutter locating pin *B*. This pin is required in order to locate the cutter in a certain position relative to the crank, because it was necessary to have the gear teeth in a certain relation to the crankshaft. After the cutter has been set, the V-shaped locating stop serves to hold each succeeding crankshaft in the proper position. The upper supporting arm *C*, containing a bushing which fits the shaft bearing, not only serves to center the upper end but also prevent excessive deflection of the shaft due to the thrust of the cut.

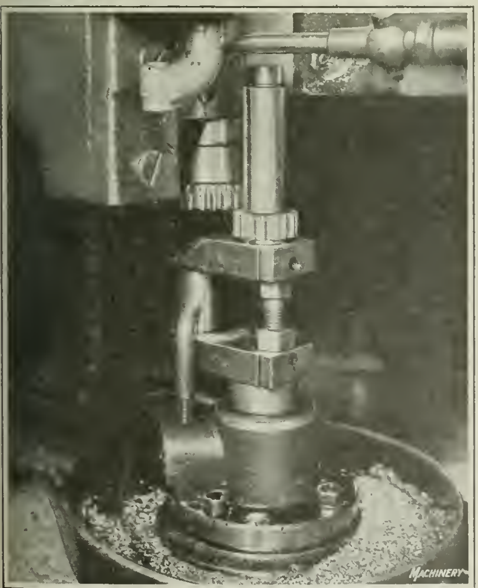

Fig. 9. Cutting Gear Teeth Close to Crankshaft Web, using Push Stroke

Cutting Spur Gears on Shaper of Multiple-tool Type

The usual method of cutting gears is either by forming one tooth or tooth space at a time, or by progressively cutting all of the teeth as the gear blank revolves to present the entire circumference to the cutting tool. Gang cutters which completely form more than one tooth at a time have been used to some extent, especially in connection with the formed milling cutter process. The multiple type of gear shaper developed by the Stevenson Gear Co., Indianapolis, Ind., is so designed that all tooth spaces may be cut at the same time, although for some classes of work it is considered preferable to cut, say, one-half or one-third the tooth spaces simultaneously. The usual method, however, is to equip the machine with as many tools as there are teeth in the gear to be cut, these tools being located radially around the circumference of the gear. When the machine is in operation, the gear blank (or blanks) is given a reciprocating motion past the cutting tools, which remain stationary except for a radial in-feeding movement which gradually sinks the cutters in to the required depth.

This is a formed-cutter process, the tooth spaces receiving their shape from the formed ends of the cutting tools. Each tooth space, however, is not formed by a single tool because the work is indexed after each cutting stroke. The object of this indexing is to equalize any slight irregularities which may exist in the different tools, thus making the teeth uniform in shape by causing each tool to operate in a succeeding space every stroke. To insure uniformity of tooth spacing, the tools are held at the full-depth position while the gear blank makes a complete revolution, thus permitting light finishing cuts to be taken. One or more gears may be cut at a time, depending on the face width of the blanks. The blank or blanks, as the case may be, are held on an arbor having a tapered shank which fits into the ram or work-spindle. When cutting plain, external spur gears, usually from two to ten blanks can be placed on an arbor. As soon as the teeth are cut, this arbor is removed and replaced by one holding uncut blanks. This type of machine cuts gears rapidly, the actual cutting time varying from 1 to 4 minutes for an arbor of gears, the time depending upon the total face width and the depth of the teeth.

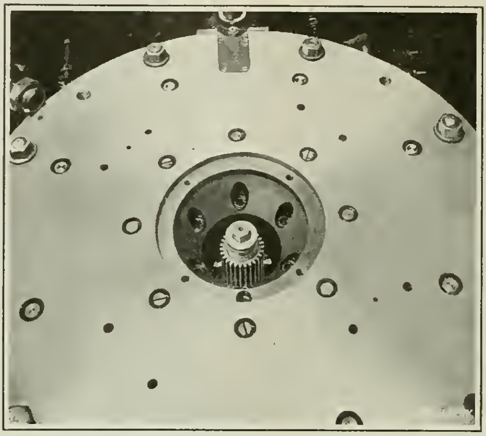

Fig. 12. Gear Shaper designed for cutting all of the Teeth in a Stack of Gears simultaneously

There are two different types of Stevenson multiple shapers, designated respectively as the "up-stroke" and the "down-stroke" types. The up-stroke machine is intended primarily for cutting plain spur gears, which can be passed through the tool-head, whereas the down-stroke type is designed more especially for cutting internal gears, cluster gears, or any form which will not pass through the tool-head. A detailed view of the up-stroke machine cutting a stack of spur gears is shown in Fig. 12. This is a view looking down on the cutter-head. The gears seen at the center are at the top of their stroke and the tools are largely concealed. In operating this machine, the changing of arbors involves stopping the machine, removing the arbor containing the cut gears by means of a foot-pedal, and dropping another arbor into place through the tool-head. In changing arbors on the down-stroke machine, which is illustrated in Figs. 13 and 14, it is necessary to stop the machine and then elevate the ram to provide additional working clearance so that the arbor may be dropped down and removed. After another arbor with uncut blanks is inserted in the spindle and fastened, the ram is lowered and the machine started. As this requires a somewhat longer time than changing arbors on the up-stroke machine, the latter type is preferable for the class of gears which it is adapted to handle.

Each machine has two tool-heads, so that while one is in use, the tools in the other may be sharpened and reset. The outer end of each tool bears against a cam attached to a ring (see Fig. 14) which is given a slow rotary movement for feeding the tools inward, this motion being controlled through change-gears. As these cam sections are adjustable relative to the ring, the radial position of each tool can also be varied. After every cutting stroke the cam ring is given a reverse movement to withdraw the tool far enough to provide relief during the return stroke. During the cutting stroke the tools are clamped to hold them rigidly, and are released at the end of the cut to permit the relieving and feeding movements. The feeding movement is limited by an adjustable micrometer stop located on the tool-head.

The arrangement of the tools varies for different classes of work. For instance, the tool-head is sometimes provided with roughing and finishing tools located alternately. The roughing tools, which may either be of the "square-nose" or stepped form are adjusted so as to remove most of the stock. This combination of roughing and finishing tools is recommended for teeth coarser than 6 diametral pitch. Another arrangement consists in using a special cam which feeds a single finishing tool forward after the other tools have roughed out the teeth. Gang tools so formed that each tool cuts several teeth may also be used for the finer pitches.

* * *

The manufacture of automobiles is the third industry of the nation, according to the *Review of Industry*. Of the 10,000,000 automobiles that are now registered, more than 3,000,000 are said to be owned by farmers.

CENTERING DEVICES

The centering devices shown in the accompanying illustrations are being used in the screw product plant of the National Acme Co. at Cleveland, Ohio, for centering parts on a production basis in a hand screw machine. While these tools do not involve a strictly new principle, they nevertheless embody an adaptation of considerable merit, and they are daily increasing production fully 100 per cent over methods previously used. The possibility of adapting these devices to any production centering problem will be obvious.

In the plant referred to, which is devoted entirely to the production of screw products of the milled and upset varieties, much of the work intended for automotive and accessory construction must be heat-treated and ground. A considerable portion of this product consists of shafts, bolts, pins, and various special parts. These parts, upon leaving the automatic screw machine department, invariably require some secondary operation before heat-treating and grinding, and in addition, the cut-off end must be centered to facilitate holding during the grinding operation, if the nature of the part requires that it be held between centers.

The necessity of cutting the second center hole in the part in alignment with the first center hole and concentric with the periphery is readily understood. The centering tool shown in Fig. 1 is placed in the turret of a hand screw machine or in the tailstock of a lathe. This tool is intended for centering shafts or special parts of a similar nature which have a uniform diameter at and for some distance back from their uncentered end so that this portion can advance through the tool and up to the centering cutter the necessary distance.

The three rolls on the tool are adjusted by screws and lo k-nuts to the diameter of the work. In addition, they are adjusted so that their contact points are at an equal distance from the center of the part so as to insure the proper locati n of the center hole. The rolls and pins on which they revolve are hardened and ground. A suitable centering cutter is placed in the holder and held firmly by a set-screw. The part to be centered is placed in the chuck and the turret advanced. The rollers receive the work, and revolving with it, guide it until the centering tool has cut to the required depth and the turret has been backed off. This tool has a range for centering work from ¼ to 1 inch in diameter.

The device shown in Fig. 2 is being used in centering parts which have, on their cut-off or uncentered end, a head or shoulder of a nature that prevents the part from entering and being guided by the rollers of the tool shown in Fig. 1. This device consists merely of a pair of hardened and ground rollers pivoted in a bracket which is fastened in the tool-holder on the cross-slide of the machine.

The two rollers are brought forward by the cross-slide, which is adjusted to the proper height. They are then adjusted by screws and lock-nuts to receive or roll against the part to be centered. The part is placed in the chuck and the turret or tailstock equipped with a plain centering tool is advanced. The centering tool enters the work while it revolves against the guide rollers and in this manner is held true.

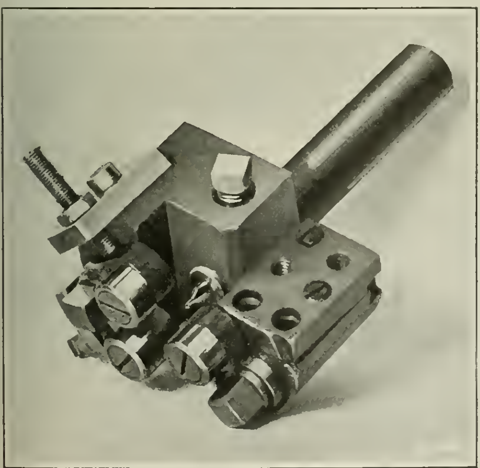

Fig. 1. Centering Tool provided with Guide Rolls

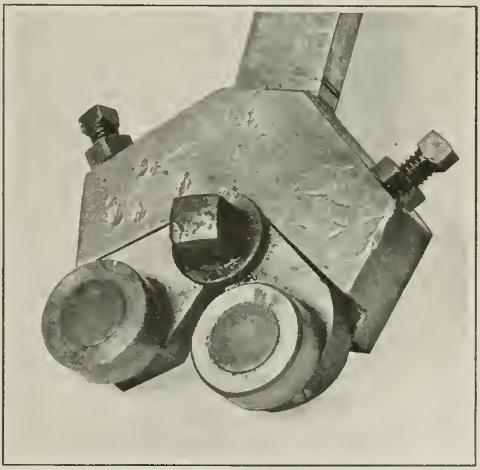

Fig. 2. Guide Roll Tool used in Centering Operations

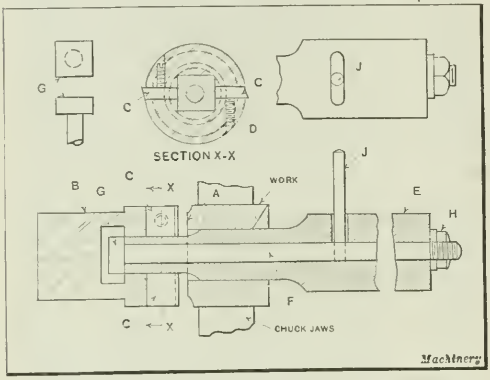
BACK-FACING TOOL

The tool shown in the accompanying illustration is designed for back-facing surface *A* so that the work can be bored, reamed, taper-turned at the front end, and back-faced at one chucking in a hand screw machine. Part *B* is made a running fit in the spindle of the lathe, the front end having a square broached hole as indicated in the sectional view. The front end of part *B* is also slotted to hold two high-speed cutters *C*. A recess is cut at the back of the square hole, and the cutters are held in place by headless screws *D*.

The shank of part *E* is made to fit the hole in the turret, and the front end is turned to fit the reamed hole in the work. The front portion of this end is milled square to fit the square hole in part *B*. Part *E* is drilled through the center to receive the piece *F*, which has a square head *G* on the front end that is the same size as the square end of part *E*. Part *F* is threaded on the back end for a nut *H*. The body of part *E* is slotted to accommodate a lever *J* which is driven into a hole in part *F*.

The action of the tool is as follows: Part *B* is inserted in the spindle of the lathe, and the work gripped in a three-jaw chuck. After the boring, drilling, and reaming operations are completed, the back-facing tool is advanced, with lever *J* in such a position that the squared end *G* will be in line with the squared end of part *E*. When *E* has advanced far enough (as determined by a stop on the machine) to allow the square end of part *F* to enter the recess in part *B*, lever *J* is pulled over, which brings the squared end of part *F* out of line with the square hole in part *B*. The corners of the squared end *G*, coming in contact with the face of the recess in part *B*, permit the facing cutters to be brought into contact with the work by pulling the turret back. After the work has been back-faced, the two members *E* and *B* are disengaged by pushing lever *J* over to its former position, and withdrawing *E* from the work.



Back-facing Tool

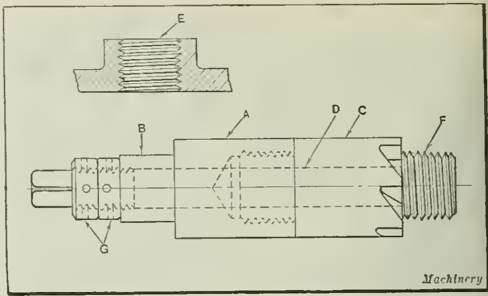
FACING TOOL FOR SPARK PLUG BOSSES

Difficulty experienced in facing the spark plug bosses on automobile engine cylinder castings led to the development of the tool shown in the accompanying illustration. Referring to the sectional view above the facing tool, *E* represents the surface of the spark plug boss that is required to be faced square with the tapped spark-plug hole. In the view of the tool, *A* is a machine steel body having a 15/16-inch square section milled at *B*. A high-speed steel cutter *C* is screwed into the other end of part *A*. The threaded pilot *D* passes through cutter *C* and body *A*. The thread on the pilot end *F* is cut exactly the same size as that on the spark plug. A 3/8-inch square is milled on the left-hand end of pilot screw *D*. The pilot screw is made a slip fit in cutter *C* and body *A*, and is held in place by lock-collars *G*. To operate the tool, end *F* of pilot *D* is screwed into the tapped hole until the cutter *C* comes in contact with the spark plug boss. The tool and cutter are then revolved by means of a special wrench applied to the squared end *B* of body *A*. Another wrench is applied to the squared end of pilot *D* and manipulated to feed the cutter to the work, one-eighth turn being made to each revolution of the cutter. When the cutter has faced the boss to the required depth, the pilot is simply unscrewed from the hole.



Facing Tool for Spark Plug Bosses

Chicago, Ill. HAROLD A. PETERS

SPECIAL SCREW MACHINE CHUCKS

A chuck of unusual design, intended for use on a hand screw machine, is shown in Fig. 1. The object in designing this chuck was to retain the desirable features of the spring collet, with which the machine was regularly fitted, and in addition to provide a hardened and ground bushing for the purpose of piloting reamers and counterbores. The piloted tools were required in performing finishing operations on parts like that shown by the dot-and-dash lines at *A*, which were roughed out from brass castings in a preceding operation. The method of obtaining this combination will be seen in Fig. 1. At *B* is shown the chuck cap, and at *C* the collet retainer which is threaded into the cap to permit inserting the bushing or pilot guide *D*, the three segments of which are pressed into *C* with a light press fit. The spring collet *E* is milled out in three equally spaced sections to allow *D* to be located in the retainer *C* before the latter is screwed into the chuck cap *B*. This construction permits the guide bushing to be located close to the work.

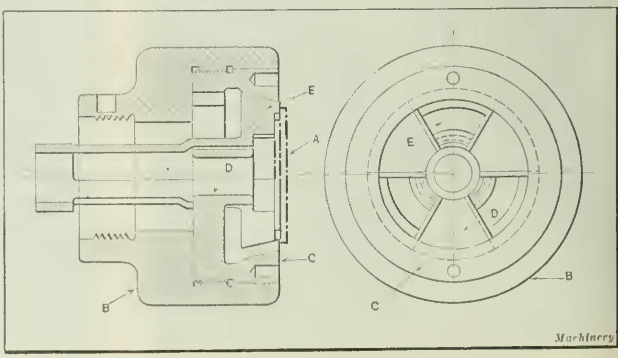


Fig. 1. Collet Chuck provided with Pilot Bushing

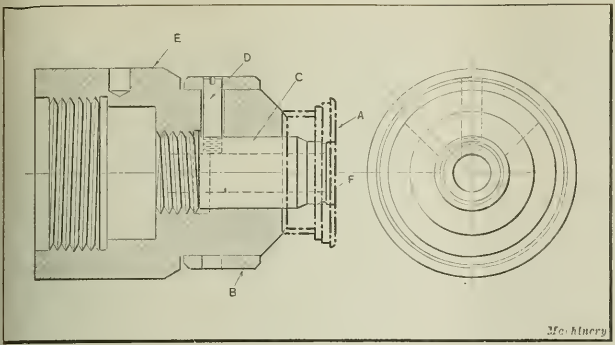

Fig. 2. Screw Chuck provided with Arbor and Pilot Bearing

The chuck illustrated in Fig. 2 was designed for the rapid production of the piece shown at *A*, which is required to be formed, faced, and counterbored with tools piloted in the work-arbor. The work is of brass, and the outside is required to be concentric with the hole at *F* in which a fine-pitch thread has previously been cut. The knurled operating ring *B* is connected to the combination arbor and pilot bearing *C* by screw *D* which passes through a slot in the chuck cap *E*. The work is clamped in place when the arbor is screwed into the chuck cap by rotating ring *B*, and although the cutting action may cause the work, with its fine-pitch threads, to tighten on the arbor, it may be readily removed without injury by unscrewing or loosening arbor *C* from cap *E* by operating knurled ring *B*.

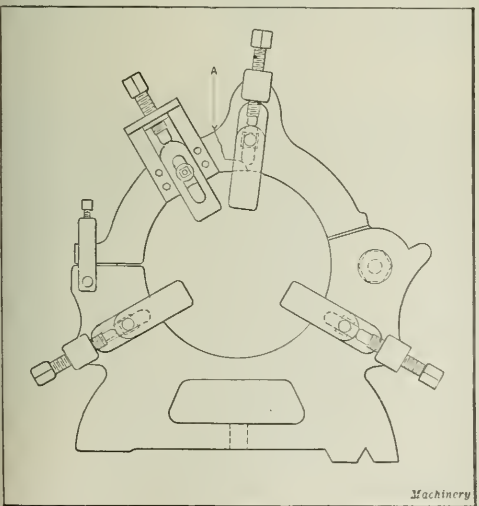
STEADYREST FOR HEAVY PIPE

A length of steel pipe 6 inches in diameter having ¾-inch walls was to be cut into sections. The pipe was set up in a lathe, using a regular chuck and steadyrest. The cutting-off tool was held in a special holder which gave it great rigidity, but from the first it was apparent that the steadyrest was too weak for the job of cutting the heavy "stringy fibered" pipe. The tool finally stuck in the cut and the work "climbed," with the result that the steadyrest frame cracked close to the upper jaw on the broken line at *A*.



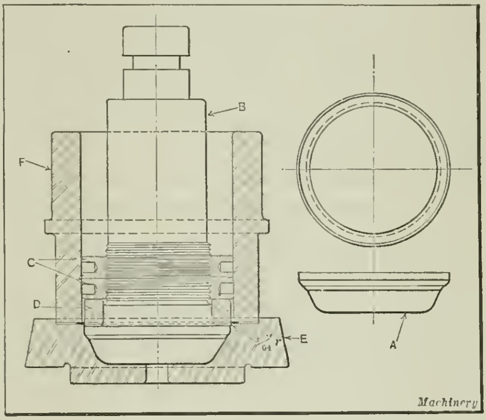
Steadyrest provided with Extra Jaw

The broken frame was welded, but it was obvious that some means of strengthening the steadyrest must be provided. A study of the work in motion showed that when the tool stuck, it acted as a pivot, so that the work was forced to "climb," thus exerting undue force on the upper jaw. The illustration shows how the trouble was remedied by providing an additional jaw at the left of the upper jaw. In this position it acted against the forces pushing the work upward, and allowed the work to be completed without further trouble.

Worcester, Mass. Roland Ljungquist

BLANKING, DRAWING AND CLIPPING DIE

In producing drawn sheet-metal parts that have to be trimmed or clipped, it is customary to blank and form the part in one operation and trim the drawn part in a separate operation. The punch and die shown in the illustration was designed to eliminate the second operation, so that only one operation is required to blank, draw, and clip the part.



Blanking, Drawing and Clipping Die used in Double-action Press

A double-action press of standard make, with a knock-out for ejecting the shell after the operation is performed, is employed. The shell shown at *A* is of sheet brass, 0.015 inch thick, and the blank diameter is 4.625 inches. The view at the right shows the shell after having been blanked, formed, and clipped. By referring to the illustration of the die it will be seen that the drawing punch *B* is threaded at the lower end, and that two check-nuts *C* hold the clipping ring *D* in place. The clipping ring should be 0.0015 inch smaller than the mouth of die *E*. In this instance, ring *D* and die *E* measure 3.4355 inches and 3.437 inches, respectively. To insure a good running fit, the blanking punch *F* should be bored to a slightly larger diameter than the check-nuts *C* which, in turn, should be from 1/64 to 1/32 inch larger than the clipping ring. The clipping ring is thus saved from unnecessary wear.

The radius at the mouth of die *E* is given as 3/64 inch, in this case, but it could be made as large as ¼ inch, if necessary, or as small as 1/64 inch, depending on which would work to the best advantage. In assembling the tools, clipping ring *D* should be so set that it will have trimmed the shell by the time that drawing punch *B* has reached its lowest position in die *E*, or within a distance from the bottom of the die recess equal to the thickness of the metal being formed, which in this instance is 0.015 inch. Some toolmakers call this the "pinch-off" method of clipping.

A die of the type described will increase production and therefore decrease the production cost. Dies of this type can be used satisfactorily on both sheet brass and steel. The wear on the tools is no greater than that on tools used to perform the same work in two separate operations. All the parts of the punches and dies are made of tool steel except the lock-nuts *C*, which are of machine steel. G. H. C.

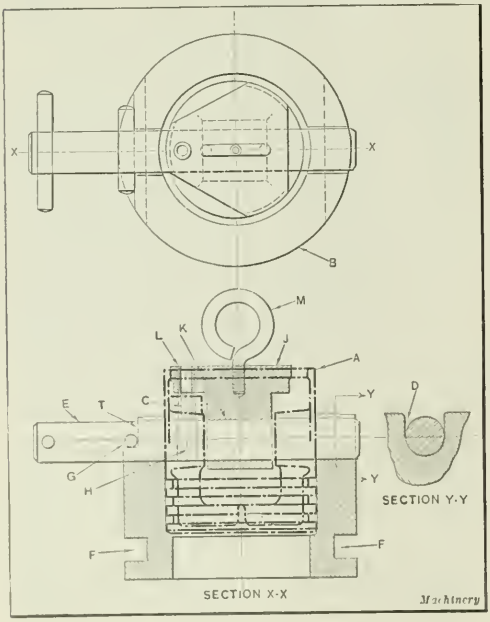
DRILL JIG FOR WRIST-PIN HOLE

The jig shown in the accompanying illustration is used for holding the engine piston *A* while drilling the wrist-pin set-screw hole at *C*. The body *B* is a round iron casting bored out to receive the piston after it has been ground on the outside. It also has a slot cut across the top, as shown at *D*, to receive the locating pin *E*. Slots *F* guide the fixture as it is slid from one spindle to another for drilling, spot-facing, and tapping the hole. The flat at *T* is used for locating the pin *E* by means of the cross-pin *G* so that the clearance hole *H* in the piston will be in line with the drill bushing *L*.

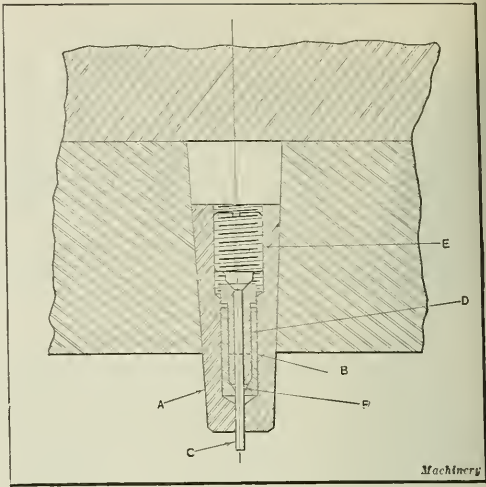
The bushing plate *J* is made of steel, and has a three-point bearing at the top that fits into the skirt bore of the piston, while at the bottom it has a ground hole *K* through which the locating pin *E* passes, lining up the plate *J*, ready for drilling the piston. The bushing plate is hardened and holds the drill bushing *L*. An eyebolt *M* is screwed into the top of plate *J* to facilitate handling. When using this jig, the bushing plate is dropped down into the piston and the locating pin *E* thrust through the wrist-pin hole, thus lining the plate up with the piston.

After this has been done the piston and plate are dropped into the jig body *B*, and the pin *E* pushed into the slots *D* and located by the flat *T* and the pin *G*. The hole is then drilled and the jig slid over to the next spindle. The pin *E* and plate *J* are next removed and the hole spot-faced, after which the jig is slid under the next spindle, where the hole is tapped and the piston removed from the jig. This jig has proved accurate and rapid, and has eliminated much wrist-pin locating trouble on the motor assembling floor.

Pittsburg, Pa. WILLIAM OWEN



Jig for locating Wrist-pin Set-screw Hole



Method of holding Small Piercing Punches

HOLDER FOR SMALL PIERCING PUNCHES

It is difficult to prevent the occasional breakage of small piercing punches, even when they are held in a rigid frame. Of the many holders that have come to the writer's notice, none seems so compact and rigid as the one shown in the accompanying illustration. This holder permits the punch to be easily replaced in such a manner that its location will not be disturbed. Thus all other subsequently pierced holes will be in alignment.

In the illustration, *A* is a punch-holder of any desired taper, which is driven tightly into the punch-plate. Part *B* is a hardened steel bushing which is a slip fit in *A*. The punch *C* is driven lightly into the holder *D*, which is slotted across the tapered end to give it spring, similar to a spring collet. Holder *D* is machined so that it will be a slip or sliding fit in *B*. Punch *C* is made of drill-rod so that it can easily be replaced in case it is broken, although breakage seldom occurs when a holder of this type is used. The upper end of the punch is riveted over, as shown, and retained by a set-screw *E*. When the set-screw *E* is tightened, the holder *D* is forced down against the angular surface *F*, thus gripping the punch *C* firmly.

Trenton, N. J. I. BERNARD BLACK

A PRODUCTION DRILL JIG

In the production of pieces having a drilled and reamed hole, it is customary to provide the drilling machine with a quick-change chuck and the drilling jig with slip bushings. For each piece completed, two changes of tools and two changes of bushings have to be made, and where only a short hole is to be drilled, a large portion of the operation time is consumed in changing tools and bushings. Fig. 1 shows a fixture for drilling and reaming a 3/4-inch hole through 3/4- by 5-inch steel pieces, in which the necessity of changing tools and bushings has been entirely eliminated.

The jig is used on a small drilling machine of the hand-feed type. The piece to be drilled is held in the V-block *B* by a clamping screw *C*, and is located by the stop-pin *D*. A large cast-iron sleeve *E* is made a good turning fit in the jig body and is held from axial movement by the nut *F* shown in the sectional view, Fig. 2. This sleeve carries two hardened tool-steel spindles *G*, located 90 degrees apart. One spindle carries the drill and the other the reamer. An index-plunger *H*, Fig. 1, secured to the sleeve *E*, permits either of the spindles to be locked in position over the work. The upper end of each spindle has two clutch teeth *J* that match those in the hardened steel driver *K* which is held in the spindle of the drilling machine.

The teeth are so formed that their engaging sides form an angle of about 20 degrees with the vertical. Vertical movement of the drilling machine spindle automatically engages or disengages the tool-spindles. Thus the only movements required of the operator are the manipulation of the drilling machine feed-lever and the changing of the spindles *G* from the drilling to the reaming position by means of the index-plunger *H*. Hardened bushings *L*, Fig. 2, guide the drill and reamer. The lower portions of the spindles are made larger in diameter and are held in position by retaining straps *M*, Fig. 1. Light coil springs *N* and thrust washers *O* help withdraw the tools and hold them out of contact with the work while not being used.

A pilot *P* in the driver *K* enters a corresponding hole in the upper end of each spindle and helps to steady it. The driving teeth on the end of the spindles are made with inclined faces so as to cause them to follow the upward movement of the drilling machine spindle on the return stroke. A Graham shank twist drill is used, and is secured in the spindle by four headless set-screws, the points of which enter the two V-grooves in the drill shank. The reamer shank is made a loose fit in the spindle and is driven by a loose pin so that it has a chance to float slightly. By removing the screws *R*, the spindles may be taken out of the sleeve for inspection or sharpening of the cutting tools.

Obviously the use of such a fixture is not confined to the drilling and reaming of round work, as this type of fixture could be used equally well for drilling and counterboring work of any shape, drilling body and tap drill holes, and similar operations.

SALVAGING WITH THE ACETYLENE TORCH

A concrete example showing the value of the oxy-acetylene torch for machine shop salvaging work is given in the following. In a large plant building a line of medium sized machinery and having its own iron foundry, a careful record was kept of every job for a period of about six weeks. This record was then used for calculating the approximate savings realized by employing the oxy-acetylene torch to repair defective and broken castings and broken parts of shop equipment. All costs for welding mixture and other incidental supplies were combined with labor costs to obtain the following figures, which show the result of the investigation:

Number of jobs	160
Total number of hours worked	290
Total weight of work repaired, in pounds	41,000

SALVAGE COSTS

Welding mixture and incidentals	$450
Iron scrap (valued at $0.006 per pound)	246
Cost of remachining after welding	800
Wages of one welder and assistant (at a rate of $1.54 per hour)	447
Total cost of salvaging	$1943

As the total value of the product salvaged was $3400, the net saving is obviously $3400 — $1943 = $1457. Of the entire 160 jobs referred to, only 104 represented work done on the product, the other 56 being odd jobs such as cutting off material and making repairs to small tools and equipment, the cost of performing the latter work being included in the totals given. In calculating the value of parts salvaged, none of the equipment repair jobs were included, because the value of these miscellaneous items was difficult to determine. Account was taken of the value of parts only up to the point of breakage. It is evident then that had the savings in respect to tools and equipment been included, the item of net profit would be much larger than the amount recorded.

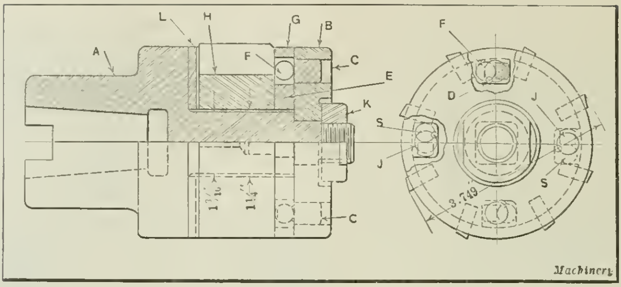

Fig. 1. Floating Reamer for reaming Automobile Engine Cylinders

The work on 76 out of the 104 parts repaired consisted of filling small blowholes and similar defects in castings that did not show up until the greater part of the machine work had been done. In the case of the other 28 parts, the repairs consisted of welding on pieces of flanges or other projections that had been broken off. All the jobs were relatively small ones, but nevertheless sufficient to make the part useless unless repaired, and these repairs could be satisfactorily accomplished only by welding.

In addition to the actual savings shown, many of the parts repaired were of such a nature that considerable and serious delays in production schedules would have resulted had it been necessary to recast and entirely replace them. It is hardly necessary to point out that a reduction in the number of defective castings and shop breakage is to be continuously striven for, but when one considers that the figures given here for the number of pieces repaired comprise but a fraction of 1 per cent of the total number of good parts produced, it is evident that no out-of-the-ordinary opportunities for using the welding torch were presented by the conditions under which the tests were made. The same possibilities exist in hundreds of other plants.

Cambridge, Mass. FREDERICK A. POPE

FLOATING REAMER

A "front-drive" floating reamer that has proved very satisfactory for reaming automobile engine cylinders is shown in Fig. 1. Some of the more important details of the reamer are also shown in Fig. 2, the same reference letters being used as in Fig. 1. The shank *A* is provided with a ground section 7/8 inch square which fits snugly into a square hole in the driving plate *B*. The driving plate has two tool-steel pins *C*, which are assembled in the plate and held in position by 1/8-inch pins *D*, while their projecting ends are milled to the shape shown in the detail view at *C*, Fig. 2. After the pins are machined, they are hardened and drawn.

The equalizing drive-plate *E* is provided with four equally spaced slots, the sides of which are ground where they make contact with the pins *C* and *J* and the 3/8-inch hardened steel balls *F* and *S*. A collar or ring *G* is pressed over the drive-plate *E* to retain the 3/8-inch balls.

The reamer body *H* is also provided with two pins *J* which are duplicates of those used in plate *B*. A nut *K* draws plate *B* up tight against the shoulder on shank *A*. In order to insure a good fit, or rather to allow the desired floating action, a thrust plate *L* is provided, which has three slightly raised portions on one face, as shown in Fig. 2. This plate is pack-hardened and ground to the proper thickness to compensate for any discrepancies that may exist in the thickness of the reamer body, driving plate, or length of shank. Details of the reamer blade used in the reamer body are shown in the lower right-hand corner of the illustration Fig. 2.

STEEL TREATERS' SECTIONAL MEETING

A number of interesting papers were read before the New York sectional meeting of the American Society for Steel Treating, held at the Hotel McAlpin, New York City, on March 3. These papers included "New Developments on the Influence of Mass in Heat-treatment"; "Calite—a New Heat-resisting Alloy"; "Stainless Steel in Cutlery Use"; "Cold-headed Bolts—their Metallography and Heat-treatment"; "The Magnetic Testing of Small Casehardened Chain"; "Perfecting a Drop-forging"; and "The Manufacture of Steel." Several of the papers were illustrated.

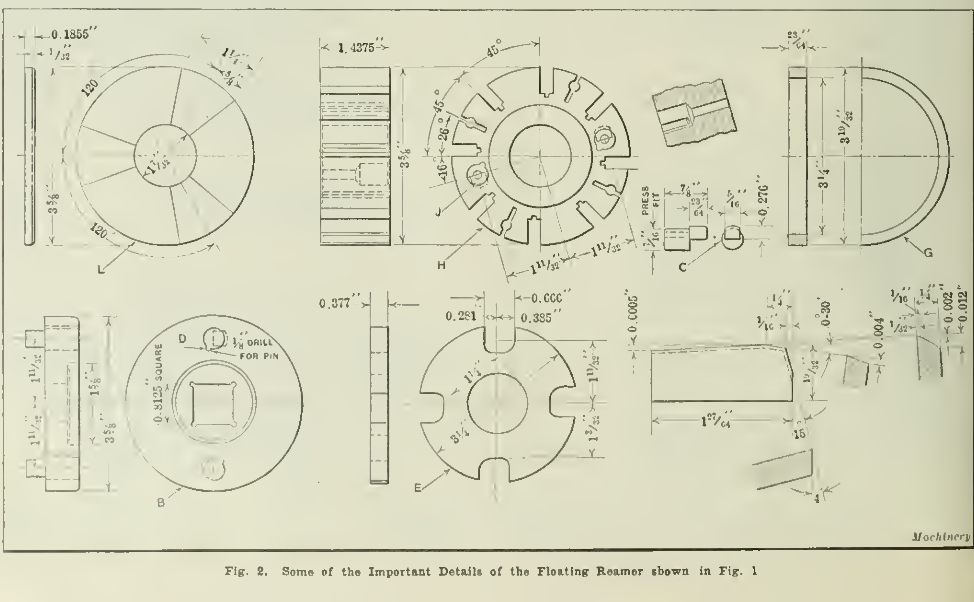

Fig. 2. Some of the Important Details of the Floating Reamer shown in Fig. 1

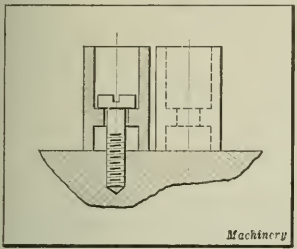
SHOP AND DRAFTING-ROOM KINKS

CENTERING AND LOCATING BUTTONS

The toolmakers' buttons shown in the accompanying illustration may be used to advantage when it is necessary to locate two or more buttons so close together that an indicator cannot be employed in the usual manner. Referring to the cross-sectional view, it will be noted that the button is counterbored to receive the head of the screw that is used to attach the button to the work. The counterbored hole is ground true or concentric with the outside of the button, so that the indicator contact point can be applied to the surface of the counterbored hole instead of to the outside of the button.



Centering and Locating Buttons

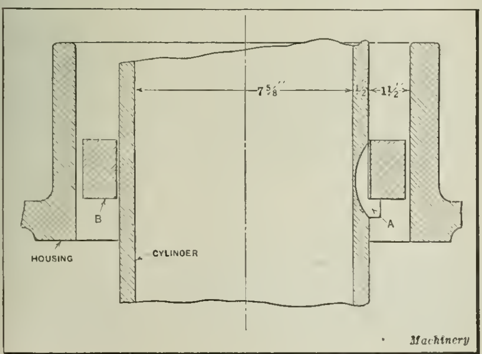
Ontario, Cal. CHARLES HOMEWOOD

SECURING COLLAR TO HOLLOW CYLINDER

The writer was recently confronted with the problem of securing a collar to the outside of a hollow cylinder in such a manner that it would withstand considerable end thrust, be easily and quickly removable in the direction of the thrust, and operate inside a circular housing which was concentric with the cylinder and 1½ inches from it all around as shown in the illustration. The use of set-screws or shoulders was out of the question, as screws could not be conveniently inserted or removed, and a shoulder would prevent removal of the collar.

Three keyways were finally cut, 120 degrees apart, on the outside of the cylinder, with a half-inch wide milling cutter. The gib keys, one of which is shown at *A*, were made with clearance enough to permit of their removal with the fingers or with a pair of pliers. To assemble the parts, collar *B* is pushed on the cylinder past the center of the keyways, the keys are inserted, and the collar drawn back over the keys until it rests against the gibs. To remove the collar the operation is reversed.

Montreal, Canada A. L. MORGAN



Method of securing Collar to Hollow Cylinder

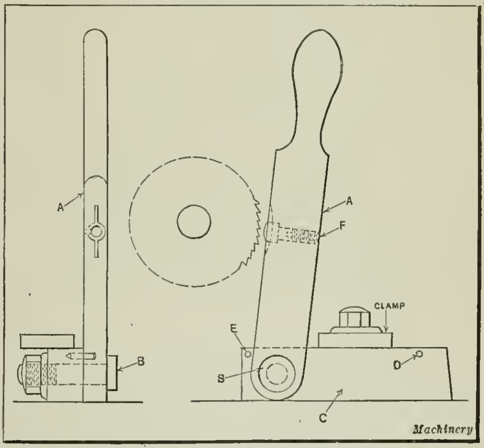
CENTERS MADE FROM DRILL SHANKS

The taper shanks of high-speed drills which are generally thrown away when the drills are worn out can be easily converted into lathe centers by hardening one end and grinding it to the required 60-degree angle. Centers made in this way are obviously inexpensive, and they will be found to give excellent service when used in lathes, grinding machines, etc.

Wilkinsburg, Pa. BERNARD E. LITOT

FIXTURE FOR SLOTTING SCREWS

A screw-slotting device which can be operated quite rapidly is shown in the accompanying illustration. The lever *A* is pivoted on the stud *B* held in base *C*. Lever *A* is drilled and counterbored to receive the screw to be slotted, the counterbore being deep enough to allow the screw-head to come about flush with the face of the lever. The screws can be slotted without chatter when held in this way. A pin *D*, driven into the base, enters a slot *F* cut into the side of the screw hole in lever *A* and provides for ejecting the screw when the lever is brought down after the slotting operation has been performed. The pin *E* prevents lever *A* from being pushed too far forward, and thus eliminates the danger of cutting the slot too deep. The device is clamped to the saddle of a lathe, or if a small speed lathe is used it is clamped to the slide-rest.



Screw-slotting Fixture

Rosemount, Montreal, Canada HARRY MOORE

FASTENING HAMMER TO HANDLE

A method of fastening a hammer to its handle so that it will not come off is to first secure the handle to the hammer by means of three iron wedges set in the usual H form, and then boil the hammer and handle in linseed oil for several hours. A hammer thus treated has been in fairly constant use for thirty years without showing the slightest sign of coming off the handle. The handle is made of good hickory.

Wilkinsburg, Pa. WILLIAM S. ROWELL

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

PROBLEM INVOLVING VOLUME OF A CONIC FRUSTUM

A. R. I.—Can any reader of MACHINERY show how to find the depth of water in a tank which is in the form of a frustum of a cone, when the tank is only partly filled? If a tank is 9 feet in diameter at the top, 10 feet in diameter at the bottom, and 5 feet high, what is the depth of water when it is one-quarter full?

ANSWERED BY W. W. JOHNSON, CLEVELAND, OHIO

Referring to the accompanying diagram, let *ABCD* represent the vertical section of the given frustum taken

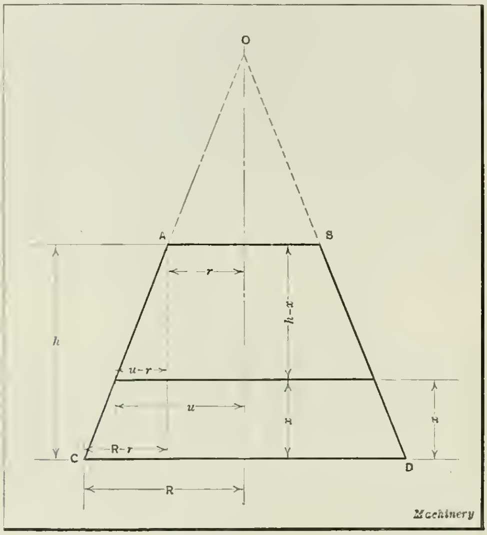


Diagram illustrating Solution of Tank Problem

through the center. Also, let r equal the radius of the top of the tank; R the radius of the bottom of the tank; h the height of the tank; n the number of parts in the total volume of the frustum, that is, the denominator of the fraction representing the part of the tank which is filled; and x the depth of water when the tank is $\frac{1}{n}$ full.

Denote the volumes of the three cones whose bases are circles having radii r, u, and R by the letters A, B, and C, respectively.

Then,

$$A:C = r:R \quad \text{and} \quad B:C = u:R$$

since corresponding volumes vary as the cubes of the radii or altitudes.

Therefore

$$A = \frac{r^3}{R^3}C \quad \text{and} \quad B = \frac{u^3}{R^3}C$$

Volume of water: volume of frustum = 1 : n

Then

$$\frac{\text{Volume of water}}{\text{Volume of frustum}} = \frac{C - B}{C - A} = \frac{C - (u^3 \div R^3)\,C}{C - (r^3 \div R^3)\,C}$$

$$= \frac{R^3 - u^3}{R^3 - r^3} = \frac{1}{n}$$

from which

$$u^3 = \frac{R^3(n-1) + r^3}{n} \quad \text{and} \quad u = \sqrt[3]{\frac{R^3(n-1)+r^3}{n}} \qquad (1)$$

From the theorem of similar triangles,

$$\frac{u - r}{R - r} = \frac{h - x}{h} \quad \text{or} \quad u = R - \frac{x}{h}(R - r) \qquad (2)$$

Solving (1) and (2) for x, we find

$$x = \frac{h\left[R - \sqrt[3]{\dfrac{R^3(n-1)+r^3}{n}}\right]}{R - r}$$

Reducing all dimensions to inches and putting $n = 4$, $R = 60$, $r = 54$, and $h = 60$ in this formula, we find $x = 13.97$. Hence, the depth of the water when the tank is one-fourth full is 13.97 inches.

HEIGHT OF CREST ON WHITWORTH THREAD

H. H. G.—A lap is to be made for lapping the crests of Whitworth thread gages, and the height x (see accompanying illustration) must be determined. How can this be calculated?

A.—The vertical depth x from the crest of a Whitworth thread to the horizontal line intersecting the points where the crest and straight sides meet may be determined by the

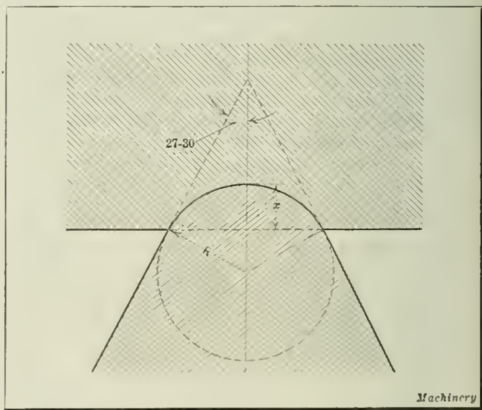

Diagram used in finding Height of Crest on Whitworth Thread

following formula, in which x equals the required height of the crest, and R equals the crest radius:

$x = R - R \sin 27$ deg. 30 min.; or $x = R - R \times 0.46175$

The radius $R = 0.1373 \times$ the pitch of the thread.

THREADED PIPE JOINTS

J. G. H.—What is the best material to apply to pipe threads before making up the joints in order to obtain a tight joint that will resist the action of gases or liquids?

A.—Red lead mixed with pure boiled linseed oil has been widely used and is very satisfactory. This mixture should have a heavy fluid-like consistency, and if applied to a clean, well-cut thread will give an excellent joint.

LOCATING A POINT ON THE HYPOTENUSE OF A TRIANGLE

F. I. D.—Referring to the illustration, ABC is a right triangle. Please show how to find distance x.

ANSWERED BY W. W. JOHNSON, CLEVELAND, OHIO

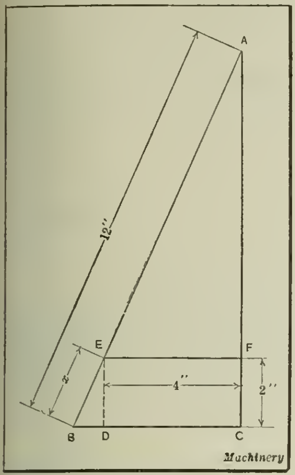

Diagram used in the Solution of a Trigonometric Problem

The triangles AEF and EBD are similar, as they are right triangles having angle B in common.

Hence,

$$\frac{EF}{AE} = \frac{BD}{EB}$$

Now, $EF = 4$ inches; $AE = 12 - x$; $BD = \sqrt{x^2 - 4}$; and $EB = x$. Then,

$$\frac{4}{12 - x} = \frac{\sqrt{x^2 - 4}}{x}$$

or

$$4x = (12 - x)\sqrt{x^2 - 4}$$

Squaring both sides and combining,

$$x^4 - 24x^3 + 124x^2 + 96x - 576 = 0$$

Solving this equation by Horner's method, we have

$$x = 2.1904 \text{ inches}$$

STANDARD ANGLES FOR RIVET HEADS

J. F. G.—Is there a standard angle for countersunk rivet heads, and does this angle vary for different classes of work?

A.—An included angle of 80 degrees has been adopted by the American Boiler Manufacturers Association for countersunk rivet heads, but this angle is not invariably used; for instance, the angle adopted by a prominent rivet manufacturer is 78 degrees. According to the handbooks of prominent steel manufacturers, an included angle of 60 degrees is the standard for bridge and structural work.

MASTER TOOL PROBLEM

L. M. S.—The profile of a master tool is outlined in the accompanying illustration. In making this tool, it is required to find dimension AB. Please show how dimension AB can be obtained when the known values are as follows: Angle FEN equals 40 degrees; angle NEJ, 60 degrees; diameters of circles R and S, 0.5 inch; dimension DC, 0.875 inch; ED, 0.125 inch; and radius CT, 1.375 inch.

ANSWERED BY GEORGE WARMINGTON BEVERLY, MASS.

First draw line CK parallel to JE making angle HCK equal to angle NEJ, or 60 degrees. Then draw line AK from A perpendicular to KC, and line CL from C perpendicular to KC, making CL equal to JK. Next draw line CI parallel to EF, making angle ICG equal to angle FEN, or 40 degrees, and draw line BI from B perpendicular to CI; also draw line EM from E perpendicular to CI and equal to FI.

$$CE = \sqrt{ED^2 + CD^2} = \sqrt{0.125^2 + 0.875^2} = 0.8839 \text{ inch}$$

Cot $PEC = 0.875 \div 0.125 = 7$ and $PEC = 8$ degrees 8 min.

As angle $LEP = 30$ degrees, $LEC = 30$ degrees $+ 8$ degrees 8 minutes $= 38$ degrees 8 minutes.

$$CL = CE \sin LEC = 0.8839 \sin 38 \text{ degrees } 8 \text{ minutes} = 0.8839 \times 0.61749 = 0.5458 \text{ inch}$$

Now

$$AK = AJ + JK = AJ + CL = 0.250 + 0.5458 = 0.7958 \text{ inch}$$

and

$$AC = 1.375 + 0.250 = 1.625 \text{ inches}$$

Then

$$\sin ACK = AK \div AC = 0.7958 \div 1.625 = 0.4897$$

and

$$ACK = 29 \text{ degrees } 19 \text{ minutes}$$

Also

$$HCA = HCK - ACK = 60 \text{ degrees} - 29 \text{ degrees } 19 \text{ minutes} = 30 \text{ degrees } 41 \text{ minutes}$$

and

$$HA = AC \sin HCA = AC \sin 30 \text{ degrees } 41 \text{ minutes} = 1.625 \times 0.5103 = 0.829 \text{ inch}$$

Also

$$HC = AC \cos HCA = AC \cos 30 \text{ degrees } 41 \text{ minutes} = 1.625 \times 0.86 = 1.3975 \text{ inches}$$

Angle $ECG = 90$ degrees $- PEC$

Then

$$ECG = 90 \text{ deg.} - 8 \text{ deg. } 8 \text{ min.} = 81 \text{ deg. } 52 \text{ min.}$$

Also

$$\text{Angle } ECM = ECG - ICG = 81 \text{ deg. } 52 \text{ min.} - 40 \text{ deg.} = 41 \text{ degrees } 52 \text{ minutes}$$

$$EM = CE \sin ECM = CE \sin 41 \text{ degrees } 52 \text{ minutes} = 0.8839 \times 0.6674 = 0.5899 \text{ inch}$$

$$BI = IF - BF = EM - BF = 0.5899 - 0.250 = 0.3399 \text{ inch}$$

$$BC = 1.375 + 0.250 = 1.625 \text{ inches}$$

$$\sin BCI = BI \div BC = 0.3399 \div 1.625 = 0.2091$$

and

$$BCI = 12 \text{ degrees } 4 \text{ minutes}$$

Now

$$BCG = ICG + BCI = 40 \text{ deg.} + 12 \text{ deg. } 4 \text{ min.} = 52 \text{ degrees } 4 \text{ minutes}$$

and

$$BG = BC \sin BCG = BC \sin 52 \text{ degrees } 4 \text{ minutes} = 1.625 \times 0.7887 = 1.2816 \text{ inches}$$

and

$$GC = BC \cos \text{ angle } BCG = BC \cos 52 \text{ degrees } 4 \text{ minutes} = 1.625 \times 0.6147 = 0.9989 \text{ inch}$$

Now draw line BO parallel to EP and AO perpendicular to BO. Then

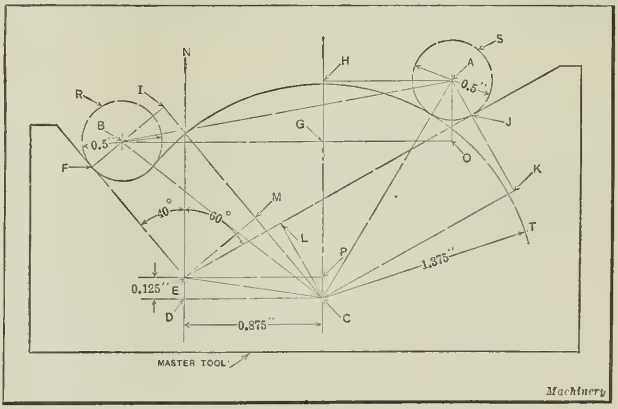

Diagram used in solving Master Tool Problem

$$AO = HG = HC - GC = 1.3975 - 0.9989 = 0.3986 \text{ inch}$$

and

$$GO = HA = 0.829 \text{ inch}$$

$$BO = BG + GO = 1.2816 + 0.829 = 2.1106 \text{ inches}$$

Therefore

$$AB \; \sqrt{AO^2 + BO^2} = \sqrt{0.3986^2 + 2.1106^2} = 2.147 \text{ inches}$$

Methods of Computing Pitch of Spur Gears

By GEORGE F. NORDENHOLT, Instructor in Mechanical Engineering, Lehigh University, Bethlehem, Pa.

WITH the exception of Equation (4), which was derived by the author, the methods of computing the pitch of spur gears, as here presented, were originated and developed by Professor P. B. de Schweinitz, of the Department of Mechanical Engineering of Lehigh University. The Lewis formula is employed in these formulas in such a way that they may be readily applied to the solution of spur gear problems without resorting to the cut-and-try methods commonly employed. The pitch obtained by the use of Formula (4) will be the smallest that may be used under the conditions specified and will accordingly result in the smallest gears permissible. In cases where the center-to-center distance of the shafts is not specified this is a distinct advantage.

The well-known Lewis formula for the computation of the pitch of spur gear teeth is often presented in the following form:

$$P = fpby \qquad (1)$$

where

P = load on tooth;
f = allowable tooth stress;
p = circular pitch;
b = width of tooth; and
y = Lewis factor.

By means of simple algebra, the foregoing equation may be transformed to read:

$$p = \frac{P}{fby} \qquad (2)$$

In designing gears, the ratio of the width to the circular pitch is always an important matter, and is chosen by the designer to meet the proper conditions, the usual value for this ratio being 2½ or 3. This ratio may be incorporated in the above formula by dividing the denominator on the right side of the equation by p and multiplying the left side of the equation by p also. If we then designate the reciprocal of the Lewis factor by c, we get

$$p^2 = \frac{Pc}{\frac{b}{p} \times f} \qquad (3)$$

As c is determined by the number of teeth, and the number of teeth depends upon the pitch, it is evident that this equation could not be solved as it stands, except by a cut-and-try method. In order to eliminate this, substitute the term $\left(\frac{2\pi r}{z}\right)^2$ for p^2. This gives the equation

$$\frac{cz^2}{4\pi^2} = \frac{r^2 f \times (b \div p)}{P} \qquad (4)$$

in which z = number of teeth in pinion; and
r = radius of pitch circle of pinion.

When the problem is to design a pair of gears to transmit a certain horsepower at a given speed and velocity ratio, and the center-to-center distance between the shafts is specified, the right-hand member of Equation (4) may readily be solved, basing all computations on the pinion, which, having the smaller number of teeth, will have the weaker tooth. In this case

$r = \frac{C}{R+1}$, in which R is the velocity ratio and C the distance between the shaft centers.

The value $\frac{b}{p}$ is chosen by the designer and P may be obtained from the formula $Pr = 63025 \frac{H}{n}$, where H is the horsepower transmitted, and n is the number of revolutions per minute of the pinion. The allowable tooth stress f may be the value recommended by Lewis, or it may be obtained by Barth's formula, or the Reuleaux formula. The accompanying table contains the reciprocals of the Lewis factor in the second column. The third column is the reciprocal multiplied by the square of the corresponding number of teeth, the result being divided by $4\pi^2$, thus giving $\frac{cz^2}{4\pi^2}$.

Having computed the value of $\frac{cz^2}{4\pi^2}$ from Formula (4),

TABLE OF GEAR CONSTANTS FOR 15-DEGREE INVOLUTE SYSTEM

Machinery

find the next smaller value in the table, and the number of teeth corresponding to it will be the maximum number of teeth the pinion should have. Dividing by the pitch diameter, gives the diametral pitch, from which the next lower standard diametral pitch may be chosen.

Solution when no Distance between Shafts is Specified

When no distance between the shaft centers is specified, the solution is as follows:

$$r = \frac{pz}{2\pi}$$

Then

$$P = \frac{Pr}{r} = Pr\,\frac{2\pi}{pz} \qquad (5)$$

Substituting this value of P in Equation (3), we obtain:

$$p^2 = \frac{2\pi c Pr}{zf \times (b \div p)} \qquad (6)$$

As z may be chosen by the designer, $2\pi c$ is obtained directly from the table and the value of p can thus be computed, provided we are able to determine the proper tooth stress. To do this, we may use Reuleaux's formula,

$$f = \frac{S}{\sqrt[3]{V}} \qquad (7)$$

where S is the allowable stress for velocities up to 1 foot per second, and V is the velocity at the pitch line in feet per second. It should be noted that if V were less than one foot per second, f would be greater than S, which, of course, is not permissible. Hence if the velocity is equal to or less than one foot per second, S should be used in place of f, in Equation (6), and p may then be solved for. If the velocity, however, proves to be greater than 1 foot per second, we may substitute for V in Equation (7) its value $\frac{z\,p\,n}{720}$, and place this value for f in Equation (6), which, when solved to obtain p, results in

$$p^8 = \left(\frac{\frac{2\pi c}{\sqrt[3]{720}} \times Pr}{\frac{b}{p} \times S} \right)^3 \times \frac{n}{z^2} \qquad (8)$$

This equation may be solved from the data given, using the value of $\frac{2\pi c}{\sqrt[3]{720}}$ as given in the table.

Equation (8) has an added advantage in that even a considerable error made in computing the right-hand member of the equation is practically eliminated when the square root is taken three times consecutively in order to obtain the eighth root; for example, if the arithmetical work had resulted in $p^8 = 2088$, while the result should have been $p^8 = 6561$, then in the first case $p = 2.6$ while in the second case $p = 3$; both of which would call for a standard diametral pitch of 1¼. Even if the error makes the right-hand member come out within 200 per cent of what it should be, the final resulting error would be only about 9 per cent.

Having obtained the required standard diametral pitch, the diameter may be obtained by dividing the value of z used in solving Formula (6) or (8), by the diametral pitch obtained. After obtaining the diameter, the pitch velocity should be computed to make certain that the proper formula, either (6) or (8), has been used, which depends on whether the velocity comes out less than or greater than one foot per second. For instance if the velocity is thus calculated to be less than one foot per second it shows that Formula (6) is the correct one to use.

Comparison of Allowable Stresses

The value of S to be used in the Reuleaux formula may be the same as that used in the Barth formula. Up to a velocity of about 1.1 feet per second, the Reuleaux formula gives a higher unit stress. Then up to a velocity of about 14.2 feet per second, the Reuleaux formula gives slightly lower values for the allowable tooth stress. At a speed of 14.2 feet per second the resulting values are the same in both cases, while above this speed, the Reuleaux formula gives higher stresses. The accompanying chart shows a comparison of stresses when using the values recommended by Lewis and those obtained by the Barth and Reuleaux formulas.

It is not claimed that the Reuleaux formula gives more accurate results, but it is simple algebraically, which enables it to be combined with other formulas, as in the development of Formula (8). An attempt to use the Barth formula here would result in a very cumbersome equation, while the

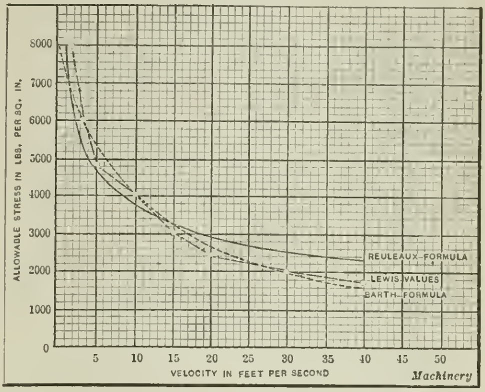

Chart showing Comparative Values obtained by Three Well Known Formulas, allowing an Initial Stress of 8000 Pounds per Square Inch in Each Case

Lewis value could not be used at all. With slight modifications, and using mean values, the formulas here developed may be applied to bevel gears for the determination of the proper pitch.

Application of Formulas

The application of the method for computing the pitch of spur gears, as outlined in the foregoing is illustrated in the following examples:

Example 1—Given the center-to-center distance C between two shafts as 40 inches, and the revolutions per minute of the pinion and gear as 90 and 30, respectively; what should be the diametral pitch if 100 horsepower is to be transmitted?

$$R = \frac{90}{30} = 3 \quad \text{and} \quad r = \frac{C}{R+1} = \frac{40}{4} = 10 \text{ inches}$$

$$Pr = \frac{63025H}{n} = \frac{63025 \times 100}{90} = 70{,}000 \text{ (approximately)}$$

Also

$$P = \frac{Pr}{r} = \frac{70000}{10} = 7000$$

aud

$$V = \frac{2\pi rn}{720} = \frac{2\pi \times 10 \times 90}{720} = 8 \text{ feet per second (approx.)}$$

Using Formula (7) and assuming that the allowable stress $S = 6000$ pounds per square inch, we have

$$f = \frac{6000}{\sqrt[3]{8}} = 3000 \text{ pounds per square inch}$$

Choosing a value for $\frac{b}{p} = 3$ and substituting the numerical values, we obtain from Formula (4):

$$\frac{cz^2}{4\pi^2} = \frac{r^2 f \times (b \div p)}{P} = \frac{100 \times 3 \times 3000}{7000} = 128.6$$

Referring to the table, it will be noted that the nearest value, less than 128.6 in the third column is 121.8. Hence the pinion may have 21 teeth, which will be equivalent to a diametral pitch of $\frac{21}{20} = 1.05$. The next lower standard diametral pitch is 1, and this pitch or any coarser standard pitch may therefore be used. Using a diametral pitch of 1, we would have 20 teeth in the pinion and 60 teeth in the gear.

Example 2—Four horsepower is to be transmitted from one shaft to another through spur gearing. The pinion is required to make 25 revolutions per minute and the gear 5 revolutions per minute. No center distance is specified. The gears are to be made of cast iron and as small as it is practicable to make them. Find the proper diametral pitch.

As the speed of the pinion is only 25 revolutions per minute, or less than half a revolution per second, we will assume that the peripheral velocity will be less than one foot per second, and hence base our calculations on Formula (6). To obtain the desired velocity ratio, we may use 12 teeth in the pinion, and 60 in the gear. Considering the tooth of the pinion, which is the weaker,

$$Pr = \frac{63025H}{n} = \frac{63025 \times 4}{25} = 10{,}000 \text{ (approximately)}$$

Referring to the table, we find that the value c for a gear having 12 teeth is 14.9, and $2\pi c = 93.6$

Now taking a value for $f = 6000$ and a value for $\frac{b}{p} = 3$ and substituting these values in Formula (6) we obtain,

$$p^3 = \frac{93.6 \times 10{,}000}{12 \times 3 \times 6000} = 4.33$$

$$p = \sqrt[3]{4.33} = 1.63$$

The nearest standard diametral pitch is 1¾. The pitch diameter would therefore be 12 ÷ 1¾ = 6.857 inches, which gives a peripheral velocity of about $\frac{3}{4}$ feet per second, which is less than one. Therefore we were correct in using Formula (6). Had the velocity proved to be greater than one foot per second, we would have had to recalculate, using Formula (8) instead of Formula (6).

Example 3—The revolutions per minute of two shafts are to be 45 and 135, respectively. The horsepower to be transmitted is 100. The other conditions are to be the same as in Example 2.

Here the speed ratio is 1 to 3. As the velocities are considerable, it might be preferable to use gears having 15 and 45 teeth, rather than 12 and 36; the latter would be really smaller in diameter, yet they would probably not run as smoothly. The peripheral velocity may be assumed to be greater than one foot per second, as the pinion makes 135 revolutions per minute. Hence we will use Formula (8).

From the table we find that the value of $\frac{2\pi c}{\sqrt[3]{720}}$ for 15 teeth = 8.97

$$Pr = \frac{63025H}{n} = \frac{63025 \times 100}{135} = 47{,}000 \text{ (approximately)}$$

Take $\frac{b}{p} = 3$ and $S = 6000$,

Then from Formula (8), we get

$$p^3 = \left(\frac{8.97 \times 47000}{3 \times 6000}\right)^2 \times \frac{135}{225} = 7860$$

$$p^6 = \sqrt{7860} = 88.6 \text{ and } p^3 = 9.4 \text{ and } p = 3.06$$

The next larger circular pitch corresponding to a standard diametral pitch is 3.1416, which is a standard diametral pitch of 1. With 15 teeth, this gives a pitch diameter of 15 inches. The peripheral velocity of the gears would then be about 8.8 feet per second. As this velocity is greater than one foot per second, we were correct in using Formula (8). Had it figured out less, we would have had to recalculate, using Formula (6).

MAGNETIC TESTING OF DEPTH OF CASE

A demonstration of a magnetic method of determining the depth of case on small carburized and casehardened chain links was one of the interesting features of the recent New York sectional meeting of the American Society for Steel Treating. The demonstration was conducted by A. V. de Forest, research engineer of the American Chain Co., Bridgeport, Conn. The magnetic apparatus consisted of a simple form of inductance bridge operating on 60-cycle commercial current. The chain tested, which was made from wire ranging from 0.192 to ⅜ inch in diameter, is used as the cross-member of automobile tire chains, and consequently is subjected to wear from hard roads and from shocks produced by pounding over car-rails and cobblestones. If the case of the chain links is too thin, they wear out quickly, and if the case is too thick, they break in an even shorter time than it would take for soft links to wear out. It was to determine whether or not the depth of case is within the desired limits that the magnetic testing apparatus was developed.

The apparatus has a peculiar type of separately excited galvanometer which is used as an indicator, while a small rheostat and ammeter control the current operating the instrument, about 0.2 ampere at 110 volts being used. Resistance coils control the sensitivity of the instrument, and the deflections of the indicator can be adjusted to any desired limits. An adjustable resistance which balances the galvanometer is altered to compensate for different sizes of chain links or to change the scale of the instrument.

The magnetizing coil will operate on 1/16-inch wire, chain formed of ⅜-inch wire, or bar stock up to 1¼ inches in diameter. The outfit requires no setting up beyond connecting to an alternating-current lighting circuit. In testing a chain, several links are lowered into the magnetizing coil, the indicator of the galvanometer immediately moving across the dial and showing whether or not the depth of case is within the specified limits. Modifications of this apparatus would probably prove practical for testing other parts.

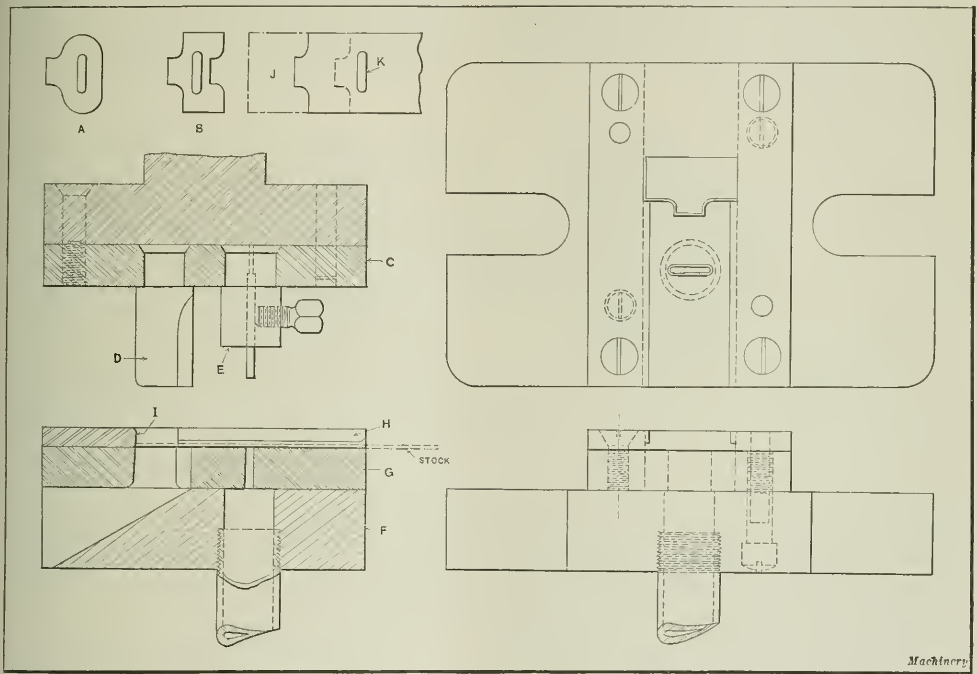
POWER TESTS OF A HEAVY LATHE

In order to determine the power and endurance of a certain type of lathe, the Houston, Stanwood & Gamble Co. recently conducted a series of tests on a 60-inch heavy engine lathe, driven by a Westinghouse 35-horsepower variable-speed motor. The results of these tests were as follows: At a speed of 15 feet per minute, and ¼ inch feed, a huge steel roll was reduced 3¾ inches in diameter, the depth of cut being 1⅞ inches. The ampere reading during the test showed that the motor was developing between 74 and 80 horsepower. Running the lathe at a higher speed of 35 feet per minute, with ¼ inch feed, a depth of cut of ¾ inch was next taken. The tests were completed by taking an eccentric cut, and one of the chips measured was found to be 1½ inches wide and 1 inch thick. In view of the fact that the motor was greatly overloaded in each particular case, the cuts were run for short periods only. In some instances the motor was relieved of the extreme strain by passing a continuous spray of air through it.

FOLLOW-DIE FOR SHEET-METAL KEYS

By S. A. McDONALD

The accompanying illustration shows a follow-die designed by the writer for manufacturing box-opener keys. The original design of these keys was as shown at *A*, but it was realized that by changing the design slightly, considerable stock could be saved. Accordingly, the key was redesigned as shown at *B*, which enabled a simpler die to be constructed. The construction of the die is as follows: A machine-steel punch-holder carries the machine-steel punch-plate *C* in which the shearing punch *D* and the machine-steel punch-holder *E* are riveted. The shearing punch is shaped to the contour indicated at *J*, which represents the shape of the stock cut off from the end when first fed into the die, and this punch is hardened only on the front cutting edge. The tool-steel piercing punch is secured in the holder *E* by a set-screw, so that it can be easily removed for regrinding. The die-block or shoe *F* is made of machine steel, and supports the hardened tool-steel die *G*, which is fastened by screws and dowel-pins to it. The stripper plate *H* is a machine-steel member, and serves not only as a stripper, but also as a backing plate for the shearing punch *D*.



Dies used in making Key from Strip Stock

The stock is fed into the die until it abuts against the stripper plate at *I*. The shearing punch *D* then descends, cutting out the piece *J*, and at the same time the piercing punch produces the hole *K* in the strip. On the next downward stroke of the ram a second piece is blanked out without a hole, and it is not until the third stroke that a completed piece, as shown at *B*, is punched out. By providing a suitable stop for the stock, even these two pieces of stock could be saved, so that there would be no waste except the punching from holes *K*. The keys are pushed through the die and slide down the inclined surface of the die-block and into a suitable receptacle. The scrap from the hole passes through a tube screwed into the under side of the die-block. A press of the inclinable type was used, operating at 200 revolutions per minute.

REPRODUCING LARGE DRAWINGS

By H. R. BOWMAN

A slide-rule can often be employed to advantage in making small-scale reproductions or copies of large drawings for notebooks, record files, etc., when no great accuracy is required. In using the slide-rule, first find the over-all length of the drawing and determine the corresponding length of the small-scale drawing to be made, and set the slide-rule so that the graduations on the C scale representing one dimension will be opposite the graduation on the D scale which represents the other dimension.

This gives the proportion between the two drawings; for instance, if the length of the large drawing is 27 inches and the corresponding length of the small-scale drawing is to be 9 inches, the proportion would be 9 to 27, or the small drawing would be one-third as large as the original. The 9 on the C scale would be placed over 27 on the D scale, or 1 on the C scale over 3 on the D scale. As the ordinary slide-rule has an inch scale on one edge, it can be readily used to scale the dimensions on the larger drawing.

After locating the graduation on the C scale that is equivalent to the measurement taken on the large drawing, the corresponding dimension for the small drawing can be read directly opposite on the D scale. The writer has found this method a very convenient one for properly proportioning the lines on a small-scale drawing, especially where the scale of the smaller drawing is one not generally employed.

Firms who have occasion to employ the services of legal advisers in foreign countries will be interested to learn that the Division of Commercial Laws, Department of Commerce, is compiling a list of names of attorneys practicing in foreign countries who have been recommended by trustworthy sources as competent in their profession and in a position to care for American interests. These names will be furnished to American business houses on request.

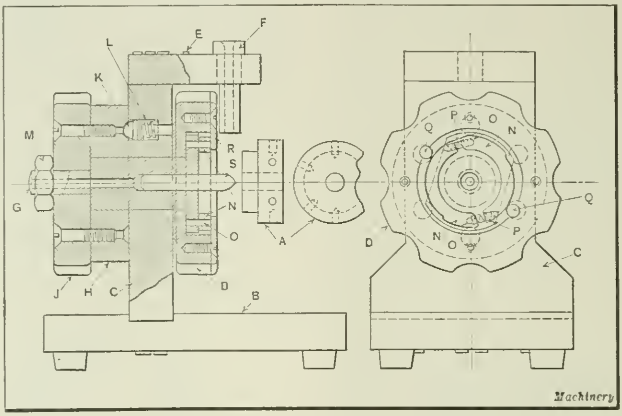
INDEXING DRILL JIG

By C. G. YOUNGQUIST

A quick-acting indexing drill jig designed to lower production costs is shown in the accompanying illustration. The work for which this jig was designed consists of drilling six equally spaced radial holes on the outer edge or circumference of an aluminum piece such as shown at *A*. The holes are required to be spaced quite accurately, as the drilled piece is made to serve as a sprocket by driving short pins into the holes. The fixture is mounted on a base *B* which has four short feet. An upright *C* is fitted into a slot in base *B*, and fastened by screws. Upright *C* is made narrower at the top so that handwheel *D* can be easily gripped.

A plate *E* carrying bushing *F* is fastened to the top of upright *C*. A shouldered stud *G* carries on one end the handwheel *D*, and on the other the index-plate *H* and the handwheel *J*. The latter is fastened to the index-plate by means of screws as shown. Both handwheels are notched so that a good grip can be obtained. The face of the index-plate in contact with upright *C* has six countersunk holes in it, equally spaced on a circular line. A plunger *K* engages the indexing holes, and is held against the plate by a coil spring *L*. The plunger has a half-spherical head and a shank of small diameter, and is made a sliding fit in a hole in upright *C*.

Both index-plate *H* and plunger *K* are hardened. Handwheel *J*, index-plate *H*, and stud *G* are held together by nut *M*. These parts, being rigidly fastened to each other, operate as one solid piece. Wheel *D* is counterbored to receive the head of stud *G* and the two clamping jaws *N* which swing on pins *O*, driven into holes in the head of stud *G*. The jaws are semicircular in shape and are located centrally from their inner surfaces; they are held apart by two small springs *P*. The springs are located in the holes drilled in the ends of jaws *N* as shown.



Indexing Drill Jig with Quick Loading and Unloading Features

The outside surface on each jaw is also semicircular, but is offset in such a way as to provide a clamping action when acted upon by pins *Q* embedded in handwheel *D*. Pins *Q* and jaws *N* are hardened. A guard plate *R* is fastened to the outside of handwheel *D*, to keep the chips out and to hold the jaws in place. The guard plate is omitted in the end view in order to show the chuck jaws more clearly. A locating pin *S* is driven into a reamed hole in stud *G*. This hole is extended through the stud to provide for driving the pin out in case this should become necessary.

The head of stud *G* is milled away on two opposite sides to give the necessary clearance for pins *Q*. The movement of handwheel *D* relative to stud *G* is limited by the clearance spaces milled on the head of stud *G*. In loading the jig, wheel *J* is held in a fixed position, while wheel *D* is turned to the left to give the jaws the largest possible opening. The work is then centered on pin *S*, and pushed up against guard plate *R*. Wheel *D* is then turned to the right until the work is securely clamped by jaws *N*. After drilling a hole, the drill is withdrawn and the wheel *J* turned until the spring-actuated plunger *L* is forced out into the next countersunk spacing hole in the index-plate *H*, which locates the work for drilling the next hole. This operation is repeated until the six holes are drilled. To obtain the best results, the jig is clamped in position on the drilling machine table and the drill set to the desired depth. The quick and effective loading and unloading feature of this jig, combined with the simple convenient method of indexing, not only resulted in lowering the production cost, but also made it possible to maintain a uniform quality of work.

BRITISH MARKET FOR SMALL TOOLS

According to a special report just issued to its members by the American Chamber of Commerce in London, there is practically no market for American small tools in Great Britain at the moment, but it is generally agreed that when trade becomes more normal, certain small tools, for which there was previously a good market will again be in demand.

The presence of large stocks in the hands of the government and dealers, and severe foreign competition aggravated by depreciated exchanges are the chief factors affecting American trade. In addition, the price of American precision tools has been considerably increased by the imposition of an import duty of 33 1/3 per cent owing to these tools being scheduled as a key industry under the Safeguarding of Industries Act.

The report further discusses the future position of American small tools, pointing out that in some instances American designs have been copied and are now being manufactured by British firms. Hints on marketing are also given, and American firms that contemplate entering the British market are advised to take up the question with the American Chamber of Commerce in London, which is always willing to give the benefit of its experience to such firms. Full details are available only in the report which has been circulated to members, but firms interested can secure copies by writing to the American Chamber of Commerce in London.

* * *

OBTAINING CHINESE TRADE

A forward-looking innovation in the development of foreign trade has been made by the South Bend Lathe Works, South Bend, Ind. This company has published an instruction book in Chinese containing eighty pages relating to lathe operation. The book is a translation of the company's well-known text-book, entitled "How to Run a Lathe," which has been widely distributed among trade schools. This is undoubtedly a step forward in the development of Chinese trade, because it is generally recognized that the manner in which this trade will be obtained is by American machinery gaining a place in Chinese trade and technical schools. In many instances the book contains the English names of machine tool parts and processes, doubtless because there is no equivalent word in the Chinese language, and before long these English words will be accepted and become incorporated into the Chinese language. The Far Eastern trade in machine tools has increased rapidly during the last ten years, and machine tool builders who keep in touch with the developments in that section of the country will doubtless find it worth while, even if immediate results should not be obtained.

TAPPING AND TAP DESIGN

By J. C. NICHOLSON

In tapping bottoming holes in cast iron, the use of a great amount of oil is objectionable. When too much oil is used, the fine chips or particles of cast iron invariably float into the spaces back of the cutting edges where the tap is backed off for clearance. These particles cause the tap to wedge in the hole as it is being backed out, making it more difficult to remove, besides causing the lands or clearance to be worn down more rapidly. If just enough oil to make a stiff paste of the chips is used, these difficulties will be avoided. The advantage of getting most of the chips out of the hole, thus leaving it clean for the part that is to be screwed into it, will also result from this practice.

The foregoing applies particularly to hand tapping, although it should not be disregarded in tapping by power. In the latter case, since the work is done more rapidly, more oil may be required to insure its reaching the right point soon enough to have the desired effect. In any case, however, cast iron requires but little lubricant when being tapped, and may even be tapped without it, though the practice is not recommended on all classes of work.

Tapping Holes in Steel

In tapping a bottoming hole in steel—particularly tough steel—the requirements are exactly the opposite. Here it is absolutely necessary that a copious supply of lubricant reach the cutting point. In order that it may do so, one of two courses must be followed: Either the tap must operate very slowly and be flooded with oil under pressure, or it must be stopped and backed up just a little at frequent intervals in order to allow the lubricant to reach the front of the cutting points. In tapping steel by hand, it is common practice with machinists to back the tap frequently until the chip is broken, the idea being that this allows the tap to cut more freely. The fallacy of breaking the chip may easily be proved by backing the tap only a very little at frequent intervals, putting no stress whatever on the reverse side of the lands. This allows the lubricant to reach the front of the cutting side of the lands where it is needed, and it will be found that the work proceeds just as well as when the tap is backed a sufficient amount to cause the back side of the land to shear off the chip. Breaking the chip does not help matters, and the lands were never designed for this purpose. It is evident therefore that the only useful purpose served by backing up the tap is that of permitting the oil to reach the proper place.

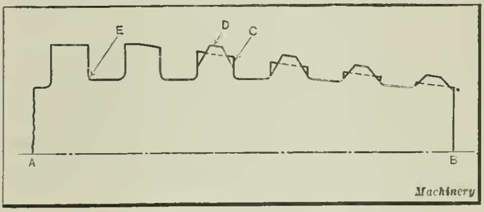
Of course, if a hole is very deep it may become necessary to remove the tap in order to clean out the chips that fill the flutes. In any case these chips will be found broken, and it is the breaking of the chips that consumes much of the power required for the tapping operation. Anything that obstructs the free movement of the chip—even at some distance from the cutting point—will have a decided effect upon the cutting action. If, for instance, in turning a shaft, some obstruction is placed squarely in the path of the chip, even though it is two or three inches from the tool point, the additional resistance to the chip will produce a noticeable effect on the work. The work will be left rough and the tool will heat more rapidly as a result of obstructing the chip. Of course, in the case of a tap, the chip is being more or less violently obstructed at all times—especially when tapping material that does not easily break in pieces—and this no doubt makes lubrication in such cases all the more necessary. The shape of the flute will, of course, have some influence on the cutting action.

Difficulty in tapping is sometimes due to the taps being so made that too little stock is removed by each cutting point. Many taper taps have a longer taper than is desirable for general use. A plug tap will often do the work from the beginning and operate almost as easily as a starting tap. The writer believes that taper taps in general would be improved by making the tapers about half as long as they are usually made. The practice of making pipe taps with half the cutting points removed is excellent.

Tool for Tapping Square Threads

In tapping square threads in steel there is a tendency for the chip to bind in the groove, which often results in breaking the tap. A tap made as described in the following will effectively overcome this difficulty. Referring to the accompanying illustration, *AB* is the center line of the tap. The tap has four flutes, and as far as the tapered portion extends, two opposite lands have threads of truncated V-shape as shown at *D*. The other two lands have square threads as shown at *C*. The last few threads on the tap are all alike, thus insuring the finishing of the thread to the correct size and form. In the illustration two adjacent lands are shown superimposed one upon the other in order to indicate more clearly how the tap is made.

It will be seen that for most of the tapered distance the diameter across the truncated V-lands is greater than that of the other two lands. The truncated points will therefore cut deeper than the square ones, thus leaving a slight V-thread in the bottom of the square thread, so that as the succeeding square points begin to cut, the chip will be in two parts. This prevents the objectionable binding in the grooves previously mentioned. For instance, as the tap is turned to the right, land *D* takes a cut of truncated V-form, while land *C* following this cut removes metal only at its corners.



Tooth Profiles of Tap used for cutting Square Threads

The taper and other features are purposely exaggerated in the illustration in order to make clear the principle involved. The tap is made by first cutting a square thread having the same taper and diameter as the truncated lands. After it is fluted, two of the opposite lands have the threads formed to the shape indicated at *D*, while the other two are made as shown at *C*. This work may all be done with a file, since uniformity is unimportant and in fact undesirable in many cases. A tap of this design was thoroughly tried out in tapping nuts for pipe wrenches. Although the pipe wrench nuts were made from tough steel, the tap cut rapidly and produced accurate threads when used with a drilling compound as a lubricant. The corners at the bottom of the tap thread are filleted slightly, as shown at *E*. In this way all burrs were removed from the nut so that the thread was left smooth.

* * *

It has been asserted that one of the causes of high railway rates is the large salaries paid to executives of the road, and that the first step in decreasing expenses should be to reduce these salaries. In this connection the following facts, taken from the *Review of Industry* are illuminating. If all salaries of general officers of steam railroads in the United States in 1920 had been abolished, rates and fares could not have been reduced as much as 1 per cent. If the total of all general officers' salaries of 1920 had been added to the employes' payroll for that year, it would have increased the men's wages only 1.3 per cent. It will be seen from the foregoing that the item of salaries of general officers in such an extensive business as railroading is not a major part of its expense.

The Machine-building Industries

It is gratifying to be able to report a slow but definite improvement in the metal-working industries. This improvement is especially noticeable in the automobile manufacturing districts of Michigan, northern Ohio and Indiana, and in the Ohio and Pennsylvania iron and steel districts. The demand for standard lines of machine tools is still very small, but a majority of the machine tool builders we have seen state that their sales for the last three months exceed the sales for any similar period during the last eighteen months. The demand for special and single-purpose machine tools, on the other hand, is increasing to a considerable extent. Several of the makers of machine tools of this type say that their February business was 50 per cent, or more, of the average for the first three months of 1920, which has been taken as a basis of comparison by the National Machine Tool Builders' Association.

Another indication of increased activity is found in shops specializing in pressed parts, especially in the Central States, where several shops are running at 100 per cent capacity, one, at least, even employing a night shift. The tool and contract shops in and around Detroit, Toledo, and South Bend—the centers where the automobile business shows the greatest activity—also report a satisfactory volume of business, but competition is keen and prices consequently very low. Other evidences of increasing business in the machine-building field are improvements in the sales of ball bearings and better business in bearing bushings for machine tools and other lines of machinery.

General Conditions in the Machine Tool Industry

It is impossible at this time to make a general statement about conditions and prospects in the machine tool industry that would cover the industry as a whole. Conditions vary greatly according to locality and lines of machines manufactured. Some manufacturers report that during the last two months there has been a very active demand for gear-hobbing machinery and for small electrical grinders. In the lathe field the demand has been mainly from technical and trade schools, and four orders are under way for over forty machines each from this source. But on the whole the current trade school's demand for machine shop equipment has been somewhat overestimated because of the relatively light demand for machines for general industrial purposes.

The garage and repair shop demand for machine tools is still fairly active, but price is so important a consideration that some machine tool builders are considering building cheaper tools than their standard products in order to meet the specific needs of the repair shop.

Although the demand for standard types of machine tools has been quite small during the last year, the industry as a whole is in a healthier condition than it was a year ago. Early last summer most of the manufacturers ceased adding to their stocks, and the total stocks of practically all standard tools are materially reduced, compared with last June. In the case of upright drilling machines, present stocks are only 60 per cent of what they were nine months ago.

Taking Care of Excess Plant Capacity

Many machine tool manufacturers are turning to other fields of machine-building and metal-working as an outlet for their excess shop capacity. It is generally recognized that plant capacity in the machine tool field is from 30 to 40 per cent in excess of probable requirements for several years to come. This excess capacity is being gradually utilized for other purposes. Pistons, piston-rings, woodworking machinery, foundry machinery, bakery machinery, excavating and road-building machinery are among the lines upon which machine tool builders have entered, in addition to those previously mentioned in MACHINERY—laundry and domestic washing machines, printing presses, motorcycles, automatic refrigerators, automatic ice-cream freezers, etc.

The machine tool industry has gradually adjusted itself to the reduced volume of business that seems inevitable during the next two or three years compared with the war period. Some of the firms doing from 50 to 60 per cent of the business of the peak period have accepted this as normal business, and others now doing 30 per cent of their peak business figure this to be 50 per cent of a normal business. Many machine tool builders have so reduced their greatly expanded overhead and their organizations that they are able to make a profit when operating at 30 per cent capacity, and some have readjusted their business to a pre-war basis. These steps are even more important for the healthy advancement of the industry at the present time than an increasing volume of business. The heaviest drag on the industry has been the war-time overhead which was out of all proportion to the demands likely to be placed on the industry within the near future.

Prices of machine tools have been reduced by many makers to a definite low level, and it would undoubtedly be for the benefit of the entire industry if all manufacturers would definitely determine upon selling prices that can be maintained, and then adhere to those prices without deviation. The uncertainty as to prices that exist in some lines of machine tools retards the resumption of buying.

Reduced Costs Due to Improved Machine Tools

In this review in March MACHINERY several examples were given showing how costs have been reduced by the application of modern machine tools. Other examples have come to MACHINERY's attention offering comparisons of unusual interest. In one case an automobile manufacturer employed eight machines of a standard type, working two shifts and requiring sixteen operators, the production being 50 pieces in 22 hours. The cost of the machine and tool equipment was $26,000. This equipment was replaced by a single-purpose machine occupying considerably less floor space, which requires only four operators, working in one shift. The cost is only $11,000 and the production 63 pieces in 9 hours.

In another case two machines and two men produced 25 pieces per hour, while a new machine requiring but one operator produces 37 pieces per hour. The cost of this machine is $2300, and the direct saving is $1800 a year.

The Automobile Industry

It is frequently stated that the automobile industry is operating at from 50 to 60 per cent capacity, but it is also generally conceded that the normal demand on the industry for some years to come will not be materially above 60 per cent of the total output capacity of existing automobile plants. Hence many of the plants that now operate at from 60 to 75 per cent capacity might well be said to operate at a normal rate of output. The competition in the automobile field is very keen, and certain standard makes of cars appear to have taken a definite lead over their competitors, by reducing costs and prices to the lowest practicable levels Some of the leading plants are carefully and thoroughly revising their manufacturing methods, and are installing machinery that will reduce costs.

The substance of this month's review of the machine-building industries is that the period of decline is definitely ended, the heavy liquidation is about completed, and the slow climb upward has really started.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW AMERICAN METAL-WORKING MACHINERY

The New Tool descriptions in MACHINERY are restricted to the special field the journal covers—machine tools and accessories and other machine shop equipment. The editorial policy is to describe the machine or accessory so as to give the technical reader a definite idea of the design, construction, and function of the machine, of the mechanical principles involved, and of its application.

Walsh Power-press Push or Pull Feed

Automatic feeding of stock of various widths on any make of power press may be accomplished by means of a mechanism now being placed on the market by the Walsh Press & Die Co., 4709 W. Kinzie St., Chicago, Ill. An application of this mechanism is illustrated in Fig. 1, and a close-up view of all members except the connecting-rod and eccentric crank is shown in Fig. 2. The casting on which the members shown in Fig. 2 are mounted is attached to the bolster plate of the press by means of four cap-screws which pass through slots in the casting. This method of attachment permits shifting the cap-screws to suit the holes in a bolster plate.

Power for the mechanism is derived from the eccentric crank *A* which is mounted on the main shaft of the press. Adjustment of the pin by means of which connecting-rod *B* is attached to this crank provides for obtaining any desired feeding movement of the stock past the die. At the lower end of the connecting-rod is a vertical rack which meshes with a pinion on one end of a horizontal shaft. A second pinion mounted on the opposite end of this shaft meshes with rack teeth on the under side of pusher-rod *C*. The stock is held in grooves machined in the inside faces of pusher rod *C* and the stationary rod *D*. During each return stroke of the press ram, rod *C* moves toward the right and pushes the stock forward (when the mechanism is arranged for pushing the stock to the die).

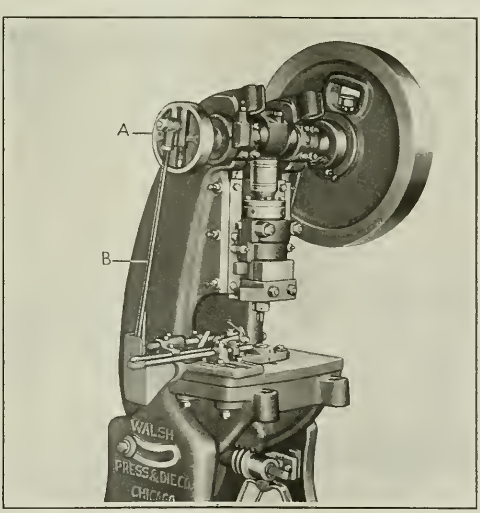


Fig. 1. Application of a Power-press Stock-feeding Mechanism placed on the Market by the Walsh Press & Die Co.

Gripper *E* holds the stock and causes it to move forward with rod *C*. When the stock has been advanced to the required position over the die a trip on the gripper comes into contact with the adjustable dog *G* and releases the hold of the gripper on the stock. Rod *C* then pulls the gripper back, and while this movement takes place an adjustable retaining pawl *I* prevents the stock from moving. When the gripper has returned to the desired point the trip engages a second adjustable dog *J*, which re-engages the stock for the next operation. A handle on the gripper provides for releasing its hold on the stock at intermediate points when necessary.

Ordinarily a V-point is used on the gripper, but a floating flat-ended contact point may be substituted. This will insure that a secure grip is obtained on the stock without marring the surface in any way. From the description it will be evident that the operation of the device is positive and that by adjusting the positions of the dogs G and J, the stock may be fed to the die without unnecessary waste of material.

When it is desired to use the mechanism for pulling the stock to the die instead of pushing it, the position of crank A is changed 180 degrees on the press shaft. The stock will then be pulled from the right instead of being pushed from the left. Crank A is mounted on a plate by means of cap-screws placed in circular slots. This design provides for readily adjusting the movement of the feeding mechanism to the proper relation with the movement of the press ram.

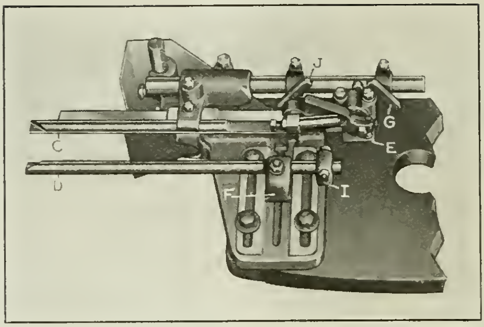

Fig. 2. Close-up View of Walsh Stock-feeding Mechanism for Power Presses

After the device has been attached to a press and the correct relation has been obtained between the feed and the ram movements, the next step is to adjust the mechanism to suit the width of stock to be handled. This is done by shifting the position of bracket F which holds rod D. The bolt on this bracket serves the double purpose of clamping the bracket to the attachment in the proper transverse position to suit the width of the stock and also of setting the rod in the desired longitudinal position relative to the die. The pinion under the reciprocating rod C is next released from the rack teeth of this rod and the rod moved longitudinally to the desired setting, after which the pinion is again placed in mesh with the rack. The mechanism is now set for operation.

HOLLANDER ADJUSTABLE BROACHES

The broaching of square and hexagonal holes, splines, keyways, and round grooves in small lots of work may be accomplished economically by using adjustable broaches made by the Edward Hollander Tool Co., 142 Miller St., Newark, N. J. These broaches are intended to be attached to the spindle of a drilling machine, ram of a shaper or arbor press, toolpost of a lathe carriage, or other machine members suitable for traversing a tool without rotating it. The broaches are made in various styles, the square and hexagonal types being regularly made in all sizes from 1/4 to 3/4 inch across flats. As will be seen in Fig. 1 at A, the broach is held in a holder having a micrometer adjustment. Each broach is hollow, the front end being ground to the shape of the hole to be produced and split. The rear end is threaded as shown at D and E to screw into the holder.

A rod extending through the hollow broach has a pilot screwed on the forward end after the broach has been assembled. This pilot is of the same diameter as the hole to be machined, and thus serves to keep the entire unit steady in an operation. The pilot is provided with ribs which engage the splits of the broach and keep the cutting edges of the tool from swerving sidewise. A detail view of a pilot is illustrated at C. The pilot is also employed for adjusting the cutting edges. Prior to the first cut, the ribs of the pilot only slightly engage the splits of the broach. Then, after the broach has been given one pass through the work, the pilot is pulled back to engage the splits a greater amount. In doing this, the taper surface of the pilot causes the cutting edges of the broach to be expanded.

The adjustment of the pilot is accomplished by revolving the knurled member of the holder the desired number of graduations, each of which represents an expansion of 0.001 inch of the cutting edges. By forcing the broach through the work a number of times and making an adjustment after each traverse, the work may be machined satisfactorily to the required dimensions. Each broach is supplied with a gage ring for setting the cutting edges properly to take the first cut. A number of parts finished by broaches of this type are illustrated in Fig. 2.

WARNER & SWASEY STAYBOLT THREADING MACHINE

A machine intended for threading staybolts in railroad shops has been placed on the market by the Warner & Swasey Co., Cleveland, Ohio. This machine is really the No. 4 turret lathe manufactured by this concern provided with a special attachment instead of the regular turret slide and saddle. When not required for staybolt threading, the attachment may be replaced by the regular turret slide and saddle and the machine used for the production of the miscellaneous studs and bolts ordinarily required in railroad shops. The machine is capable of cutting any size of thread on crown, buttonhead, and swivel staybolts up to 40 inches in length. Self-opening die-heads are supplied to meet the requirements of the particular shop in which a machine is installed. In an operation on upset buttonhead forgings which were taper-formed under the head and on which a thread was cut both under the head and on the opposite end, the production rate was one staybolt per minute.

The rough forging is passed through the forward die-head into the square collet of the automatic chuck. The die-head has an enlarged hole in the shank, and the chasers open

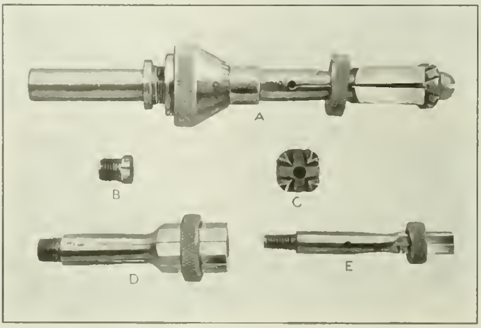

Fig. 1. Adjustable Broach made by the Edward Hollander Tool Co.

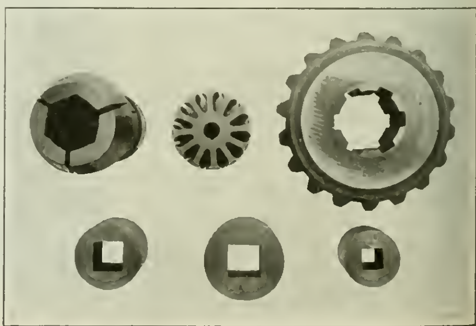

Fig. 2. Specimens of Work produced by using Adjustable Broaches

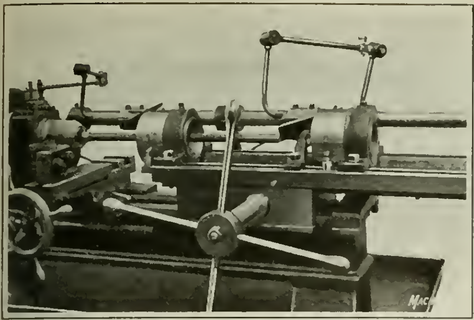


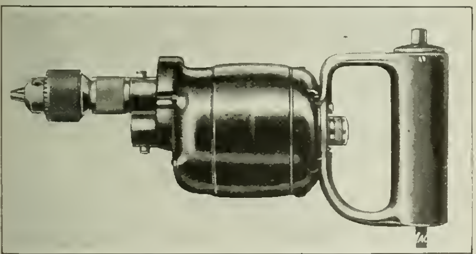
Staybolt Threading Machine built by the Warner & Swasey Co.

exceptionally wide to enable the staybolt to be chucked in this manner. After the work has been chucked, the staybolt carriage is fed forward until the extended end of the bolt is supported in the steadyrest between the two die-heads. The head end is then formed by a cutter on the cross-slide, after which the staybolt carriage is again fed forward during which time the die-heads, being operated by cams at the rear, close automatically and cut the threads.

When the die-heads have passed the cams, the die-heads again open. The carriage is then returned to the back end of the machine. As the action of the heads is dependent on the contour of the cams, the latter are made to suit the job. The threads on both ends of the staybolt are cut in a continuous lead, the thread on the extended end being cut without any previous machining.

JONES PORTABLE ELECTRIC DRILL

A portable electric drill of 1/4-inch capacity equipped with a high-speed universal motor operating on either direct or alternating current, has been placed on the market by the Consolidated Instrument Co. of America, Inc., 41 E. 42nd St., New York City. The gears are of the helical type, cut from tool steel, heat-treated and mounted on shafts ground to size. Ball bearings are provided to take the end thrust of the spindle. The spindle is equipped with a No. 1 Jacobs chuck. The housing is an aluminum casting having a black finish. The over-all length of this tool is 10 inches; the greatest diameter of the motor, 3 inches; and the weight of the equipment, about 4 pounds.

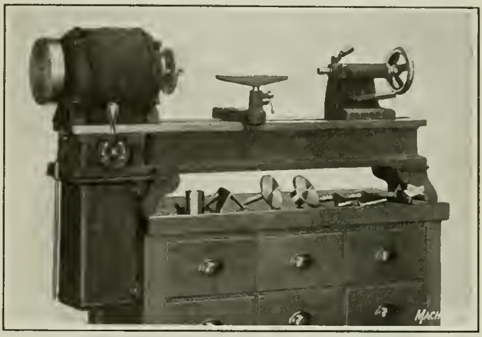


Jones Portable Drill placed on the Market by the Consolidated Instrument Co. of America, Inc.

BLOUNT MOTOR-HEADSTOCK PATTERN-MAKER'S LATHE

Patternshop foremen and vocational school instructors will be interested in a bench wood-turning lathe, having a 12-inch swing, which is now being placed on the market by the J. G. Blount Co., Everett, Mass. From the illustration it will be apparent that the driving motor is contained in the headstock. The rotor, outside frame, and necessary windings of the headstock are supplied by the Westinghouse Electric & Mfg. Co. Openings at the bottom of the motor frame provide for connecting leads to the controller directly beneath. The motor end brackets are without openings, and so the unit is fully enclosed. The spindle bearings are mounted in dustproof housings, S K F bearings being furnished. A handle on the front of the bed beneath the headstock is manipulated for starting and stopping the motor. The controller has four running positions giving spindle speeds of 575, 1160, 1750, and 3450 revolutions per minute.

The spindle is made from 0.45 per cent carbon steel, is ground, and has a hole 5/8-inch in diameter bored throughout its entire length. A No. 2 Morse taper hole receives the center. By providing a taper hole of this size, a larger hole may be bored through the spindle than would otherwise be possible. The spindle nose is threaded to receive faceplates, screw or hollow chucks, and other similar equipment. The bed is made in 4-, 5-, and 6-foot lengths, the maximum distance between centers on the 4-foot bed being 25 inches.

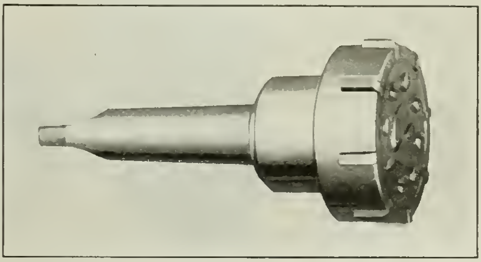


Alternating-current Motor-headstock Wood-turning Lathe made by the J. G. Blount Co.

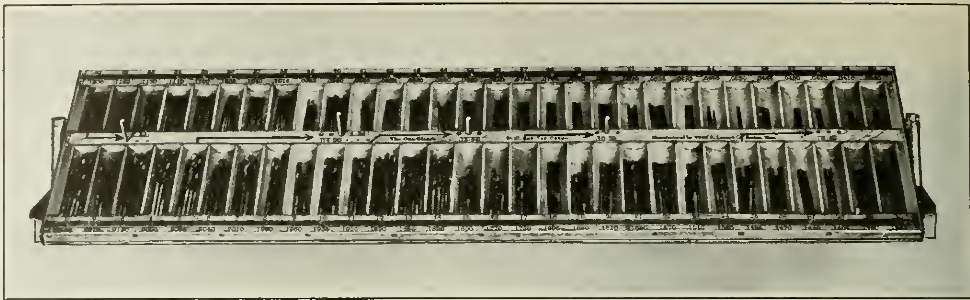
CAMPBELL EXPANDING CYLINDER REAMER

A reamer or boring head intended for refinishing automobile cylinders and having an expansion of approximately 3/8 inch has been brought out by the Campbell Auto Works, 238-240 N. El Dorado St., Stockton, Cal. This head may be screwed on the end of a boring-bar for application on machines of different types. The adjustable members of the reamer are concealed within the head so that dirt or chips cannot interfere with the making of an adjustment. During an adjustment the blades remain in the same relation to one another, and so do not require regrinding to true them up.

An adjustment is quickly and accurately made by first loosening the eight screws on the face of the head which hold a plate securely on the cutters. As the screws are loosened,



Expanding Reamer or Boring Head brought out by the Campbell Auto Works



"One-glance" Drill and Tap Crib made by the Victor R. Lawson Co., which makes it Possible to determine quickly what Drills may be used with a Given Tap

the plate is raised by four coil springs in the body, after which the cutters are free to slide easily in the radial slots in which they are contained. By finally turning the center adjusting screw on the face, the blades are forced outward or inward as desired, and after an adjustment the eight screws are retightened to lock the blades. This reamer is made in different sizes up to 4½ inches in diameter. It has a wide application in turret lathes and similar machines. Application has been made for a patent on this tool.

AMERICAN AMPLIFYING GAGE

An amplifying gage which differs from a larger gage of this type manufactured by the same concern, in that it is limited in range and does not have all the attachments supplied with the larger gage, is now being introduced to the trade by the American Gauge Co., Dayton, Ohio. The new gage is made in two sizes, one of which is intended for work from ¼ to 2 inches in diameter, and the other for work from 2 to 4 inches in diameter. The larger amplifying gage was described in detail in April, 1918, MACHINERY and several of its applications were mentioned in the article entitled "The Delco Inspection System" which appeared in September, 1921, MACHINERY.

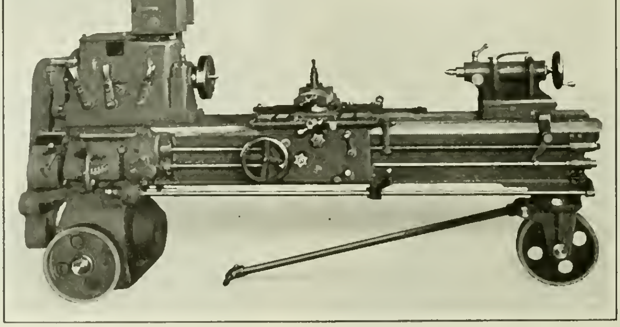
LAWSON DRILL AND TAP CRIB

A drill and tap crib in which gaging holes readily show the proper compartment in which a drill should be placed according to its size has been placed on the market by the Victor R. Lawson Co., 35 Hartford St., Boston, Mass. Another feature of the crib is that the location of the holes for the taps indicate the drills with which a tap of a given size may be used. As will be seen from the illustration, this crib has sixty semicircular drill compartments arranged in two rows. Just above the top row and below the bottom row is a series of gaging holes in a hardened steel strip. Above each of the holes is the number of the drill for which the compartment adjacent to the hole is intended. Beneath the hole is the decimal diameter of the drill. The holes for the taps are located in the maple strip separating the two rows of drill pockets, the taps being held in a perpendicular position. There are three holes for each tap size, each set of holes being arranged adjacent to the correct drills for drilling either a full-, three-quarter-, or half-thread hole. For example, 14-20 taps are in line with the pocket for No. 10 drills. This signifies that a drill of this number is suitable for drilling a hole to have a full thread when tapped by means of a 14-20 tap. The arrow line running from the tap holes to the pocket for No. 5 drills indicates that a drill of that number is the largest that may be used with a tap of this size, a No. 5 drill thus being suitable for drilling a hole in which a half thread is to be tapped.

Each tap hole has sufficient clearance for the tap body except at the bottom where the hole is just small enough to prevent the tap from sliding through. The next smaller size of tap will slide through, and this indicates that it is not the size for which the hole is intended. This crib is mounted on supports which permit it to be tilted to different angles.

LEHMANN PORTABLE GEARED-HEAD LATHE

For use in railroad and other shops handling comparatively large work, where it is often necessary to bring the machine tool to the job, the Lehmann Machine Co., 3560 Chouteau Ave., St. Louis, Mo., has brought out a portable geared-head lathe which, except for the portable feature, is similar to the Lehmann lathe described in January, 1921 MACHINERY. The lathe dealt with in the present article is motor-driven through a belt and pulleys, the speed of the motor being 1800 revolutions per minute. The motor is mounted in the cabinet of the lathe at the head end of the machine. All driving members are covered by suitable guards. The headstock gives sixteen spindle speeds through ten heat-treated gears. The shafts of the headstock run in ball bearings, with the exception of the spindle, which has phosphor-bronze bearings. Two surfaces of different diameters are provided on the spindle nose for faceplates and chucks. Forward or reverse rotation of the spindle is obtained through patented friction clutches which run in oil and are operated by two handles located on the control rod.



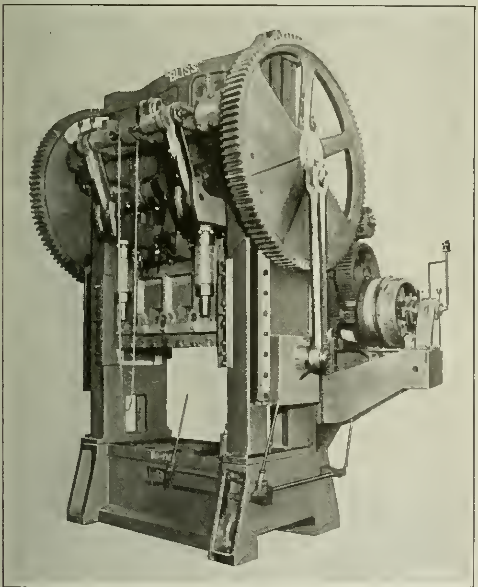
Portable Geared-head Lathe built by the Lehmann Machine Co.

BLISS DOUBLE-CRANK TOGGLE PRESS

During the last few years rapid strides have been made in the development of steel stampings to replace castings, especially in the automobile industry. In order to keep pace with such requirements, it has been necessary to build power presses of sizes and capacity far beyond the dreams of a decade ago. The accompanying illustration shows a press built by the E. W. Bliss Co., Brooklyn, N. Y., for the purpose of drawing pressed-steel axle housings for automobile trucks. These housings are drawn in two sections from steel 3/8-inch thick, which are later welded together. The press is of the tie-rod construction, twin-driven and triple-geared. The ratio of the gearing is 85 to 1. All gears are made of steel, and have machined teeth.

Power is transmitted from the main driving gears to the outside slide or blank-holder through a series of toggles, a dwell of 120 degrees being obtained. In order to keep the construction simple, and at the same time avoid torsional strains, power is transmitted to the blank-holder from both sides of the press. This method is also followed for driving the crankshaft that operates the inner slide, the crankshaft having a driving gear on each end. A 15-horsepower motor mounted on the front of the crown furnishes power for adjusting the inner slide or plunger. The press is driven by a 100-horsepower motor through a hand-actuated friction clutch of the double-grip type.

Some of the principal dimensions of the machine are as follows: Distance from bed to inner slide (stroke down and adjustment up), 59 inches; distance from bed to outer slide (stroke down and adjustment up), 56 inches; stroke of inner slide, 28 inches; stroke of outer slide, 20 inches; area of blank-holder face, 5 feet by 8 feet 6 inches; and area of plunger face, 3 feet by 7 feet 3 inches. The weight of this press is about 300 tons.

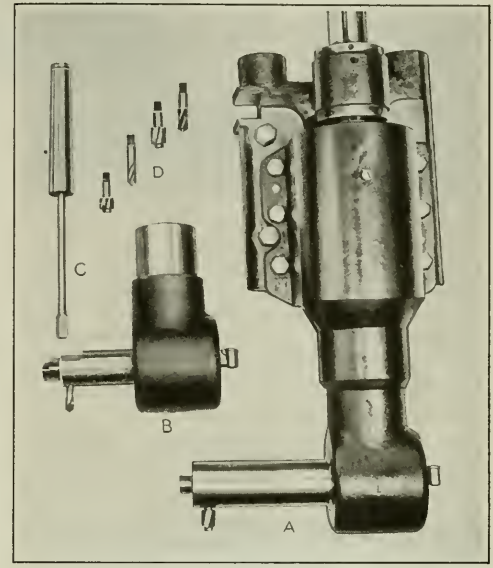


Double-crank Toggle Press built by the E. W. Bliss Co.

HARRIS OFFSET DRILLING ATTACHMENT

Port holes and grooves in pneumatic drills, hammers, and riveters can be conveniently drilled, milled, countersunk, and counterbored by the use of an offset drilling attachment brought out by the Harris Engineering Co., Bridgeport, Conn. Another style of offset drilling attachment made by this company for use in standard lines of manufacture was described in September, 1917, MACHINERY. The attachment here dealt with is made to reach into the main bore of the work, and to drill or mill from the inside. It is possible to drill to a specified depth and mill circular, transverse, or longitudinal slots.

Owing to the long overhang under which the tool must work, the offset arm is made as large in diameter as the bore of the air chamber and the depth of the drilling or milling will permit. The entire patented transmission and the offset arm are made from vanadium tool steel and heat-treated. The drills, mills, and counterbores are ground and lapped to fit the spindle in the outer end of the arm. They can be quickly interchanged, and have a limited adjustment for depth which allows for grinding, setting, etc.



Offset Drilling Attachment made by the Harris Engineering Co.

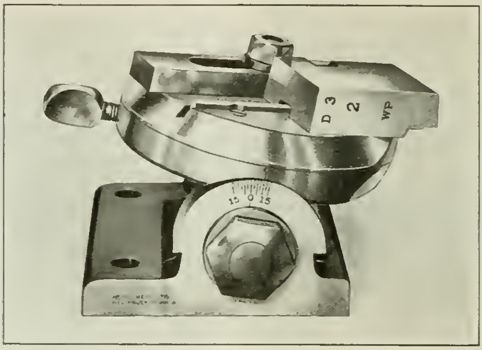
An attachment mounted in a special bracket provided on a vertical milling machine is shown at *A* in the accompanying illustration. To the left of this at *B* is an attachment having a shorter arm which is interchangeable in the special bracket. Spindle *C* has a taper shank that is inserted in the regular machine spindle, while the lower end is squared to fit a hole in the attachment and thus transmit power to it. Several tools for the attachment are shown at *D*. This equipment may also be used for the inside drilling or milling of oil-grooves, straight or spiral holes for holding babbitt in bearing boxes, blind keyways to retain a feather or key, etc.

GEOMETRIC CHAMFER GRINDING FIXTURE

One of the essential points in thread chaser grinding is that the chamfer be ground an equal amount on all chasers of a set. When the chamfer is ground unevenly, the burden of cutting comes on one or two of the chasers with the result that threads are cut out of lead, tapered, or with other irregularities. In order to grind thread chasers satisfactorily, the Geometric Tool Co., New Haven, Conn., has brought out the fixture here illustrated. This fixture is intended principally for grinding chamfers on the Geometric milled form of chasers, but it may also be used for grinding chasers of the tapped form. With chasers of the latter form, however, the grinding is straight and does not conform to the contour of the chaser threads.

The table of the fixture is graduated and may be set for grinding long or short chamfers. The narrow key engages the keyway of the chaser and acts as a guide while grinding. An adjustable stop governs the position of the chaser with respect to the grinding wheel. The side of the fixture is also graduated to enable the table to be tilted accurately to the desired angle of chamfer clearance. One fixture accommodates all sizes of chasers, and left- as well as right-hand chasers can be ground. When used for 5/16-inch chasers, it is necessary to remove the key, and guide the chaser in the keyway.

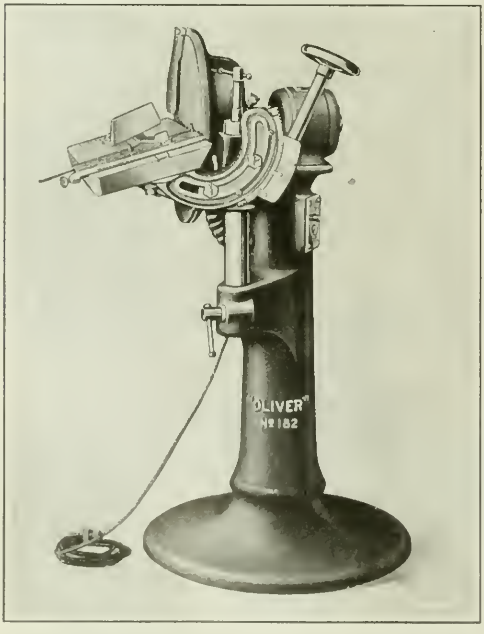
When the fixture is bolted to the table of a grinding machine, the chaser must be slid forward by hand to the wheel and against the stop provided on the fixture. However, on machines that permit of so doing, the chaser may be fed forward by means of the machine handwheel or lever to a stop arranged on the machine. The fixture may also be mounted on a machine slide, and the chaser ground by passing it back and forth across the edge of the grinding wheel.



Thread-chaser Grinding Fixture brought out by the Geometric Tool Co.

OLIVER MOTOR-DRIVEN DISK SANDER

Patternmakers will be interested in a motor-driven disk sander now being placed on the market by the Oliver Machinery Co., Grand Rapids, Mich. This machine is particularly adapted for accurately sanding segments, angular sections, core-prints, and circular and taper work. It can also be used in machine shops for medium and light metal work.



No. 182 Motor-driven Disk Sander placed on the Market by the Oliver Machinery Co.

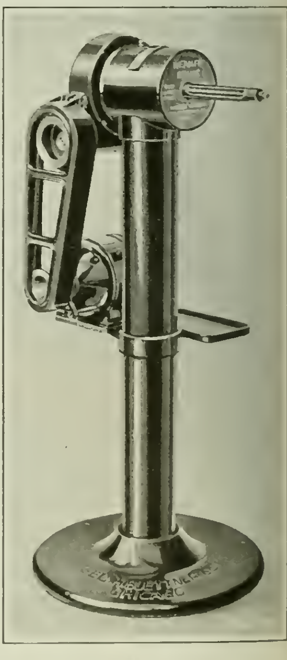
The steel disk plate which is 15 inches in diameter, is removable for renewing the sandpaper or emery cloth on its front face. The disk travels at a speed of 1725 revolutions per minute.

The table has a groove to receive angle, and circle, segment and duplicating gages. It tilts 45 degrees downward from the horizontal plane and 25 degrees upward, a graduated index showing the angle at which it is positioned. A vertical adjustment of six inches provides for handling a variety of work. The angle gage is graduated from 0 to 45 degrees both to the right and left to enable accurate settings. Either an alternating- or direct-current motor is provided, the motor being coupled to the disk shaft in such a manner that it does not receive thrusts from the latter. The controlling switch is of the push-button type, and is located on the column. This machine is portable and is intended to receive electric current from a lighting circuit.

BLETTNER REAMER DRIVING MACHINE

Reaming finished holes to size in the assembly of machines or mechanical units is facilitated by a machine produced by the George H. Blettner Co., 1841 W. Jackson Blvd., Chicago, Ill., which is shown in the accompanying illustration. This machine drives hand and machine reamers of various styles up to 1½ inches in diameter. The driving mechanism is located at the top of the pedestal, and driven from a 1/6-horsepower alternating- or direct-current motor through a round belt. A three-step pulley provides three spindle speeds of 10, 20, and 30 revolutions per minute, respectively. The operator stands directly in front of the machine, and, while holding the work in his hands, feeds it on the slowly revolving reamer which centralizes itself.

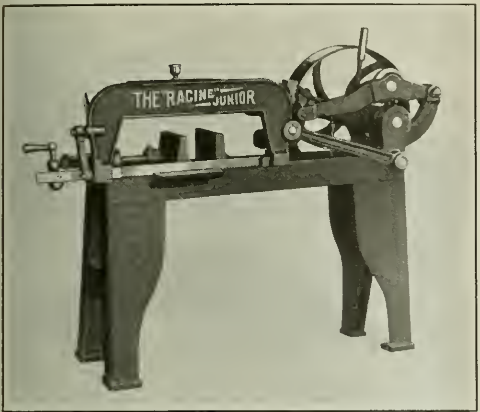
The spindle is fitted with a 5-inch Cushman geared scroll chuck. All end thrust in the machine is taken up by ball bearings, and the gear-case is oil-tight so as to retain the lubricant. The electric current switch is of the self-contained tumbler type. It is said that by using this equipment holes will be given a better finish than when sizing by hand, and the work can be done more quickly. The distance from the floor to the center of the spindle is 38 inches, and the weight of the machine is approximately 145 pounds.



Reamer Driving Machine made by the George H. Blettner Co.

RACINE HIGH-SPEED HACKSAW MACHINE

Light-gage or hand hacksaw blades may be used advantageously on the "Junior" medium-duty hacksaw machine built by the Racine Tool & Machine Co., Racine, Wis., because of the positive mechanical lift on the non-cutting stroke of the blade. The machine operates on the draw-cut principle, gravity alone being relied upon for feeding the blade an amount suitable for the different grades of metal being cut. An automatic knock-out stops the saw when a piece has been cut through. The saw-frame guide is held automatically at any height, which is a convenience when plac-



Racine "Junior" Metal-cutting Machine built by the Recine Tool & Machine Co.

ing stock in the vise. Adjustment for wear is provided on the saw frame guide which slides on V-ways. The normal capacity of this machine is for stock 4 by 4 inches, but by a simple adjustment the capacity may be increased to 6 by 6 inches. The stroke range of the machine is from 60 to 100 per minute, and the stroke is 6 inches in length. The weight of the equipment is 150 pounds.

DAVIS-BOURNONVILLE TUBE-BENDING MACHINE

The bending of No. 22 gage 7/16-inch diameter tubing to the shape of a tennis racket frame is accomplished by means of a machine built by the Davis-Bournonville Co., Jersey City,

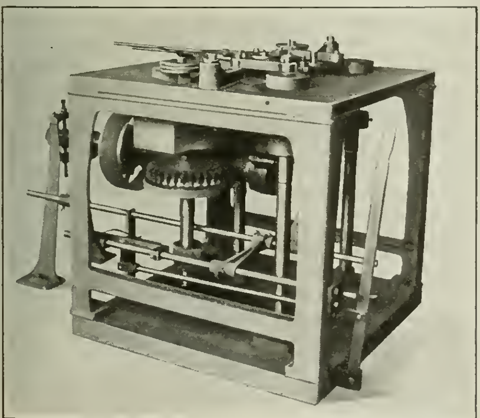


Fig. 1. Tube-bending Machine built by the Davis-Bournonville Co.

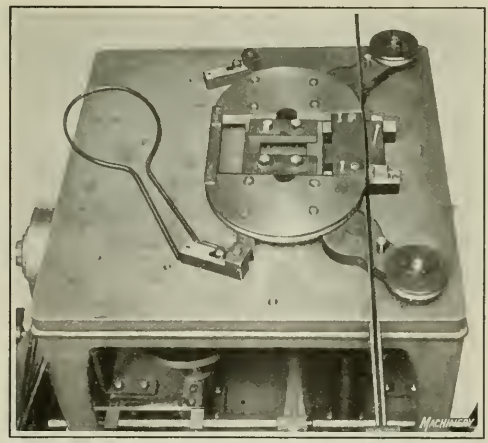

Fig. 2. Tool Set-up for the Preliminary Bending Operation

N. J. A general view of this machine is shown in Fig. 1. Two separate operations are required to complete the bending, the machine being first set up for giving a preliminary bend to a quantity of work, and then arranged for giving these parts a subsequent bend. The preliminary shape is obtained by bending the tube around a form on the table by means of two arms or cranks keyed to vertical oscillating shafts. These members are clearly shown in Fig. 2. The cranks are driven through worm-gearing and a crank motion beneath the table, a clutch being provided for starting and stopping their operation. The rollers on the end of the

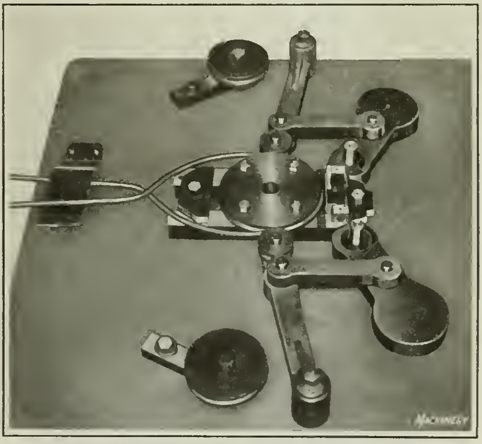

Fig. 3. Final Operation in bending Tubing

cranks engage the tube and bend it around the large form. The normal cycle of steps in this operation is to bend and release the part and stop the machine, the operator then removing the part and replacing it with another straight tube.

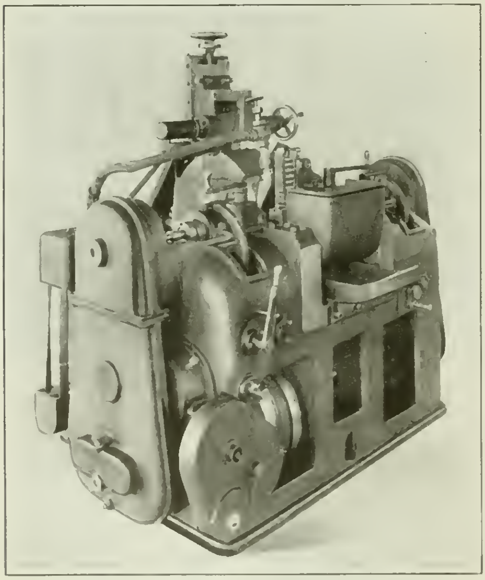
After a quantity of frames has been run through the first operation, the bending tools are changed for those shown in Fig. 3. It will be noted that the rollers on the crank ends have been removed and are employed as stops. They are so positioned that the partly bent frame, when placed on the machine for this operation, will be located by the rollers midway on the form at the center. Links which are connected to studs midway on the crank arms are attached at their opposite ends to another pair of swinging arms having small rollers which engage the tube. In the second operation the frame is closed by the rollers on the swinging arms as the cranks are operated, one leg of the frame passing under the clip at the left of the table, and the other riding over the top. It is necessary to bend the frame through a greater angle of curvature than is actually desired on the finished part, in order to overcome the spring and allow the tubing to set.

The machine normally operates at an average rate of 600 bends per hour, the speed of the driving shaft being 300 revolutions per minute. On normal production, the machine is started and stopped for each bend, but when facility in handling the work has been acquired and maximum production is essential, the clutch latch may be thrown out and the machine then operated without stopping to insert the tubes and remove the bent shapes. The production is thus increased to about 1000 bends per hour.

FRASER AUTOMATIC CYLINDRICAL GRINDING MACHINE

Shackle and king bolts, valve tappets, piston-pins and other parts having cylindrical surfaces to be ground may be handled rapidly in large quantities on the automatic grinding machine here illustrated. This machine has been patented and is now being built by the Warren F. Fraser Co., Westboro, Mass. The work is held either between centers or in a draw-in chuck. The wheel-head is heavy, and the spindle of generous proportions to enable it to carry grinding wheels 18 inches in diameter and up to 6 inches in face width. Force-feed lubrication is furnished for all bearings, and all controls can be easily and quickly reached. The machine is self-contained, being driven by a 15-horsepower motor through a 4½-inch belt. However, the machine may also be driven from an overhead countershaft or jack-shaft through a constant-speed belt.

The time required for setting up this machine for a job is no greater than for rigging up an automatic screw machine, and in grinding piston-pins ⅞ inch in diameter and 3¼

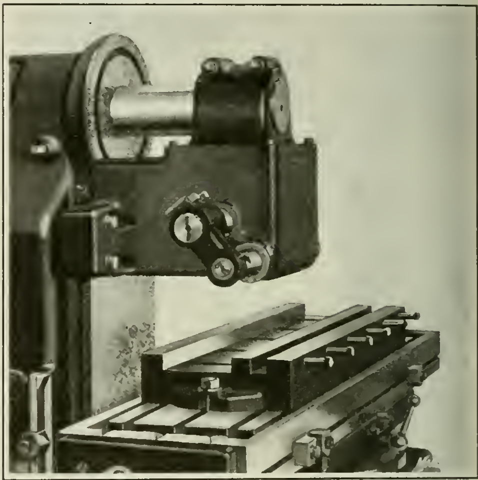


Automatic Cylindrical Grinding Machine brought out by the Warren F. Fraser Co.

inches in length, an average production of five pins per minute was attained. One operator can run as many as four machines. This machine will grind pieces from ½ inch in diameter upward, and up to 6 inches in length, the maximum distance between centers being 10 inches. The machine weighs approximately 7000 pounds. This company also has a small machine in the process of development which will weigh about 4000 pounds and will grind surfaces from ⅛ to 1½ inches in diameter and up to 2 inches in length. The maximum length of work which can be placed between the centers of this machine will be 8 inches.

ROCKFORD RACK CUTTING AND INDEXING ATTACHMENTS

Rack cutting and indexing attachments designed especially for application to the heavy-duty and No. 1½ milling machines built by the Rockford Milling Machine Co., Rockford, Ill., have been placed on the market by the same concern.



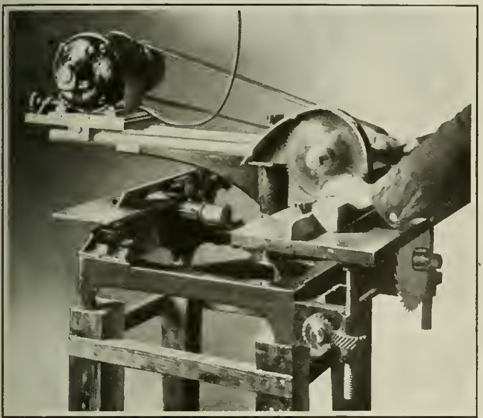
Rack Cutting Attachment and Special Vise added to the Equipment made by the Rockford Milling Machine Co.

The rack cutting attachment is securely clamped to the face of the column and is further supported by the overhanging arm at a point directly above the attachment spindle, where there is the greatest strain. The attachment is driven through a shank held in the machine spindle by means of the tang and a drawback. A hardened spur gear keyed and pinned to the shank drives a second gear keyed to a double-lead worm. The latter engages a worm-wheel which has two spur gears keyed to it, one on each side. These transmit power to the attachment spindle through gears cut solid on this member. The attachment spindle is made of alloy steel, and runs in bronze taper bearings that have means of adjusting for wear.

The rack indexing attachment (which is not illustrated) is fastened to the left-hand end of the table by means of the central T-slot. It consists of a bracket carrying an indexing and locking disk and change-gears. This device permits of cutting rack teeth and making other settings without relying on the usual dial. Various gear combinations enable racks of different pitches to be indexed by making one-half, one, or two turns of the locking disk. The cutting of racks to the following diametral pitches is possible by means of the eighteen change-gears furnished: 3 to 6 by half pitches, all pitches from 7 to 16, and all even pitches from 18 to 32. Racks having circular pitches of from 1/16 to 1 inch may also be cut. The special rack vise shown in the illustration has jaws 30 inches long, which have a maximum opening of 5⅝ inches.

HUTCHINSON COMBINATION WOODWORKING MACHINE

Fifteen different operations may be performed on a small combination woodworking machine brought out primarily for pattern shop use by the Hutchinson Mfg. Co., Inc., Norristown, Pa. This machine can be employed as a swing saw, for cross-cutting square ends of long stock, for mitering and for dadoing. In performing such work, the operator can always clearly observe the cuts being taken. The machine is especially suitable for routing out core-boxes, cutting all kinds of segments, jointing, and planing. The table moves up and down while the machine is in operation and may also be swiveled. Another advantage of this design is that two men can work on opposite sides at the same time.

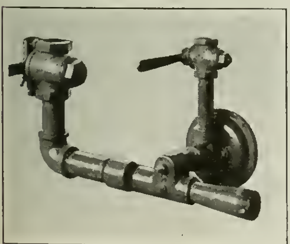


Small Combination Woodworking Machine brought out by the Hutchinson Mfg. Co., Inc.

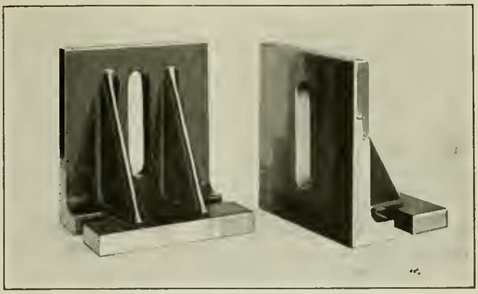
The machine may be mounted on a small stand having rollers which will enable it to be readily moved about the shop. It is driven by a ½-horsepower motor, and weighs 245 pounds.

SURFACE COMBUSTION AIR-GAS INSPIRATOR

The low-pressure air-gas inspirator supplied in past years on furnaces built by the Surface Combustion Co., 362 Gerard Ave., Bronx, New York City, has been redesigned so as to be applicable to other makes of gas furnaces. The entire operation of a furnace equipped with this device is controlled through one valve. An increase or decrease in the air supply automatically causes the amount of gas delivered to be also increased or decreased, so that the mixture proportions remain in a constant ratio. The gas cock is operated only when starting or stopping the heating of a furnace, and is either altogether on or off, no intermediate positions being required. It is said that no explosive mixtures are possible in any part of the distribution mains, as the gas and air are mixed only at the point of supply to the burners. The advantages claimed are an automatic supply of air and gas in the desired proportions under all conditions, thorough mixing of the air and gas just prior to entering the furnace, and an instantaneous combustion.



Air-gas Inspirator made by the Surface Combustion Co.



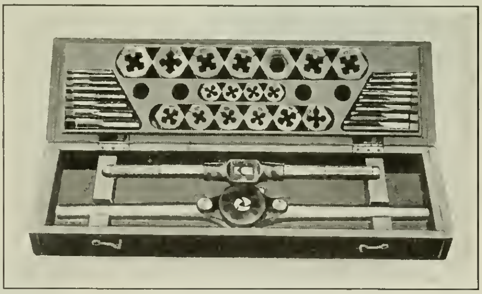
Precision Angle-irons made by the Simplex Tool Co.

SIMPLEX PRECISION ANGLE-IRONS

Two of a set of precision angle-irons made in three sizes, to provide for a variety of combinations suitable for the general run of machine shop work are shown in the accompanying illustration. These irons are manufactured by the Simplex Tool Co., Woonsocket, R. I. They are made of a high grade of cast iron, and the clamping surfaces are accurately finished. Slots provide a means of holding the irons to surfaces of machine and other parts. The sizes in which the angle-irons are made are 4 by 5 by 5 inches; 6 by 6 by 8 inches; and 8 by 10 by 12 inches.

WELLS SCREW-PLATE SET

A screw-plate set having several new features has just been brought out by the Frank O. Wells Co., Inc., 305 Wells St., Greenfield, Mass. It will be seen from the illustration that the dies of this set are hexagonal. The die-stock is made of an aluminum alloy, and the tap wrench is made of steel and has hollow handles to reduce its weight. The dies are made adjustable by splitting one side and providing a fillister-head screw for drawing the split ends together. By holding these ends in this manner the dies may be turned with an ordinary socket wrench instead of using the stock. This is convenient when working under cramped conditions.



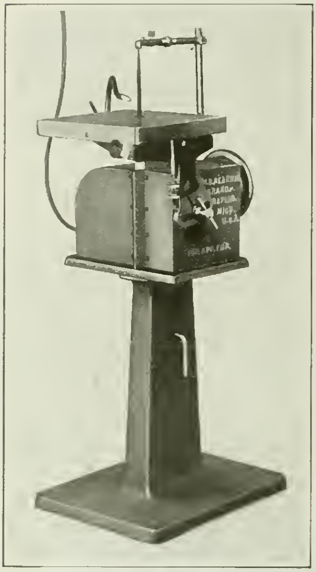
Hexagon-die Screw-plate Set introduced to the Trade by the Frank O. Wells Co., Inc.

The dies are of standard form and chip clearance, and are intended to cut full and perfect threads. A hexagonal adapter turnished with the set provides for holding dies that are small in outside diameter in the same stock. Attached to the stock by means of knurled-head screws is an adjustable guide which may be swung to one side to permit the changing of dies after the screws have been loosened. When retightened, the screws hold the guide in position over the center of the die and lock the jaws of the guide so that they will not move while threading a number of pieces of one size. The cutting faces of the dies are formed by broaching, the correct shape being produced and an equal distance maintained between all cutting lands in this way. The set is made with both U. S. standard and S. A. E. forms of thread.

REARWIN DIE-FILING MACHINE

A No. 4 small-size die-filing machine which may be mounted on a bench or on a pedestal having elevating rollers has been added to the line of die-filing equipment manufactured by W. D. Rearwin, 716 Monroe Ave., Grand Rapids, Mich. When the rollers are lowered and the pedestal raised the machine can be conveniently moved about the shop. After it is taken to a desired location, the base of the pedestal furnishes a solid foundation when the rollers are again raised. Power for driving the machine may be obtained from any electric light socket. A 1/8-horsepower motor running at 1720 revolutions per minute is provided, which is fully enclosed in a sheet-metal case to protect it from filings and dirt.

The file is reciprocated by a ram driven through a crank and connecting-rod. By adjusting the throw of the crank it is possible to obtain any length of stroke up to 3 inches. The effective length of the connecting-rod can also be adjusted to bring the working section of the file into any desired position relative to the work. Three changes of speed are obtained through a cone pulley, namely 200, 300, and 400 strokes per minute.

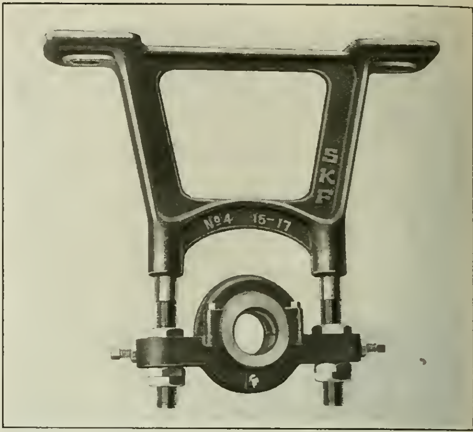


Die-filing Machine built by W. D. Rearwin

To enable various degrees of clearance to be filed in dies, the work-table is pivoted on a yoke, and this, in turn, is pivoted on the frame of the machine. Each of these pivotal supports has a graduated dial which facilitates rapid and accurate setting of the table to the desired clearance angles. There is an outboard support for the file, and files of standard or special types can be used. The table is at a convenient height for a man sitting on a stool. The table is 12 inches square, and the entire machine weighs about 80 pounds. A smaller size machine built along the same lines and known as the No. 3 is made with a table 8 inches square and a file stroke of 1½ inches.

SKAYEF BALL-BEARING HANGER

An improved ball-bearing hanger with a two-point suspension for the bearing box is now being manufactured under the supervision of the S K F Industries, Inc., 165 Broadway, New York City. The self-aligning ball bearing incorporated in the old type hanger is also included in the new. The bearing is contained in a split housing rigidly held by two suspension rods. This arrangement gives a compact unit, easily assembled, located, or inspected. Vertical or horizontal adjustments can be readily made at the end of the housing by means of lock-nuts and set-screws. This obviates the possibility of applying pressure to the bearing while making adjustments.

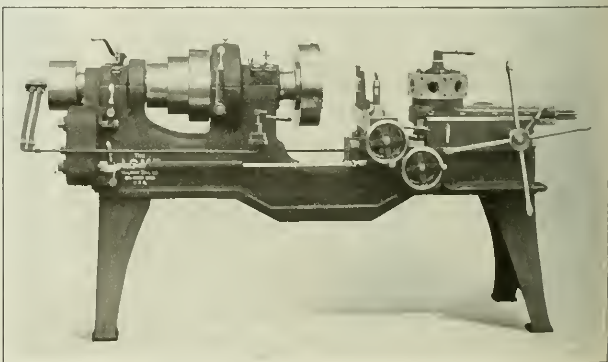


Skayef Ball-bearing Hanger

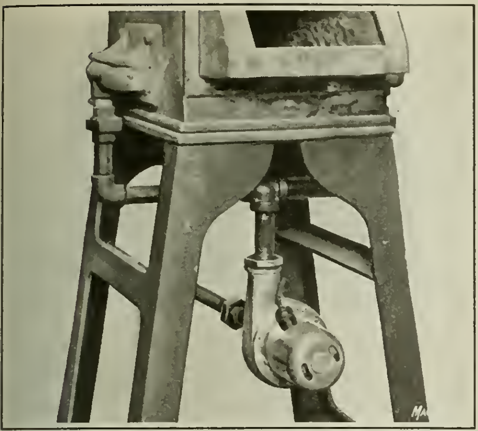
The self-aligning feature of the bearing allows the shaft to turn freely at all times with a minimum amount of friction and subsequent heating. Millwrights will appreciate the fact that when using these hangers for an installation the shaft may be laid out on the floor with the bearings in plain view and then raised into position for final adjustment with the upper half of the housings off.

CINCINNATI ACME GAP TURRET LATHE

A departure from the standard design of turret lathes has been made by the Acme Machine Tool Co., Cincinnati, Ohio. in bringing out the gap turret lathe here illustrated. This machine was designed particularly for the handling of chucked work that is large in swing relative to its length. Many castings and forgings which ordinarily cannot be machined on a turret lathe of corresponding nominal size can thus be accommodated because of the gap. The machine is made to the dimensions of the regular 20-inch Cincinnati-Acme turret lathe built by the same concern, except that the gap provides for a maximum swing of 28 inches. The length of the gap from the front end of the spindle is 9⅛ inches. The machine is equipped with an air chuck, and has a power feed for the cross-slide and a longitudinal power feed for the turret. The minimum distance from the end of the spindle to the turret face is 14¾ inches; the minimum distance from the end of the spindle to the inside edge of the cross-slide, 8⅛ inches; the transverse movement of the cross-slide, 7 inches, and the lateral movement, 4 inches.



New Design of Turret Lathe built by the Acme Machine Tool Co.



Gas Furnace equipped with Electric Blast made by the Clements Mfg. Co.

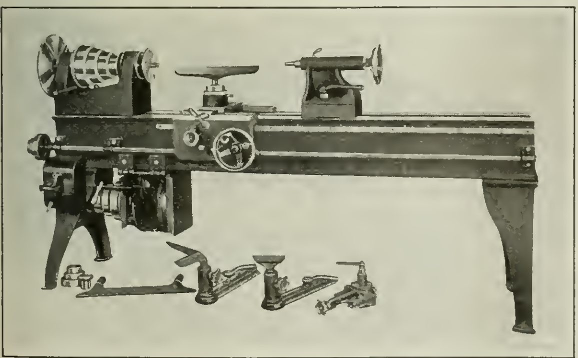
CADILLAC ELECTRIC GAS-FURNACE BLAST

An electrically operated blast intended for application to gas furnaces for regulating the mixture of air and gas delivered to the furnace is now being placed on the market under the trade name of "Cadillac" by the Clements Mfg. Co., 606 Fulton St., Chicago, Ill. This blast is driven by a 1/6-horsepower universal motor and delivers 210 cubic feet of air per minute at a motor speed of 10,000 revolutions per minute. Current for driving the motor is taken from a lighting socket; this offers a convenient means of heating a furnace after regular working hours.

The functioning of the device is similar to that of an automobile carburetor. The mixture of air and gas should be rich until the furnace has been warmed up, after which a damper on the blast adjacent to the blower should be gradually opened to admit more air. This blast is not dependent upon a normal gas pressure, a sufficient amount of gas being drawn from the mains to heat a furnace without variation.

IMPERIAL PATTERNMAKER'S LATHE

A motor-driven patternmaker's lathe built in sizes of 16-, 20- or 24-inch swing and with standard bed lengths of 8 and 10 feet, is a recent product of the Imperial Metal Products Co., Ionia and Newberry Sts., Grand Rapids, Mich. This lathe has a headstock which can be swung about five degrees each side of the center to provide for turning tapers. The spindle is threaded on both ends for the accommodation of faceplates. Double-row self-aligning S K F ball bearings take the end thrust of the spindle as well as radial loads. The tailstock is of the open-side type and may also be set over for turning tapers. The compound rest is graduated to enable quick settings to be made at various angles.

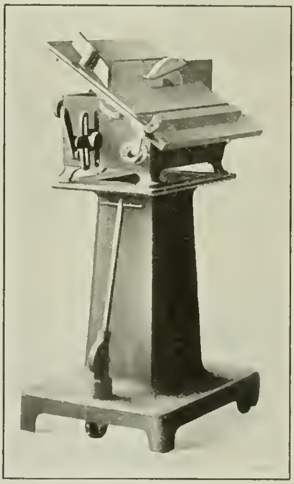


Porter Patternmaker's Lathe manufactured by the Imperial Metal Products Co.

The carriage is regularly furnished with a power feed, but a hand-fed carriage can also be supplied. On the power-fed machine, the feed can be started or stopped by turning a friction knob on the apron, or reversed by the manipulation of a lever. The two-horsepower motor with which the machine is equipped is mounted on an adjustable base which allows for tightening the driving belt. Belt shifters and a controlling box are conveniently located. A brake lever operating on the inside of the spindle cone pulley enables the rotation of the spindle to be stopped instantly. The machine may also be equipped for driving from a countershaft.

UNION PORTABLE SAW BENCH

A universal saw bench mounted on a pedestal having rollers and a handle which facilitate its transportation about the pattern shop is now being introduced to the trade by the Union Machine Co., 30 Ottawa Ave., N. W., Grand Rapids, Mich. The saw is driven by a ½-horsepower motor, and will cut stock up to 2 inches thick. The table can be tilted to any angle up to 45 degrees and locked in place, a graduated dial and pointer indicating its position.



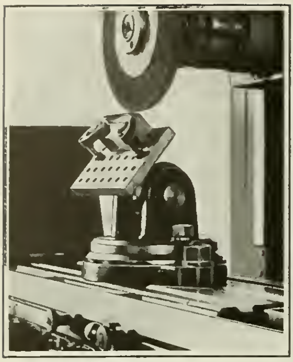
Portable Saw Bench made by the Union Machine Co.

The cross-cut gage may be used on either side of the saw, and can be quickly set to any angle and clamped in position. The ripping gage may also be used on either side of the saw. This gage is automatically lined up with the saw when locked in position. The saw is seven inches in diameter, and may be either of the ripping or cross-cut type, or a combination of the two suitable for both classes of work. A splitter guard keeps the stock from pinching the saw. The saw arbor yoke is hinged so that it can be raised and lowered to adjust the height of the saw above the table surface.

Two rollers at the back of the pedestal and two stationary feet at the front furnish a firm support on the floor when the machine is in operation. Pulling the handle forward raises the feet and brings the weight of the front of the machine on a third roller carried on a swivel bearing that moves with the handle.

KRAG UNIVERSAL ANGLE FIXTURE

Tool-room jobs in which it is necessary to hold the work in angular positions while being machined may be performed readily by using the "Little Bob" universal angle fixture made by E. L. Krag & Co., 50 W. Randolph St., Chicago, Ill. This device has a work-holding plate which may be swiveled 90 degrees on either side of a horizontal



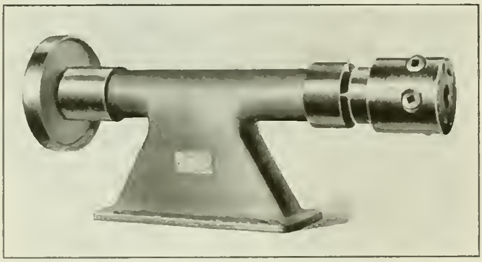
Universal Angle Fixture made by E. L. Krag & Co.

plane and which may also be revolved around an entire circle. Graduated dials facilitate the settings. All surfaces of the plate are ground square with each other, and this member has a series of holes which provide for the quick clamping of work by means of patented clamps.

The plate is hinged on a 3/4-inch stud, threaded on one end, which is used to clamp the plate in desired positions relative to the horizontal plane. Large flanges on the plate engage the faces of bosses on the yoke lugs and produce a sufficient friction to hold the plate fast under all conditions. The yoke casting revolves on a 1 1/2-inch pilot at the center of the base, the yoke being secured by two 1/2-inch bolts which ride in a circular T-slot machined in the base. The size of the fixture plate holding surface is 3 3/8 by 4 3/4 inches, and the weight of the entire fixture, 25 pounds.

MARVIN & CASLER LAPPING AND FILING LATHE

To provide for lapping and filing small work without tying up a lathe or other more expensive equipment, the Marvin & Casler Co., Canastota, N. Y., has brought out the lapping and filing head or "lathe" shown in the accompanying illustration. This head consists essentially of a casting which supports a spindle running in ball bearings. The spindle is driven by a pulley mounted on one end, while at the other end is attached either a Casler twin-screw drill chuck or a three-jaw chuck. The twin-screw chuck was described in April, 1919, MACHINERY. The casting is designed to permit the ready attachment of a guard for the driving belt. The base of the casting is 10 3/4 inches long and the distance from the pulley to the drill chuck is 14 3/8 inches.

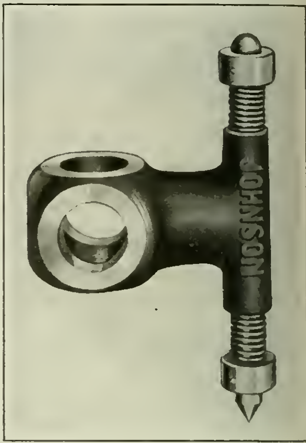


Lapping and Filing Head made by the Marvin & Casler Co.

JOHNSON CENTER-LOCATING PUNCH

Toolmakers and diemakers will appreciate a means for quickly and accurately locating centers of holes on such work as jigs, dies, etc., without relying on the button method. The combination prick-punch and scriber here illustrated has been designed for this purpose, and is manufactured by Bernard F. Johnson, 3476 Boulevard, Jersey City, N. J. One method of using this device is to mount it on the cutter-arbor of a milling machine, with the punch perpendicular, and with the part to be laid out attached to the machine table. Then the centers of holes to be bored later may be located by shifting the work beneath the punch, using the adjusting screws of the table and saddle. By reference to the dials of these screws, centers for holes may be located within the limits of the accuracy of the machine. After each adjustment, a prick mark is made by tapping with a hammer on the upper round head of the punch. Then, when all centers have been located, the work may be mounted on the faceplate of a lathe and drilled and bored in the customary manner after centering by means of an indicator. It will be apparent that the coil springs normally hold the punch from the surface of the work.

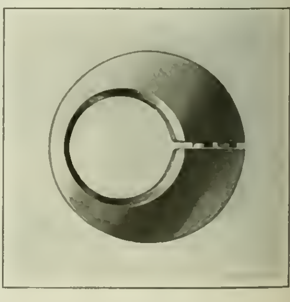
The tool may also be placed in a horizontal position for locating on perpendicular surfaces, and it may be conveniently employed while horizontal or perpendicular in connection with a dividing head for locating holes at an angle. By pressing the lower end of the punch against the work, the sharp point may be used for scribing lines as the work is moved past the tool. This application is especially useful for laying out dies. The punch is hardened and ground all over, and lapped where it is contained in the bearing. The collars on the punch are of equal size and facilitate the alignment of the tool. The holes in the supporting member of this device provide for mounting it on either 3/4- or 7/8-inch arbors.



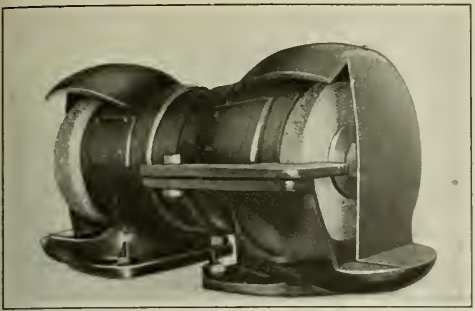
Precision Punch and Scriber manufactured by Bernard F. Johnson

ADJUSTABLE TEMPLET THREAD GAGE

Templet thread gages which are made adjustable by the provision either of one half-way slot leading from the threaded hole or two half-way slots at the periphery, were described in March MACHINERY. These tools are products of the Superior Thread Gage Mfg. Co., Inc., 1985 Troy Ave., Brooklyn, N. Y. Another adjustable ring gage in which the threaded hole is located eccentrically relative to the periphery, in order to obtain the necessary spring for adjustment, is now being made by the same concern. This gage, which is here illustrated, is adjusted in the same manner as the other ring gages referred to, that is, by tightening up a screw placed perpendicular to the split ends of the gage. A hardened drill-rod pin at these split ends keeps the gage from twisting. The outside diameter of gages of this type is considerably less than when half-way slots are provided for obtaining the adjustment. The gage is made in all sizes from 3/16 inch up, for special threads as well as for standard threads.



Thread Gage made by the Superior Thread Gage Mfg. Co., Inc.



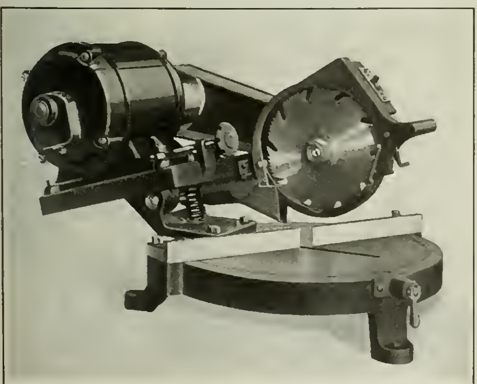
Self-contained Centrifugal-fan Grinder made by Forbes & Myers

FORBES & MYERS GRINDER

The provision of self-contained centrifugal fans for exhausting the dust is the principal new feature of an improved grinder added to the line of products manufactured by Forbes & Myers, 178 Union St., Worcester, Mass. These fans are adjacent to the outside bearings of the grinder spindle and blow the dust directly back through an exhaust pipe. The grinding wheels are located outside of the fans. The motor is of ½ or ¾ horsepower, of the induction type, fully enclosed, and operates on single-, two- or three-phase current. Hess-Bright bearings are used in the construction of this grinder. In the illustration only one wheel is supplied with the tool-rest; however, each wheel may be so equipped or tool-rests may be omitted altogether. While the exhaust action of the fans is effective, they are not intended to take the place of large exhaust systems, for blowing dust through long pipes.

TANNEWITZ PORTABLE SAW BENCH

The accompanying illustration shows a portable wood-cutting saw bench in which the motor and saw are mounted on a frame which swivels 45 degrees each side of a central position. This permits both right- and oblique-angle cuts to be taken. A locking pin engages slots in the periphery of the swiveling member so that the saw can be held at any desired angle. The saw and motor support is pivoted, which enables the saw to be depressed to cut through stock. A coil spring elevates the saw as the operator releases the pressure on the handle used for depressing the saw. The motor is controlled by a simple finger-switch adjacent to this control handle. An adjusting screw provides for varying the tension of the driving belt. This equipment is built by the Tannewitz Works, Grand Rapids, Mich.

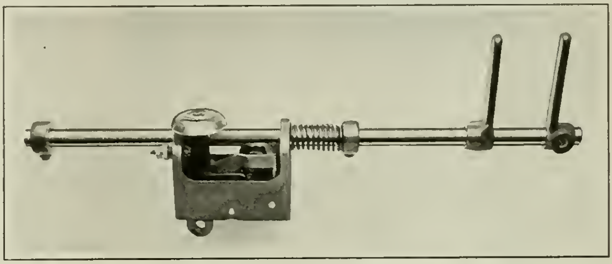


Portable Wood-cutting Saw Bench made by the Tannewitz Works

"SIMPLEX" ELECTRIC SAFETY STOP

Instantaneous operation of a clutch or shifting of a belt on various types of automatic machines in the event that the stock is over-size, under-size, over-fed, or under-fed, or in case some other irregularity occurs, is possible by employing the "Simplex" electric stop. This device is manufactured by the Atlantic Co., 452 Classon Ave., Brooklyn, N. Y., and is intended to be used on a lighting circuit, although it will also function on battery or generator current. Among the various applications of this stop may be mentioned its use on roll-feed blanking presses or four-slide wire formers.

On a blanking press the stop is mounted on the foot-treadle rod, a latch on the stop engaging a notch in this rod. When the stop operates, the latch is disengaged from the notch and the rod is forced forward by the spring. A small spring-lever is also arranged to bear on the blanked scrap as the latter is fed from the die. When the scrap has been fed the desired amount, the lever rests on the metal between the blanked holes, and while thus positioned, the circuit is open. However, if the scrap is over-fed or under-fed, the lever will extend into one of the blanked holes and the circuit will be closed. This will cause the stop to actuate and halt the operation of the machine. In this way injury to a die as a result of punching the metal at a point where it has already been partially blanked out is avoided.



"Simplex" Automatic Safety Stop manufactured by the Atlantic Co.

Wires may be run from the stop to contact points located on a machine wherever trouble is likely to happen. The pressure of the clutch or belt-shifter rod against the stop latch is reduced by means of two unequal levers. A spring for exerting pressure up to 75 pounds may be used in connection with the stop, and such a spring is ample for shifting a 6-inch belt. A hand-trip enables the stop to be operated at any time. The device may be so arranged that it will not interfere with the ordinary method of starting and stopping a machine.

DIAMOND SPROCKET-TOOTH HOBS

On page 592 of March MACHINERY, attention was called to hobs for cutting sprocket teeth to the "American Standard" form. These hobs are not manufactured by the Diamond Chain & Mfg. Co., Indianapolis, Ind., although they were developed by this concern. They are supplied by the Brown & Sharpe Mfg. Co., Providence, R. I., Illinois Tool Works Co., Chicago, Ill., and Union Twist Drill Co., Athol, Mass.

* * *

Reports from Germany indicate that a great development has taken place in recent years in the utilization of compressed air locomotives in mines. In a group of mines at Dortmund, for example, in the year 1919, the number of locomotives in operation was nearly 2300, of which 624 were propelled by compressed air.

NEW MACHINERY AND TOOLS NOTES

Pressed-steel Hanger: Dodge Sales & Engineering Co., Mishawaka, Ind. A pressed-steel lineshaft hanger suitable for use under conditions where excessive vibration is not encountered. The bearing floats in the hanger so as to align itself with the shaft. Set-screws equipped with lock-nuts permit bringing the bearing to the proper height and lateral position.

Bench Lathe: A. V. Carroll Machine Tool Co., Norwood, Cincinnati, Ohio. A bench lathe driven by motor through a countershaft supported by an extension cast on the bed. The swing over the bed is 10 inches, and the distance between centers 24 inches. The carriage is fed by means of a long screw at the front of the machine which is turned by a crank-handle at the right-hand end.

Heavy-lift Portable Crane: Elwell-Parker Electric Co., 4223 St. Clair Ave., Cleveland, Ohio. A heavy-lift portable crane which is similar in general design to a crane brought out by the same concern about a year ago. The new crane has a capacity for lifting loads of 3000 pounds at a six-foot reach and 1000-pound loads at an eight-foot reach. The boom is 12 feet long, but it may be quickly lowered to permit the crane to enter buildings.

Electric Grinder and Buffer: Columbia Mfg. Co., Belleville, Ill. A motor-driven buffer and grinder, which, when used as a grinder, is intended for sharpening tools and performing general light grinding. The motor is of 1/3 horsepower and operates at a speed of 1800 revolutions per minute. The machine is equipped with adjustable tool-rests and guards for the wheels, and wheels 8 inches in diameter, either 1- or 1¼-inches thick, are used. When the machine is employed for buffing purposes, the guards and other fittings are removed.

Metal-parts Washing Machine: Colts Patent Firearms Mfg. Co., Hartford, Conn. An automatic metal-parts washing machine consisting essentially of an endless belt conveyor combined with a washing apparatus. As the work travels on the conveyor it passes through two sets of sprays which operate on both sides and on the top and bottom of the work. The fluid is circulated by means of a pump. All parts which can be handled on racks are put through the machine in that manner, but comparatively large castings may be placed directly on the conveyor.

Automotive-parts Grinding Machine: Cincinnati Grinder Co., Cincinnati, Ohio. A grinding machine particularly designed for operation on crankshaft bearings, valve seats and stems, piston-rings, pins, and push-rods. The machine is made in two styles, one for power feed and the other for hand feed. The power-feed machine provides power traverse and automatic reverse for the table and an automatic in-feed for the grinding wheel. Two back-rests with wooden shoes and two crank-heads are furnished, while adapters provide for holding flanged end cranks.

Portable Power Hacksaw: Edlund Machinery Co., Inc., Cortland, N. Y. A portable power hacksaw for cutting both machine and tool steel. The saw is driven from a small motor, direct-connected through cut gears, current being obtained through an electric light socket. The cutting is done on the back stroke, the saw blade being automatically relieved on the forward stroke to reduce the wear and prolong the life of the blade. The feed is regulated by a weight which can be quickly adjusted to suit the work. When the saw arm is raised to enable work to be put in place, it is automatically held in position until released by the operator. The machine stops automatically when a cut is finished, and can be stopped and started at any time during a cut. Any standard 8-inch blade can be used.

NEW BOOK ON JIGS AND FIXTURES

JIG AND FIXTURE DESIGN. Edited by Franklin D. Jones. 325 pages, 6 by 9 inches; 297 illustrations. Published by THE INDUSTRIAL PRESS, 140-148 Lafayette St., New York City. Price, $3.

The development of machine tools has been accompanied by a corresponding development of auxiliary equipment for increasing the quantity and improving the quality of the products of these machines. Whenever duplicate parts require some operation such as drilling, planing, or milling, the selection of a suitable type of machine is often followed by the design of whatever special tools or attachments are needed to adapt the machine to the operation required. The tool-guiding and work-holding jigs and fixtures which are now used in practically all machine shops represent the most important class of special equipment, and this book deals exclusively with their design and construction.

As most jigs are used for drilling operations, a book was previously published by MACHINERY entitled "Drilling Practice and Jig Design," covering different types of drilling machines and their use, the design of drill jigs, and, to some extent, the design of fixtures such, for example, as are used on milling machines. While the subjects of drilling and jig design are closely allied, it is no longer possible to cover them both in a single volume, owing to the extensive changes in drilling practice and the increasing use of jigs and fixtures of various types on different classes of machine tools. Therefore, the book referred to has been replaced by two volumes, of which this is one. The other book, "Modern Drilling Practice," is already well known to those interested in the latest types of drilling machines.

This new book, "Jig and Fixture Design," contains that part of the volume on "Drilling Practice and Jig Design" which dealt with jigs and fixtures. This material was used because it is a treatise on the principles of jig and fixture design which contains information that is indispensable in a book of this kind. These original chapters which explain the general procedure in designing jigs and fixtures and how work should be located, clamped, etc., have been supplemented by a large amount of new matter, thus making the present book a complete treatment of the subject. A great variety of jig and fixture designs have been described and illustrated in order to show just how the principles are applied under many different conditions.

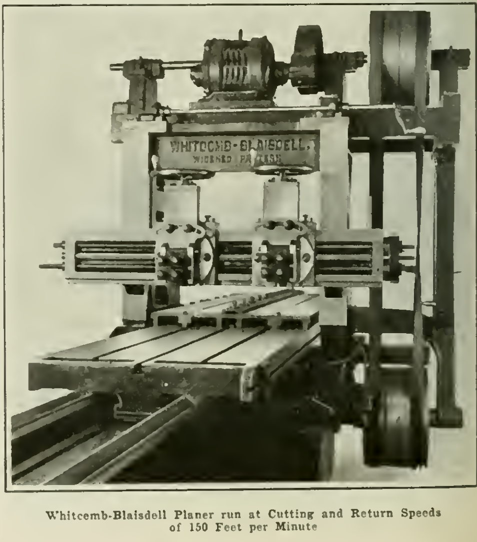
PLANER OPERATED AT HIGH CUTTING AND RETURN SPEEDS

Brass screen plates are used extensively by paper mills in the manufacture of high-grade paper. In order to machine these screen plates at high rates of production the Whitcomb-Blaisdell Machine Tool Co., 677 Cambridge St., Worcester, Mass., has modified its 26-inch planer to operate at the high cutting and return speeds of 150 feet per minute. The machine is widened to 30 inches so as to permit the holding of work two abreast in a quick-acting fixture. The screen plates are 13 inches wide and 30 inches long. Two standard heads are supplied on the cross-rail, the minimum distance between the heads being 12 inches.

The driving mechanism of the machine is that supplied regularly on the 30-inch planer of this concern. Wider belts, heavier shafts, and larger gears are thus used. Excessive belt speeds and the momentum of the driving pulleys are reduced by increasing the diameter of one pinion and decreasing the diameter of its mating gear so as to lower the ratio. The satisfactory operation of this machine at the higher speeds, however, is mainly attributed to the second-belt drive employed on Whitcomb-Blaisdell planers.



Whitcomb-Blaisdell Planer run at Cutting and Return Speeds of 150 Feet per Minute

MACHINE TOOL MERGER UNCERTAIN

The proposed merger of a number of prominent machine tool manufacturers and one of the well-known dealers in machine tools, for which plans have been under way for several months, had not been effected when this form of MACHINERY went to press (March 27), and we were informed by one of the largest companies affected that there was still considerable uncertainty as to the outcome. The companies included in the list that has been published are: Lodge & Shipley Machine Tool Co., Cincinnati, Ohio; Newton Machine Tool Works, Inc., Philadelphia, Pa.; Hilles & Jones, Wilmington, Del.; Betts Machine Co., Rochester, N. Y.; Colburn Machine Tool Co., Cleveland, Ohio; Modern Tool Co., Erie, Pa.; Carlton Machine Tool Co., Cincinnati, Ohio; and Dale Machinery Co., Inc., New York City and Chicago.

The men who are expected to control the new combination, in case it is effected, are Waldo H. Marshall, formerly president, and C. K. Lassiter, vice-president of the American Locomotive Co.; J. Wallace Carrel, vice-president and general manager of the Lodge & Shipley Machine Tool Co.; Henry J. Bailey, president and general manager of Hilles & Jones; H. W. Champion, president and general manager of the Newton Machine Tool Works; H. W. Breckenridge, general manager and treasurer of the Colburn Machine Tool Co.; J. J. Dale, president, and Robert R. Lassiter, vice-president and secretary, of the Dale Machinery Co., Inc.; A. H. Ingle, president of the Betts Machine Co.; J. C. Carlton, president and general manager of the Carlton Machine Tool Co.

If the new corporation is formed, it will be one of the largest organizations in the machine tool field, manufacturing a comprehensive line for practically all purposes. It will be particularly strong in equipment for locomotive and railroad shops and shipyards.

GEAR MANUFACTURERS' MEETING

The sixth annual meeting of the American Gear Manufacturers' Association will be held April 20 to 22 at the Lafayette Hotel, Buffalo, N. Y. This association, through a sectional committee, closely cooperates with the American Engineering Standards Committee, and the report of this and other committees on standardization promises to be of unusual interest. Special emphasis will be given to business conditions in the gear industry and the outlook for the immediate future.

Among the subjects to be discussed are "Good Hob Practice," by H. E. Harris of the H. E. Harris Engineering Co., Bridgeport, Conn.; "The Use of the Projector Comparator in Testing Gear Teeth," by Ralph E. Flanders of the Jones & Lamson Machine Co., Springfield, Vt.; "Proportions of Industrial Gears," by G. E. Katzenmeyer, of the R. D. Nuttall Co., Pittsburg, Pa.; "The Grinding of Gear Teeth and its Future in the Industry," by R. S. Drummond, of the Gear Grinding Machine Co., Detroit, Mich.; "The Gleason Works System of Bevel Gears," by F. E. McMullen and T. M. Durkan of the Gleason Works, Rochester, N. Y.; and "Conditions in the Industry," discussed from the standpoint of the member companies under the leadership of George L. Markland, Jr., of the Philadelphia Gear Works, Philadelphia, Pa., and from the automotive standpoint with R. P. Johnson of the Warner Gear Co., Muncie, Ind., presiding. An informal banquet for representatives and guests will be held on Friday evening, April 21, at which the principal speaker will be John C. Bradley of the Pratt & Letchworth Co., Buffalo, N. Y., who will take as his subject "What's Ahead."

* * *

THE POETRY OF THE MACHINE SHOP

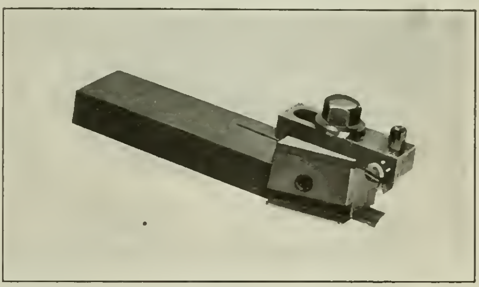
A collection of verse, the subject matter of which relates to science and engineering, is being compiled by Dr. C. E. Ruby, Box 130, Massachusetts Institute of Technology, Cambridge, Mass., who is desirous of obtaining copies or information relating to anything along these lines that has been published.

SCREW MACHINE CUTTING-OFF TOOL

By W. F. HONER

It occasionally happens that the limits on the over-all length of parts intended to be finished on automatic screw machines are much closer than is reasonably expected in the common run of commercial work. Of course, limits as close as plus or minus 0.001 inch can be maintained on such work in the ordinary manner if constant attention is given to the machines, but the improvised tool shown in the accompanying illustration will make the problem of handling this class of work much easier.

This tool was developed from a regular cutting-off toolholder with the cutting-off blade inserted. In making the holder, a hole is first drilled and tapped to receive an ordinary cap-screw, by means of which a suitable tool-holder is clamped to the upper surface of the cutting-off toolholder. The attached holder has a longitudinal slot in it to permit adjustment, and near its extreme outer end a lateral hole is bored to receive the cutting tool, which is held in place by the slotted set-screw. The slotted set-screw permits adjusting the tool so that the part to be operated upon will be cut off to the correct length.



Tool for cutting off Parts to Exact Length

As the cutting-off blade advances to the work, the newly attached facing tool, which is set to give the required overall length, trims or shaves off the outside face of the piece. No trouble was experienced by the operator of an Acme multiple-spindle automatic screw machine, in keeping the over-all length to within 0.001 inch on all work when this tool was used. The tool has proved very handy and practical.

* * *

OUTPUT OF AUTOMOBILE PLANTS

The seasonal demand is keeping many of the automobile plants well occupied. The March schedule of the Ford Motor Co. called for between 60,000 and 65,000 cars. The new Wills Sainte Claire Co. is said to have increased its output to 20 cars a day, while the Chandler shipments for March are expected to exceed 1000. The General Motors Corporation shipped twice as many cars in January and February as in the corresponding months a year ago. The Dodge plant is reported to be turning out between 2000 and 3000 cars a week, and Buick almost as many, while the Overland plant in Toledo is making between 200 and 300 cars a day. The Chevrolet plants are operating at 100 per cent capacity.

The Studebaker plants in South Bend and Detroit are working at full or nearly full capacity, the production schedule for the first three months of the year calling for 25,000 cars. The Hudson plant is also well occupied. Altogether, the General Motors Corporation is expected to turn out 60,000 cars during the first three months of 1922, compared with 24,000 for the same period last year. The leading automobile companies are unquestionably in a stronger position today than they have been at any time during the last eighteen months, but probably many of the smaller automobile organizations will pass out of existence.

PERSONALS

George J. Keller, formerly sales manager of the Frontier Chuck & Tool Co., Inc., Buffalo, N. Y., has joined the sales force of the Hannifin Mfg. Co., Chicago, Ill.

Ralph M. Sitterley has opened an office at 149 Broadway, New York City, to serve as foreign sales manager of American manufacturers of electrical specialties, marine supplies, automotive products and equipment.

J. Harvey Williams, president of J. H. Williams & Co., Brooklyn, N. Y., manufacturers of drop-forgings and drop-forged tools, has been elected president of the American Drop Forging Institute, and has been re-elected president of the Brooklyn Chamber of Commerce.

Charles B. Wilson, formerly vice-president in charge of operations of the Willys-Overland Co., Toledo, Ohio, has been made general manager of the Willys-Overland and associate companies. The executive offices in New York City are to be closed so that the entire time can be devoted to the Willys-Overland interests in Toledo.

E. M. Griffiths, the founder of Burton, Griffiths & Co., Ltd., of London, England, has resigned his position as managing director and chairman of that company, and has also retired from the board of directors of the Birmingham Small Arms Co., Ltd., so that he is no longer associated with the control of either company. His address is now 30-32 Ludgate Hill, London, E.C., England.

J. T. Slocomb, formerly with the J. T. Slocomb Co., of Providence, R. I., manufacturers of machinists' tools, who sold out his interest in that company and resigned his position as manager a year ago last June, has been devoting much of his time since then to the development of a steam pressure cooker for family use, which is made of monel metal and manufactured by the Economy Cooker Co., Providence, R. I.

Harry Fowler has been appointed district sales manager of the Cincinnati territory of the Carborundum Co., Niagara Falls, N. Y., succeeding Charles R. Cox. Mr. Fowler will take charge of the Cincinnati branch of the company, and will direct the sales force handling carborundum products throughout the Cincinnati district. Mr. Cox will be transferred to the main office at Niagara Falls, where he will take up his new duties on sales statistics.

W. C. Allen, formerly manager of the Philadelphia branch of the Black & Decker Mfg. Co., Towson Heights, Baltimore, Md., and subsequently special representative, has been made branch manager of the Chicago territory of the concern, which includes the states of Wisconsin, Illinois, Missouri, Iowa, Minnesota, and North Dakota. Mr. Allen has been connected with the company for about three years, and previous to that was assistant sales manager of the Manley Mfg. Co.

Julius S. Holl of the Link-Belt Co. was elected president of the Engineering Advertisers' Association at the annual meeting held at the Great Northern Hotel, Chicago, on March 14. The other officers elected at the meeting were as follows: Vice-president, J. B. Patterson, of the P. H. & F. M. Roots Co.; treasurer, C. H. Connell, Weller Mfg. Co.; and secretary, H. N. Baum, Celite Products Co. The members of the board of directors are E. W. Clark of the Clark Equipment Co.; A. K. Birch, Allis-Chalmers Mfg. Co.; Morris W. Lee, of Frank D. Chase, Inc.; and W. F. Leggett of the Chemical Engineering Catalogue Co., Inc.

Henry Harnischfeger and his wife are taking a combined business and pleasure trip around the world. Mr. Harnischfeger is one of the founders and the president of the Pawling & Harnischfeger Co., Milwaukee, Wis., manufacturer of cranes, hoists, monorail systems, horizontal drills, milling machines and all classes of gasoline-driven excavating machinery. They expect to go to Japan, the Philippines, China, Burma, Ceylon, India, and Europe. They will visit the various branch offices of the Associated Machinery Corporation, of which Mr. Harnischfeger is also president, with a view to looking over general business conditions and possibilities in the Far East, and also to determine upon the opening of new offices.

John McConnell has become affiliated with the United Alloy Steel Corporation of Canton, Ohio, in the capacity of vice-president in charge of operation. Mr. McConnell was previously associated with the company, in the early period of its existence, and contributed greatly to its success. He is an alloy steel expert, having been connected for ten years with the Carnegie Steel Co., for three years with the Bethlehem Steel Co. and for eleven years with the United Steel Co. (now the United Alloy Steel Corporation). He was also associated with the Central Steel Co. for one year as consulting metallurgist, and was vice-president in charge of alloy steel production with the Interstate Iron & Steel Co. for three years.

OBITUARIES

Joseph H. Shepherd, formerly mechanical engineer with the Blanchard Machine Co., Cambridge, Mass., died March 2 at his home in Needham Highlands, Mass.

John Lambert, first president of the American Steel & Wire Co., died at Pasadena, Cal., March 6, aged seventy-five years. Mr. Lambert was one of the organizers of the United States Steel Corporation.

Frank E. Cable, one of the organizers of the Porter-Cable Machine Co., Syracuse, N. Y., died in Newton Centre, Mass., on March 7. Mr. Cable was treasurer of this company until about two years ago, when he retired, moving to Nantucket, Mass., and later going to Newton Centre, where he made his home until his death.

Edward M. Barr, manager of the Chicago office of the Chisholm-Moore Mfg. Co., Cleveland, Ohio, died suddenly on March 15. Mr. Barr was born in Milwaukee, and lived there until he went into business about twenty years ago. He was the son of J. M. Barr, one of the pioneer railroad men in the West. His connection with the Chicago office of the Chisholm-Moore Mfg. Co. covered a period of eleven years, and he had a wide acquaintance among the trade in that district. His untimely death comes as a great shock, and his loss will be keenly felt by all those who knew him. He leaves a wife and one son.

James E. Greensmith, president of the Boston Scale & Machine Co. of Boston, Mass., died on March 8. He was born in Burton-on-Trent, England, where he was educated as a mechanical engineer. His early business experience was obtained in India, and he later came to this country to take charge of the Pond Machine Tool Co., which at that time was constructing a new factory in Plainfield, N. J. Mr. Greensmith supervised the construction and equipment of the plant, as well as the design and development of a new type of heavy gun turning and boring lathe which was later installed in the Watervliet Arsenal. Upon leaving the employ of the Pond Machine Tool Co. he became associated with the Portland Co. of Portland, Me., as superintendent, and later became superintendent of the Mason Machine Works, Taunton, Mass., which position he held for many years. For the last six years he has been president and general manager of the Boston Scale & Machine Co., manufacturer of electric weighing and recording scales, rotary grinders and special machinery. He was a member of the American Society of Mechanical Engineers and also of the Engineers Club of Boston.

* * *

WARNING AGAINST IMPOSTOR

The National Machine Tool Builders' Association has distributed the following letter throughout the machine tool industry in order to protect it from similar fraud. A New England member of the association wrote as follows:

On February 8, we were visited by a man who presented a card bearing the following inscription:

Member A. S. M. E.
Plant Engineer R. C. Cannon, M. E.
Pawling & Harnischfeger Co. Milwaukee, Wis.

As we have had business in the past with the above company, the bearer of the card was duly received as an accredited representative of Pawling & Harnischfeger. He claimed to be interested in behalf of his company in investigating other of our machines, and spent the entire day with us.

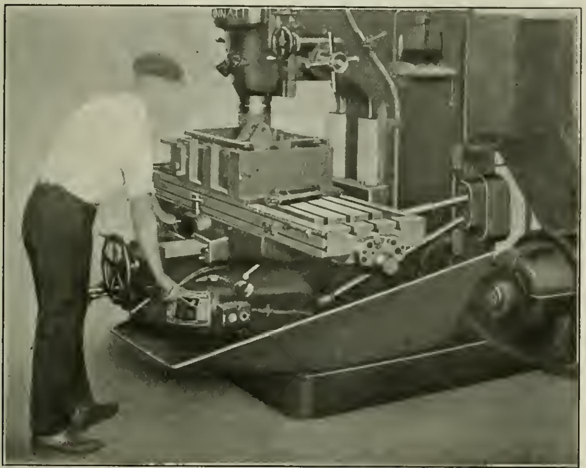
On his arrival, he informed us he had left a package of blueprints he had brought for our consideration on the train and in addition a wallet containing the most of his money, also important papers. He had, however, a certified check drawn on the West Allis Bank, West Allis, Wis., which we agreed to cash for him.

After his departure and at his request, we forwarded in his name to Pawling & Harnischfeger Co., circulars and other data relating to the matters he discussed with us. We have just received a letter from Pawling & Harnischfeger acknowledging receipt of the circulars and our letter addressed to R. C. Cannon, care of Pawling & Harnischfeger, from which it is evident that the man is an impostor. In addition, the certified check which we cashed is declared a forgery by the West Allis Bank and returned to us through our bank.

We thought it advisable to inform you at once regarding this matter, as you might, under the circumstances, wish to take some action in regard to placing other members on their guard against this party.

The same fraud has been heard of in Cincinnati, and members of the machine tool industry throughout the country should take warning.

PUT YOURSELF IN HIS PLACE! Wouldn't *you* be willing to hasten this job by changing the table direction 20 times—if you could do it by *merely moving a lever?*



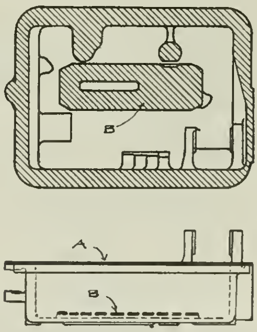
The No. 4 Cincinnati Vertical

The operator's hands are on the table quick traverse lever and the feed change lever. He uses the other two levers for cross and vertical feeds.

The operator on the No. 4 Cincinnati Vertical doesn't *have* to make all these changes. He *can* do the work with much less.

But he *does* make them because it is easy. He merely moves a lever. He doesn't change his position.

It requires very little effort and he saves time. Therefore he does it because it means more money for him. And for you it means greater production. He uses the table quick traverse (100 in. per minute) 3 times and changes feed 3 times, with the same ease and for the same reason.



The width of the flange varies end there are bosses. Time is saved by using a small mill and changing direction many times, because it is easy to change direction.

Are you missing all this by using old-fashioned Millers?

Tell us about your work and we will show what you can save.

The Cincinnati Milling Machine Co.

CINCINNATI, OHIO, U. S. A.

COMING EVENTS

April 7—Meeting of the New York Section of the American Society of Mechanical Inspectors at 29 W. 39th St., New York City. Secretary, H. M. Spitzenberg, 29 W. 39th St., New York City.

April 19-20—Annual meeting of the National Metal Trades Association in New York City; headquarters, Hotel Astor. Secretary, Homer D. Sayre, Peoples' Gas Bldg., Chicago, Ill.

April 20-22—Sixth annual convention of the American Gear Manufacturers' Association in Buffalo, N. Y.; headquarters, Lafayette Hotel. Secretary, F. D. Hamlin, 4401 Germantown Ave., Philadelphia, Pa.

April 21—Joint meeting of the Metropolitan Section of the Society of Automotive Engineers with the New England Section in New Haven, Conn. Secretary, C. F. Clarkson, 29 W. 39th St., New York City.

April 22-May 2—Sixth annual Swiss sample fair at Basle, Switzerland, in the Great Exhibition Bldg. For further information apply to F. Dossenbach, Director of the Official Information Bureau of Switzerland, 241 Fifth Ave., New York City.

April 24-26—Joint meeting of the American Supply and Machinery Manufacturers' Association and the Southern Supply and Machinery Dealers' Association at Birmingham, Ala.; headquarters, Tutweiler Hotel. Secretary, American Supply & Machinery Manufacturers' Association, F. D. Mitchell, 4106 Woolworth Bldg., New York City.

April 25-26—Spring convention of the National Machine Tool Builders' Association in Atlantic City, N. J.; headquarters, Hotel Traymore. General Manager, E. F. DuBrul, 817 Provident Bank Bldg., Cincinnati, Ohio.

April 26-28—Spring convention of the Society of Industrial Engineers in Detroit, Mich.; headquarters, Hotel Statler. Business Manager, George C. Dent, 327 S. La Salle St., Chicago, Ill.

May 8-10—Annual convention of the National Supply & Machinery Dealers' Association in Atlantic City, N. J.; headquarters, Marlborough-Blenheim Hotel. Secretary, Thomas A. Fernley, 505 Arch St., Philadelphia, Pa.

May 8-10—Twenty-seventh annual convention of the National Association of Manufacturers in New York City; headquarters, Waldorf-Astoria Hotel. General offices of the association, 50 Church St., New York City.

May 8-11—Spring meeting of the American Society of Mechanical Engineers in Atlanta, Ga. Assistant Secretary (Meetings), C. E. Davies, 29 W. 39th St., New York City.

May 10-12—Ninth National Foreign Trade Convention in Philadelphia, Pa. Secretary, O. K. Davis, 1 Hanover Square, New York City.

May 18-20—Annual conference of the National Association of Office Managers in Washington, D. C. Secretary, F. L. Rowland, Gilbert & Barker Mfg. Co., Springfield, Mass. Guests are invited to attend.

June 5-9—Annual convention and exhibit of the American Foundrymen's Association and allied societies in Rochester, N. Y. Secretary, C. E. Hoyt, Marquette Bldg., 140 S. Dearborn St., Chicago, Ill.

June 14-21—Annual meeting of the Mechanical Division of the American Railway Association in Atlantic City, N. J. Secretary, V. R. Hawthorne, 431 S. Dearborn St., Chicago, Ill.

June 15-24—International exhibition of foundry equipment and materials in Birmingham, England, in connection with the annual convention of the Institution of British Foundrymen.

June 20-24—Summer meeting of the Society of Automotive Engineers at White Sulphur Springs, W. Va. Chairman of Meetings Committee, C. F. Scott, 29 W. 39th St., New York City.

June 28-July 1—Twenty-fifth annual meeting of the American Society for Testing Materials in Atlantic City, N. J.; headquarters, Chalfonte-Haddon Hall Hotel. Secretary, C. L. Warwick, 1315 Spruce St., Philadelphia, Pa.

August 28-September 2—Annual Safety Congress of the National Safety Council in Detroit, Mich. Secretary, S. J. Williams, 168 N. Michigan Ave., Chicago, Ill.

The sectional meetings of the American Society of Mechanical Engineers for April are as follows: April 1—Oregon Section at the Oregon State Agricultural College, Corvallis, Ore. April 3—Syracuse Section at the Onondaga Hotel, Syracuse, N. Y. April 4—Eastern New York Section at Edison Hall, Schenectady, N. Y.

SOCIETIES, SCHOOLS AND COLLEGES

Melbourne Technical School, Melbourne, Australia. Prospectus of the Workingmen's College of the school for the year 1922, covering courses of study, tuition, and other related matters.

NEW BOOKS AND PAMPHLETS

Iowa Women in Industry. 73 pages, 6 by 9 inches. Published by the United States Department of Labor, Washington, D. C., as Bulletin No. 19 of the Women's Bureau.

Perpetual Inventory or Stores Control. 30 pages, 6 by 9 inches. Published by the Fabricated Production Department of the Chamber of Commerce of the United States, Mills Bldg., Washington, D. C.

The Production of Liquid Air on a Laboratory Scale. By J. W. Cook. 10 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Scientific Paper No. 419 of the Bureau of Standards. Price, 5 cents.

Method for Precision Test of Large-capacity Scales. By C. A. Briggs and E. D. Gordon. 16 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Technologic Paper No. 199 of the Bureau of Standards. Price, 5 cents.

Thermal Expansion of Nickel, Monel Metal, Stellite, Stainless Steel, and Aluminum. By Wilmer H. Souder and Peter Hidnert. 23 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Scientific Paper No. 426 of the Bureau of Standards. Price, 10 cents.

Effect of Heat-treatment on the Mechanical Properties of One Per Cent Carbon Steel. By H. J. French and W. George Johnson. 121 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Technologic Paper No. 206 of the Bureau of Standards. Price, 15 cents.

Weights and Measures. 132 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Miscellaneous Publication No. 48 of the Bureau of Standards. Price, 20 cents.

This pamphlet contains a report of the fourteenth annual conference on weights and measures of representatives from various states held at the Bureau of Standards in Washington, May 23 to 26, 1921.

Manual for Engineers. Compiled by Charles E. Ferris, Professor of Mechanical Engineering, University of Tennessee. 230 pages, 2¾ by 5¾ inches. Published by the University of Tennessee, Knoxville, Tenn. Price, 75 cents.

This little vest-pocket handbook for engineers and business men has reached its twenty-fourth edition. It contains about fifty tables considered to be of the greatest general use, including tables of areas and circumferences of circles; squares, cubes, square roots and cube roots; logarithms; sines, tangents, and secants; decimal conversion tables; weights of square and round bars; earthwork tables; wiring tables; interest tables, etc. The small size of this book makes it convenient to carry about for constant reference, but it has the disadvantage of making it necessary to use such small type that the figures in some cases are not very clear.

Mechanical World Electrical Pocket Book. 393 pages, 5 by 6¼ inches. Published by Emmott & Co., 65 King St., Manchester, England. Price, 2 s., net.

The 1922 edition of this little reference book has been enlarged considerably, and its scope has been extended to include a section on power station construction and operation. This contains considerable information of interest to those concerned with electric generating equipment. Another new section dealing with electric hoists contains much information on the construction and installation of such equipment. For the benefit of those not familiar with this book it may be stated that it represents a collection of electrical engineering notes and rules, as well as considerable tabular material, covering dynamos and motors, transmission conductors and cables, wiring systems and methods, lighting circuits and switching, electrical measurements and testing, electric lamps, telephones, small electric tools, electric welding, electric heating and cooking, etc.

Milling Cutters and Milling. 60 pages, 5 by 7½ inches. Published by the National Twist Drill & Tool Co., Detroit, Mich. Price, $1.

The purpose of this book is to present to those interested in the art of milling, data gathered by this company during a long period of intimate contact with milling work in its various branches, together with the results of extensive research work carried on at the University of Michigan within the last two years. The material should be of benefit to makers and users of milling cutters alike. The book contains fifteen chapters under the following headings: The Process of Milling; Milling Compared with Turning and Planing; Research Equipment; Rake; Clearance and Spiral; Shape of Teeth; Chip Space; Number of Teeth; Cutter Design and its Effect on Power Requirements; Feeds; Cutter Speeds; Lubrication and Cooling; the Milling Machine; its Relation to the Cutter; the Care of Milling Cutters; and Various Types of Milling Cutters and their Uses.

Burning Liquid Fuel. By William N. Best. 341 pages, 6 by 9 inches. Published by the U. P. C. Book Co., Inc., 243 W. 39th St., New York City. Price, $5, net.

It is generally recognized that the burning of liquid fuel is a science and that successful results can be obtained only by burning it scientifically. The information contained in this book is based on a study of over 42,000 burner installations, and the results should eliminate guesswork, and enable power plant owners to reduce their power costs considerably. The book gives comparative fuel costs, installation methods, ways of burning liquid fuel economically, and presents the results of a great number of tests and installations. The subject matter covers all forms of equipment for burning liquid fuels, giving information on the design and proper installation in each case. The equipment used in foundry practice, heat-treating furnace practice, forge-shop practice, and many diversified fields, is dealt with. Simple language is used so that the book will be readily understood by all.

Mechanical World Year Book. 348 pages, 4 by 6¼ inches. Published by Emmott & Co., Ltd., 65 King St., Manchester, England. Price 2s. 6d., net.

This well-known reference book is now in its thirty-fifth edition, and has been enlarged by the addition of twenty pages. The section on boiler construction has been largely rewritten, and a considerable amount of new matter has been added. A new section on pipes and tubes contains a concise collection of data on pipes of cast iron, wrought iron, steel, and copper, with many tables of dimensions, and particulars of flanged bends and tees, expansion bends, etc. The tables on the thermal properties of solids, liquids, and gases which appeared in a former issue have been restored by request, as have also the tables of weights of hexagonal and octagonal bars. A table giving the weights of fillets is also included. Many other sections of the book have been revised, and a number of new illustrations have been introduced. One of the valuable regular features of the book is the classified buyers' directory which is published in four languages—English, French, Russian, and Spanish.

Jigs and Fixtures. By Albert A. Dowd and Frank W. Curtis. 293 pages, 6 by 9 inches; 232 illustrations. Published by the McGraw-Hill Book Co., Inc., New York City. Price, $3.

This is the first of a series of three books covering the subject of tool engineering. This volume deals with the design of jigs and fixtures. It covers the important points connected with the design, compares different methods, and takes up principles of design and their application. A large number of diagrams are included to illustrate the principles involved. In this book the aim has been to deal chiefly with fundamental principles, rather than with specific designs, so that the designer can analyze his own peculiar problems and apply the principles set forth to the case under consideration. The subject matter is divided into eleven chapters under the following headings: Outline of Tool Engineering; Fundamental Points in Drill Jig Design; Details of Drill Jig Construction; Open and Closed Jigs; Indexing and Trunnion Jigs; Details of Milling Fixture Construction; Design of Milling Fixtures; Design of Profiling Fixtures; Vise Jaws and Vise Fixtures; Broaches and Broaching Fixtures; and Design of Riveting Fixtures.

Electric Arc Welding. By E. Wanamaker and H. R. Pennington. 254 pages, 6 by 9 inches. Published by the Simmons-Boardman Publishing Co., Woolworth Bldg., New York City. Price, $4.

The authors of this work have not attempted to cover the electric welding art in its broadest sense, but have confined the treatment exclusively to autogenous electric arc welding. The phenomena of the welding arc and the metallurgy of welding are in such a state of development that the authors' information has been limited to the research which has come under their observation. The effort has been made to present information that is most in demand for practical purposes. The material is conveniently arranged for ready reference. The book treats of many phases of the application of the art and covers descriptions of welding systems and their installation, phenomena of the metallic and carbon welding arc, training of operators, sequence of metal disposition for various types of joints and building up operations, electrode materials used, weldability of various metals, weld composition, thermal disturbances of parts affected by the welding process, physical properties of completed welds, efficiency of welding equipments expressed in pounds of metal used or deposited per kilowatt hour, welding cost, etc.

Materials of Construction. By the late Adelbert P. Mills. Second edition, edited by Harrison W. Hayward, Professor of Materials of Engineering, Massachusetts Institute of Technology. 476 pages, 6 by 9 inches. Published by John Wiley & Sons, Inc., 432 Fourth Ave., New York City. Price, $4.

This is the second edition of an original work prepared by the late Professor Mills of Cornell University. No attempt has been made to change the original fundamentally, but in the new edition certain chapters have been condensed, parts of others have been rewritten, and several new chapters have been added. The book has also been divided into sections. The original work was prepared to meet the need for a general textbook covering the manufacture, properties, and uses of the more common materials of engineering construction. The treatment of the various classes of materials considered follows a general systematic form which has been made uniform throughout as far as practicable. The consideration of each material or class of materials is prefaced by a discussion of its ordinary applications in engineering construction, followed by a study of its manufacture or natural occurrence, and concluded by a discussion of physical and mechanical properties in their relation to its uses. Whenever possible the data has been presented

Two handles may be better than one on a wash tub or a trunk, but not on a machine tool when one handle will do as well.

And when one handle will do BETTER than two or more, the advantage is great; on the

"PRECISION"

BORING, DRILLING AND MILLING MACHINE

one handle starts *any* feed previously selected and arranged for, so that the operator *cannot* inadvertently start a feed that is not wanted

AND THAT IS NOT ALL!

The *same* handle throws in the *constant speed quick return* motion to whichever feed is in use, and

FURTHER;

The quick return is *always* in the *opposite direction,* so that the cutting tool *cannot* be thoughtlessly jammed into the work, giving *increased efficiency* from the *simplicity.*

The accuracy of the "Precision" has been well known for 20 years and certainly will not be neglected now or ever.

NEW CATALOGUES AND CIRCULARS

Electric Controller & Mfg. Co., Cleveland, Ohio. Bulletin 1031-A, descriptive of E. C. & M., Type DR drum controllers for direct-current and alternating-current motors.

H. Gerstner & Sons, 53-63 Columbia St., Dayton, Ohio. Catalogue 22, containing specifications for the different sizes and styles of tool cases and chests made by this concern.

Kales Stamping Co., 1659 W. Lafayette Blvd., Detroit, Mich. Circular containing a list of sizes of special washers, of any gage or any material, for which the company has dies.

Wagner Electric Mfg. Co., St. Louis, Mo. Circulars outlining the main features of the Wagner "Pow-R-full" polyphase motor. Attention is called especially to the rigidity of construction.

New Departure Mfg. Co., Bristol, Conn. Loose-leaf sheets 143 FE and 144 FE, illustrating the application of New Departure single- and double-row ball bearings in metal spraying pistols and in mixing machine heads.

Deschanel Engineering Corporation, 90 West St., New York City. Bulletin descriptive of the Deschanel single-line cableway for handling coal and other materials, when unloading from railroad cars or barges into storage.

Surface Combustion Co., 362 Gerard Ave., Bronx, New York City, announces that it now has ready for distribution Bulletin 3D on Surface Combustion low-pressure air-gas inspirators, which are so designed that they may be readily applied to any make of gas furnace.

John Steptoe Co., Cincinnati, Ohio. Catalogue covering the Steptoe line of shapers, milling machines, and engine lathes. Specifications are given for the 14-, 16-, 20-, and 24-inch crank shapers, the No. 0 hand and power feed milling machines, and the 14-, 16-, 18-, and 20-inch lathes.

Technical Advisory Corporation, 132 Nassau St., New York City. Pamphlet outlining the activities of the concern, which cover service to manufacturers, bankers, and public utilities, research and development work, appraisals, the development of foreign trade, and industrial surveys.

Hamblin Tool Mfg. Co., Inc., 42 Mechanic St., Newark, N. J. Circular entitled "The Wrench that Grips and Never Slips," illustrating the use of the Hamblin reversible chain pipe wrench, which has a cam action permitting it to be reversed instantly without detaching the chain.

Black & Decker Mfg. Co., Towson Heights, Baltimore, Md. Miniature catalogue containing illustrations, specifications, and prices of Black & Decker portable electric drills, electric screw-drivers and socket wrenches, electric grinders, safety cleaning machines, and electric valve grinders.

Oliver Machinery Co., Grand Rapids, Mich. Bulletin 5, containing information on the care of circular sawing machines of the type used in woodworking plants and pattern shops. The catalogue illustrates a number of different styles and sizes of these machines. Copies will be sent to those interested upon request.

Whiting Corporation, Harvey, Ill. Circular illustrating the equipment made by this concern, which includes cranes, foundry equipment, trolley systems, hoists, transfer tables, etc. This company is also issuing to the trade a desk calendar card covering the last three months of 1921, the year 1922, and the first three months of 1923.

Foxboro Co., Inc., Foxboro, Mass. Pamphlet entitled "How Far Can You Read It?" devoted to Foxboro dial type thermometers, which are designed to give a maximum degree of visibility, the indicator having a dull black ground and white figures. These thermometers are made entirely of metal, there being no glass tubes to break.

Air Reduction Sales Co., 342 Madison Ave., New York City. Leaflet descriptive of the "Airco" D cutting torch, covering the features of design and construction, and containing tables showing the thicknesses of metals that can be cut, pressures of oxygen and acetylene necessary, and the gas consumption in cubic feet per hour when using tips adapted to the cutting of steel, cast iron, or rivets.

Wodack Electric Tool Corporation, 23-27 S. Jefferson St., Chicago, Ill. Bulletin 908, describing the Wodack combination portable electric drill and grinder, which is designed to fill the needs of shops and factories where drilling and grinding operations are performed but where there is not enough work of this kind to warrant the purchase of two separate machines. Complete specifications are given, including price.

Madison Mfg. Co., Spring and Elton Sts., Muskegon, Mich. Circular illustrating and describing Madison adjustable boring heads for rough- or finish-boring, made in sizes from 2¼ to 8 inches in diameter; adjustable boring cutters and bars for finish-boring; and counterbores equipped with cutters that are made to work both ways, so they can be used for front or back facing. In addition to the general description, complete price lists are given for the various sizes.

Ingersoll Milling Machine Co., Rockford, Ill. Circular illustrating Ingersoll milling machines, equipped with Ingersoll fixtures and cutters, for use in railway shop work and ordinary production work. The fixtures are shown applied to continuous rotary milling machines, heavy-duty adjustable-rail milling machines, fixed-rail reciprocating machines, horizontal-spindle milling machines, drum-type continuous milling machines, reciprocating continuous milling machines and multiple-spindle fixed-rail milling machines.

American Machine Products Co., Detroit, Mich. Circular illustrating "Ampco" Critchley improved adjustable reamers and Simplex gages for adjusting these reamers to the correct size for reaming the different sizes of bushings in Ford automobiles. In applying the gages, it is merely necessary to select a gage of the same size as the bushing to be reamed, place the reamer in a vise, and put the ring, or gage, over the reamer, after which the blades are adjusted until the ring is a snug fit on the tool. The adjustment by this method is said to require only five minutes, as compared with thirty minutes when adjusting with a micrometer. The reamers and gages are supplied in sets of different sizes. They are marked with corresponding letters, so that the gage to use with a reamer for a certain size bushing can be readily determined. The circular gives full particulars, including dimensions, prices, etc., for the sets, as well as for single tools.

TRADE NOTES

Gropler Bros., representatives of manufacturers of metal-cutting tools, are now located at 16-22 Hudson St., New York City.

Monarch Machine Tool Co., 209 Oak St., Sidney, Ohio, announces that it has made a reduction of 10 per cent in the price of Monarch lathes.

G. A. Ball Bearing Mfg. Co. has moved into a new factory at 3305-3335 W. Harrison St., Chicago, Ill. The building is of one-story, saw tooth construction.

Taft-Peirce Mfg. Co., Woonsocket, R. I., has moved its Detroit office from 1311 Majestic Bldg. to 2230 First National Bank Bldg. William Fairhurst is manager of the Detroit office.

Toledo Tap & Die Co., Toledo, Ohio, manufacturer of taps and dies, announces that it has opened a Cleveland office at 716 Superior Ave., N. W., and a Pittsburg office at 631 Fulton Bldg.

Chicago Flexible Shaft Co., 1154 S. Central Ave., Chicago, Ill., has moved its St. Louis office, which handles the sale of Stewart industrial furnaces, from the Railway Exchange Bldg. to 420 Wainwright Bldg.

Seneca Falls Mfg. Co., Inc., Seneca Falls, N. Y., at its annual meeting of stockholders in February re-elected Ogden R. Adams, president and general manager of the company. An entirely new board of directors was also elected.

Black & Decker Mfg. Co., Towson Heights, Baltimore, Md., has moved its Cleveland office from 6225 Carnegie Ave., to 2030 E. 22nd St. This office is in charge of Dan Paul, former manager of the Pittsburg office of the company.

Massachusetts Gear & Tool Co., 30 Nashua St., Woburn, Mass., has purchased the business of the Woburn Gear Works. The company will specialize in accurately cut small and medium size gears and sprockets of all types and of all materials.

Russell Mfg. Co., Greenfield, Mass., has appointed the **A. Z. Boyd Co.**, 126 Chambers St., New York City, as the New York agent for the sale of the Russell line of screw plates. The A. Z. Boyd Co. has had wide experience in the past in selling tools of this kind.

Tool Sales Co. announces that it is now located in the Hudson-Reade Building, New York City. This company sells tools and specialties to the hardware and automobile supply trade, and is in a position to render sales service in the Metropolitan District to manufacturers who are in need of such services.

Williams, White & Co., Moline, Ill., have taken over the Osterholm automatic surface grinding machine formerly made by the Osterholm Automatic Machine Co. of Chicago. In the future this machine will be manufactured in the Williams, White & Co.'s plant in Moline. This machine was described in the technical press about six months ago.

Colonial Steel Co., Pittsburg, Pa., has purchased a lot in Cleveland, Ohio, at 2121 St. Clair Ave., and is now having plans drawn and will begin at once the erection of a brick warehouse to be used for the storage and sale of Colonial steel. This warehouse will also be equipped with furnaces for heat-treating steel with a view to assisting customers in working out problems of this kind.

Eastern Machine Screw Corporation, 23-43 Barclay St., New Haven, Conn., manufacturer of H & G automatic die-heads, collapsible taps, and screw machine products, announces that its die-head works are now operating five days a week and ten hours a day. The business of the company has shown a decided improvement during the months of January and February.

Diamant Tool & Mfg. Co., Inc., 95 Runyon St., Newark, N. J., has appointed the **McMullen Machinery Co.**, 64-66 Ionia Ave., Grand Rapids, Mich., its exclusive representative in connection with the sale of Diamant standard punch and die sets in the territory covered by the northern and the southern peninsulas of Michigan, west of the counties of Bay, Saginaw, Shiawassee, Ingham, Jackson, and Hillsdale.

Shepard Electric Crane & Hoist Co., Montour Falls, N. Y., announces that its New York and Philadelphia territories have been consolidated under the management of Mr. Gledhill, with headquarters at the New York office, 30 Church St. Although the Philadelphia office has been closed, the number of sales engineers in that territory, as well as in the New York territory, has been increased so that closer personal contact can be maintained with concerns in these sections.

Kendell Engineering Co., 12 North American Bldg., Fort Wayne, Ind., manufacturer of Kendell piston-rings, announces that it has made definite plans for expansion, having incorporated under the state laws of Indiana and now being known as the Kendell Engineering Corporation. The construction of a new plant is to begin at once. The officers of the company remain the same as before, namely, C. A. Kendell, president; Robert L. Kendell, vice-president and sales director; and M. W. Cartwright, secretary and treasurer.

C. H. Wood Co., 214 W. Jefferson St., Syracuse N. Y., wholesale dealer in machinery, tools, factory supplies and equipment, has changed ownership, the interest of Charles H. Wood having been purchased by Wilton R. Olds, George E. Ingraham and A. J. Littlejohn. Mr. Olds has been elected president and general manager of the company; Mr. Littlejohn, vice-president, and Mr. Ingraham, secretary and treasurer. Mr. Littlejohn is also secretary of the Meldrum-Gabrielson Corporation, and will continue his activities with that firm.

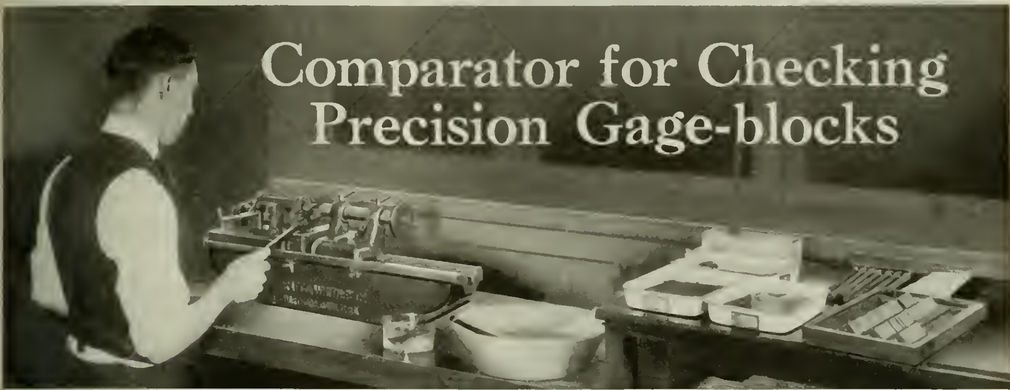
Medart Patent Pulley Co., St. Louis, Mo., manufacturer of power transmission machinery, has changed its name to the **Medart Co.** The change was made because of the fact that the former name gave an erroneous idea of the extent of the line carried by the company, which includes, besides cast-iron and wood-pulleys, friction clutches, rope drives, gears, sprockets, hangers and bearings of all kinds, turned and polished steel shafting, as well as machines for turning, polishing, and straightening shafting, and other special machinery and equipment.

Air Reduction Sales Co., 342 Madison Ave., New York City, and the Davis-Bournonville Co., Jersey City, N. J., have been amalgamated. The arrangement will make the combined sales and service facilities of both companies available to users of oxy-acetylene equipment. The firm will continue to make the "Airco" products, which include oxygen, acetylene, welding and cutting apparatus and supplies, acetylene generators, carbide, nitrogen, and argon, as well as the Davis-Bournonville welding and cutting apparatus, including the oxygraph, radiagraph, tube-welding equipment and other special devices.

Greenfield Tap & Die Corporation, Greenfield, Mass., has compiled a comprehensive telegraph and cable code for the benefit of its customers. The code was originally intended for overseas customers, but it is equally suitable for domestic concerns, and will enable cable and telegraph expense to be materially reduced. The technical nature of the company's products, which include screw plates, taps and dies, drills, reamers, gages, and machine tools makes it difficult to describe them by any standard code, and the five-letter code compiled by the company enables these products to be ordered by wire at the minimum of expense. The code is included in the new 46-A catalogue which has just been issued by the company. Copies will be sent upon request.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., has made a number of changes in personnel. The new appointments are as follows: R. L. Rathbone, branch manager of the Cleveland office, will take up special duties in connection with merchandising matters, with headquarters in Cleveland; J. Andrews, Jr., manager of the industrial division of the Pittsburg office, has been appointed manager of the Cleveland office, and will be succeeded by C. D. Taylor in the Pittsburg office; W. R. Keagy has been appointed office manager of the Cincinnati office; J. R. Deering has been made office manager of the Los Angeles office; and R. Seybold has been appointed manager of price statistics, and will also act as secretary of the domestic sales committee.

Whiting Corporation, Harvey, Ill., manufacturer of electric traveling cranes and foundry equipment, has established a branch sales office in New York City at 130 Liberty St., having discontinued its agency agreement with the Wonham, Bates & Goode Trading Corporation, who formerly represented the company in the East. J. Ross Bates, one of the vice-presidents of the Whiting Corporation, is in charge of the new office. He will be assisted in the New York territory by D. Polderman, Jr., and in the New England states by R. O. Maley, who will open an office at Springfield, Mass. A branch office has also been opened in Indianapolis, Ind., at 305 Merchants Bank Bldg., in charge of S. E. Stout, who was formerly located at the main office in Harvey. Mr. Stout will cover southern Indiana and adjoining cities in Ohio and Kentucky. The Detroit office of the company has been moved from Penobscot Bldg. to 206 Stahelin Bldg., 3000 Grand River Ave.



Comparator for Checking Precision Gage-blocks

An Extremely Sensitive Mechanical Apparatus, which has Proved Very Effective at the Plant of the Pratt & Whitney Co., for Testing the Accuracy of Precision Gage-blocks

By FRANKLIN D. JONES

CHECKING the sizes of precision gage-blocks in connection with their manufacture must necessarily be by comparison with a master block or standard of known accuracy, because a comparative test can be made quickly and is entirely reliable when all necessary precautions are taken. At the plant of the Pratt & Whitney Co., Hartford, Conn., the accuracy of the precision gage-blocks manufactured and of the working and primary standards is maintained by three different methods of testing, which are so related as to insure a uniform degree of precision, approaching very close to absolute perfection.

First, there is the well-known optical test employed to check the sizes in connection with the mechanical lapping of the commercial gage-blocks. This simple test, which requires the use of optical flats, or exceedingly accurate glass planes, has already been described in MACHINERY, and will not be considered further (see April, 1920, MACHINERY, page 705). This optical test, which is relatively accurate and quickly made, serves to compare the commercial gage-block with a working master.

The optical test has these disadvantages: (1) Its accuracy is plus or minus three-millionths inch, and a whole interferometer band may easily be missed, introducing an additional error of ten-millionths inch. (2) The gage-blocks must be handled in wringing, so that the operator may not have the block at temperature when the reading is taken. (3) It is an optical and not a contact measurement, and the condition of the block surface as regards polish may give an incorrect reading. This reading will be correct optically for the block, and yet it will not be correct for its contact value when the gage is placed in a stack with other blocks.

Making precision gage-blocks on a commercial basis requires an extremely accurate, dependable, and fairly rapid method of checking the truth of gage surfaces and their dimensions. The "millionth comparator" here described meets these exacting requirements by providing a mechanical test, which follows the well-known optical test and serves as an additional safeguard against errors. The master gages or primary standards used for this comparative test, are measured by means of an interferometer in which light waves are utilized as the ultimate standard either for originating or checking dimensions with the greatest possible degree of accuracy.

To safeguard against the probabilities referred to, a "millionth comparator" is used to check against masters. This comparator has no intrinsic temperature or band errors. The masters are not checked in the comparator except when a block gives two plausible readings in the interferometer described later. Then the masters are stacked against others which have given no trouble, and one of the two readings is selected, which checks with the observation in the comparator. The comparator is used to check every commercial block which will pass the optical test. This check can be further augmented by a test made at the Bureau of Standards, if it is desired.

Measurement of the Primary Standards

Now all blocks tested by the comparator are compared directly with primary standards, measured by the most precise method known. A bare outline of this method, which is too complex to be described fully here, will be given before considering the comparator.

While master gages or standards for checking other gages by direct comparison may also have been subjected to some purely comparative test, it is evident that there must be a fundamental method of measuring the primary standard. There is no intermediate master between the super-master and the commercial block. Every batch of blocks made is measured against a master which has been read in the interferometer just previous to the beginning of the job; thus a master may be read many times in its life. Such refinement is unnecessary in most

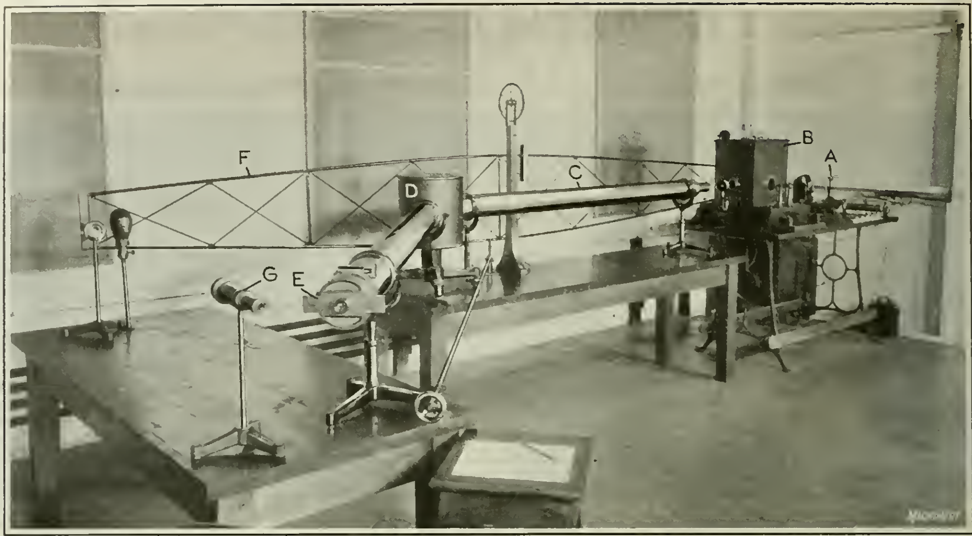


Fig. 1. Fabry & Perot Interferometer used by the Pratt & Whitney Co., for calibrating or measuring Primary Standards

cases, since successive readings check, but it is worth while because the method is absolutely safe. When one of these primary standards requires measuring either to determine the dimension of a new one or to check the size of an old one, this fundamental measurement is made by the interferometer. The use of this optical apparatus is a scientific undertaking, requiring considerable time and involving complex calculations. For this reason all commercial methods of checking accuracy must be comparative, and the taking of fundamental measurements is necessarily confined to the basic or primary standards, such as are used to a very limited extent for checking working masters, where the greatest possible degree of accuracy is required.

Use of the Interferometer

The interferometer used by the Pratt & Whitney Co. is shown in Figs. 1 and 2. This apparatus, which is one of the few in existence, is used to assist in determining the number of light waves of known wave length (or color) which at a given instant are between two planes coinciding with the opposite faces of a gage-block or whatever part is to be measured. When this number is known, the thickness can be computed because the lengths of the light waves used have been determined with almost absolute precision. The light, therefore, becomes a scale with divisions—approximately two hundred-thousandths inch apart.

The block to be measured is placed between two glass planes of great accuracy, which have previously been wrung into perfect contact, so that each plane extends beyond the block on one side. Thus the block is measured optically by contact and not by reflection from the gage surface itself. The character of the surface is likely to affect the latter reading, and the degree of polish cannot affect the first method, since the light does not strike the surface. The projecting ends of the glass planes are covered by an exceedingly thin transparent film of gold about one-half millionth inch thick, to increase the reflecting power. The planes with the block between them are secured to a suitable holder, which

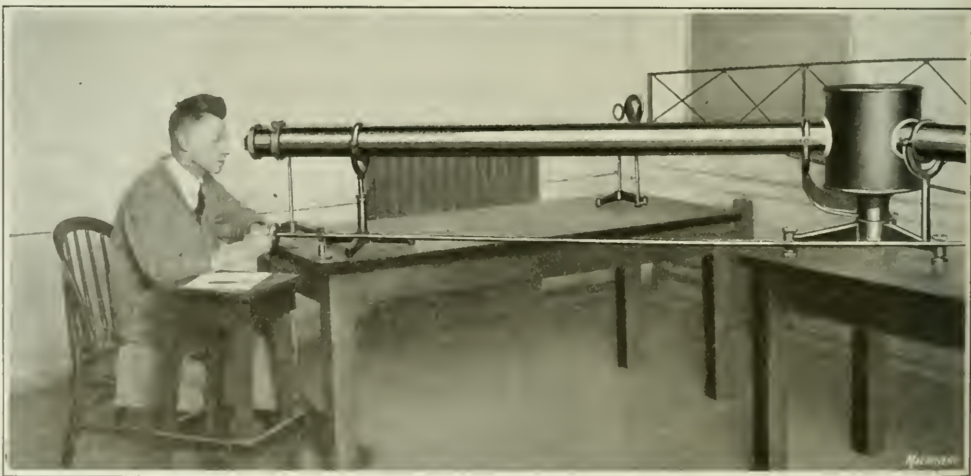

Fig. 2. Taking a Reading with the Interferometer which makes it Possible to use Light as a Scale, with Divisions approximately Two Hundred-thousandths Inch Apart, for measuring Reference Standards

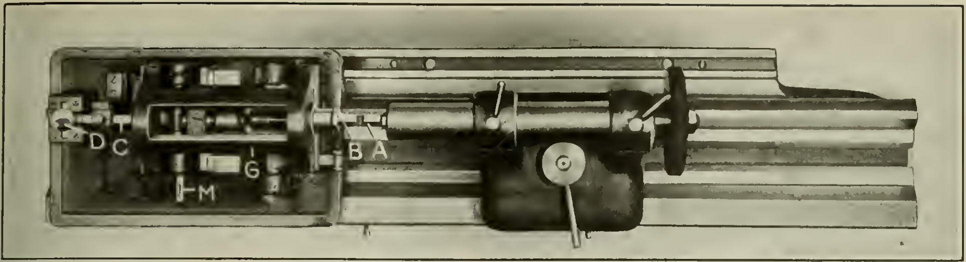

Fig. 3. Plan View of Comparator used for checking Precision Gage-blocks

is inserted in box *B*, Fig. 1, through an opening in the side. A constant temperature is maintained inside of this box by circulating oil through a series of coils and by means of a thermostat in conjunction with an electrical heating unit which serves automatically to maintain the temperature within very close limits.

The standard wave lengths used are those emitted by glowing Neon gas under electric discharge. These wave lengths have been calibrated against the Michelson-Benoit standard by Meggers and Peters of the Bureau of Standards to an accuracy of one part in four millions. It has been found to be a satisfactory and constant reference standard under easily reproducible physical conditions. The Neon light is located at *A*. Light waves from this source enter through a lens and suitable opening into box *B*, pass through the projecting ends of the glass planes referred to, and then through another lens and tube *C* to a prism or spectroscope located within the cylindrical box *D*. The light is refracted, and the rays of different lengths separated by this prism so that they can be observed through the telescope at *E*. The holder carrying the glass planes and block to be measured is attached to and turns with a long protractor arm *F* of light tubular construction. At the outer end of this arm there is a scale indicating angular movements, and this is enlarged by the telescope *G* at the observing end of the apparatus. The angular position of the protractor arm and of the glass planes is regulated by turning a handwheel (see Fig. 2) which transmits motion to the arm through suitable shafting and gearing.

Now at certain angular positions of the glass planes the phenomenon of light interference occurs. These angles, which vary for different light rays, are noted by taking readings on the scale seen through telescope *G*. When several of these angular values are known, in addition to the lengths of the different light waves, the required distance between the two planes is determined mathematically by a process of elimination carried on until the true value is obtained, as proved by the fact that it is the only value that satisfies an equation containing the other known values. When the number of waves is found (within a small fraction of a wave) it is multiplied by the known wave length, and the product is the absolute length of the block. This gage is now a master, or primary standard, and may be confidently used to calibrate commercial gage-blocks.

Before a measurement can be taken, the block must be left in box *B* until it has acquired the same temperature. Also, considerable time is needed for the various adjustments, readings, and calculations, so that the measurement of four blocks would require ordinarily an entire day. The extreme degree of precision which it is possible to attain by the interferometer method is indicated by the fact that measurements by Mr. Mueller of the Pratt & Whitney Co., have checked within one-millionth inch with measurements of the same gage-blocks made by Mr. Peters at the Bureau of Standards, each measurement being made independently on different types of interferometers.

General Arrangement of Comparator and Method of Using

When the comparator is used to compare the accuracy of a gage-block with a primary standard, the latter is first placed between the parallel surfaces of the fixed anvil *A*, Figs. 3 and 4, and the movable anvil *B*. The apparatus is then adjusted until a zero reading is obtained. The block to be checked is next placed between the gaging ends and any difference in reading is noted. The slightest change in the position of the movable spindle is transmitted through the multiplying lever *C* to a small and slightly concave mirror *D*. When this mirror is tilted, a V-shaped shadow obtained from light *E*, Fig. 5, which passes through a lens at *H* partly obstructed by a V-shaped projection, is reflected from *D* (Fig. 4) up to mirror *F* and then down to a scale located on the wooden case which encloses the comparator as shown in Fig. 6. The slightest movement of mirror *D* causes the image of the V-shaped projection to move rela-

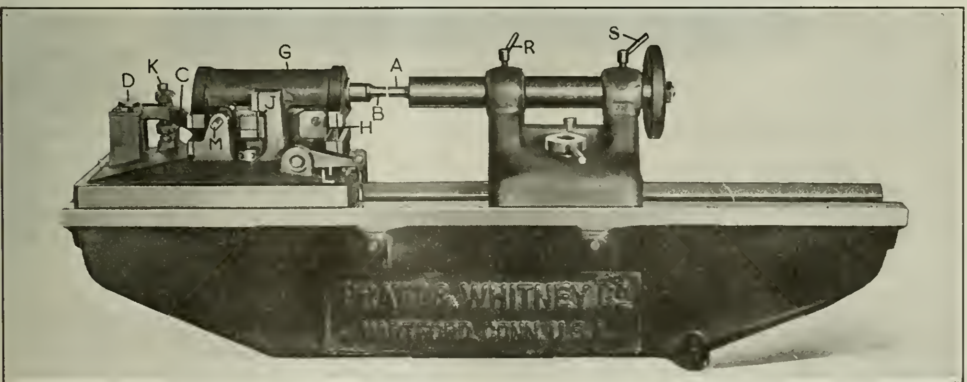

Fig. 4. Side View of Comparator which by using a Light Beam as a Lever multiplies the Movements of its Anvil 20,000 Times

tive to the zero position on the scale, thus indicating the error.

The comparator is so sensitive that a variation of even one-millionth inch causes a perceptible movement of the reflected shadow, and this sensitiveness can be increased readily by simply elevating the upper reflecting mirror and refocusing. With the two mirrors 2½ meters apart, the movements of the gaging anvil are multiplied 20,000 times, and because of this extreme sensitiveness the mechanical part of the apparatus must be enclosed when in use, since the temperature of the body causes changes that interfere with the accuracy of the test. While this comparator was built by the Pratt & Whitney Co., it is based upon a design furnished by the National Physical Laboratory of England and is one more indication of the value of this scientific organization which, like our own Bureau of Standards, has contributed so much toward scientific research and the development of apparatus for industrial uses.

One of the remarkable features of the comparator is its "dead-beat" action. There are no perceptible oscillations of the indicating shadow relative to the scale, or movements which must be allowed to die out before a reading can be taken. If the shadow is suddenly deflected from the zero position, as by lightly striking the table supporting the mechanism, the movement back to the zero point is instantaneous and without repeated vibrations. This dead-beat quality is due to the unusual method of providing for the necessary movements of the spindle frame and multiplying lever, without introducing the slightest radial or other play, such as would occur in some degree in any ordinary form of bearing.

The head or frame G (see Figs. 3 and 4) carrying the movable anvil is supported at each end by steel ribbons or thin plates about 0.003 inch thick. There is one ribbon H extending across the front, and two ribbons at the opposite end with a space between, through which multiplying lever C passes. These ribbons allow a slight lengthwise movement, but anvil B always occupies parallel positions. Any movement of the frame carrying B is transmitted to lever C, which has as the axis of its fulcrum the intersection of vertical ribbons J (located at each side of the lever) with horizontal ribbons adjacent to the vertical ribbons. These ribbons, which are about 0.004 inch thick, provide an exceedingly accurate fulcrum, and eliminate all radial, lateral, or angular play, because they form a cross and permit a turning movement about the intersection of the horizontal and vertical ribbons, but are sufficiently rigid to resist any movement except a turning of lever C about this axis of intersection.

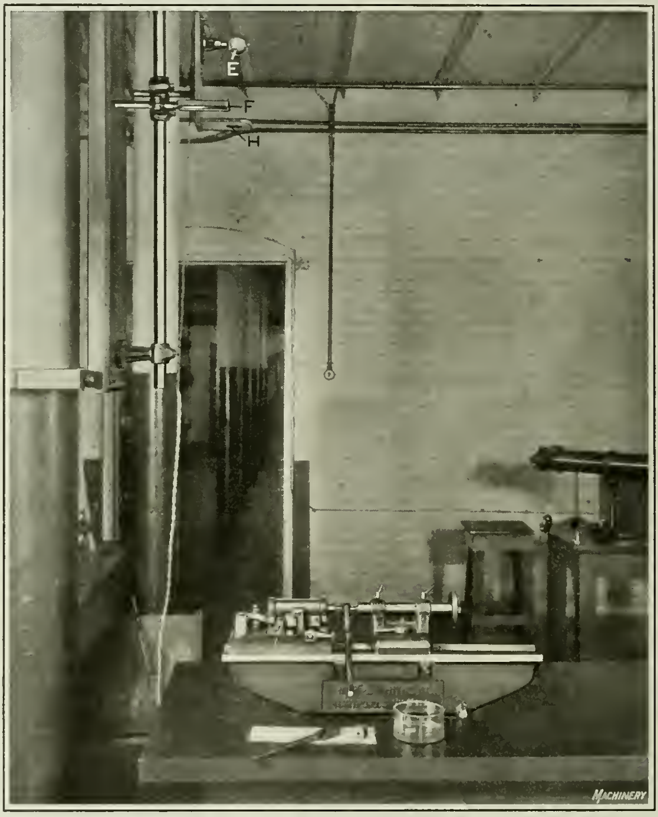

Fig. 5. Comparator with Upper Light and Mirror which reflects a Shadow upon a Scale indicating the Error

This multiplying lever C is carefully counterbalanced, and there is a point of contact between the lever and the frame through a ball located in a pocket at the upper end of the lever. The ball bears against the flat end of an adjustable plug carried by frame G. On the mirror end of lever C there are two small and very accurate plugs placed parallel to each other with a small space between. Similar pairs of fixed parallel plugs are located on each side of the lever and at right angles to those on the lever itself. These three pairs of plugs form the bearing surfaces for three very small balls which are attached to the under side of the reflecting mirror D. One ball which rests on the plugs at the end of the lever is offset relative to the other two balls, so that a 10 to 1 leverage back to this point is increased 2000 to 1, as the shadow is reflected to the upper mirror and back to the scale. The lens and circular opening, which is partly obstructed by the V-shaped projection, forms a shadow in such a way that the scale where the readings are taken is illuminated so that any movement of the shadow is readily seen. This scale has plus and minus graduations on each side of the zero position, with graduations indicating five-millionths inch and spaces between them which are sufficiently large to enable millionths of an inch to be estimated readily.

A uniform contact pressure between spindle B and the gage-block being tested is obtained by means of a weight suspended from a bellcrank L, Fig. 4, which connects with frame G through a spherical ended pin, resting in V-shaped pockets formed in the bellcrank lever and also in the frame. The frame and anvil B are withdrawn slightly for inserting or removing a gage-block, by turning shaft M which has eccentric surfaces in contact with the frame.

Adjusting and Using the Comparator

Before the comparator is used, it is adjusted so that the indicating shadow is in the zero position when the primary standard to be used is between the contact points. In setting up the comparator, the following procedure must be observed strictly or imperfect readings will result.

A weight attached to the bellcrank L is removed so that the recording anvil and its carriage assume an unstrained position. The tilting mirror and lever C are adjusted so that the mirror D is approximately horizontal. The remainder of the optical system is then adjusted until the image falls on the center of the scale and is in focus. A small block on the anvil carriage is now brought up against the ball on lever C until it is just in contact. This will insure that when the indicating shadow is on the scale, the two parallel springs supporting the anvil carriage and the cross-springs on lever C are all in mid position and unstrained. It is essential also that the machine be built with sufficient accuracy so that, in clamping the battens that bind down these springs, no warp or twist will be introduced into the springs which will not come out by taking off the bellcrank weight. The bellcrank weight is now replaced, which pulls the anvil into a strained position and tilts the mirror forward. Now the anvil may be retracted by the eccentric cams on the operating shaft M.

The whole purpose of this proceeding is simply to get the flexible springs in an unstrained condition near the point of measurement. From now on when successive blocks are placed between anvils for measurement, we can be sure that if the light remains on the scale, these springs have not been flexed a sufficient amount beyond their neutral position to affect the accuracy of the measurement.

The fixed anvil A is adjusted so that the space between the two contact points is slightly less than the width of the block to be checked. A primary standard is then placed between the contact surfaces, anvil B being withdrawn by turning eccentric or camshaft M. The spindle holding anvil A has a very accurate wringing fit in its two bearings and is next moved forward by simply turning and pushing it along until the indicating shadow is in the zero position. As a movement of a few millionths inch will cause a decided movement of the shadow, it is evident that a very sensitive adjustment for anvil A is necessary, and the degree of sensitiveness obtained simply by turning and at the same time gently pushing the spindle is an interesting feature of this part of the construction.

Fig. 8. View showing Case in which Comparator is enclosed when in Use to prevent Errors due to Temperature of the Observer's Body

When the shadow is at the zero position, the spindle holding anvil A is locked by two screws R and S, which act against bronze shoes bearing on the top of the spindle. The apparatus is so sensitive that clamping one of these screws even lightly deflects the shadow from the zero position decidedly, but it may be brought back readily by first tightening one screw and then the other until their effect on the spindle is neutralized. The rear anvil is lapped square with its axis in the bar and the sensitive anvil is then finished as nearly parallel as possible with the rear anvil when neither of the binding screws is tightened. When setting up for a block, the rear anvil is brought up against the block resting on the sensitive anvil, and since neither of the binding screws is down, it can be assumed that the two anvils are as parallel as when they were lapped. When one binding screw is put down, the flexure out of parallelism of the two faces is immediately made known by the movement of the indicating shadow. If this is brought back to its original position by tightening the other screw, it can be assumed that the anvils have again been brought parallel. This process is repeated alternately on each of the screws until they have both become tight.

It has been found that gage-blocks having dry surfaces cannot be tested satisfactorily because of minute dust particles which adhere to the surfaces and affect the reliability of the readings. This difficulty was overcome by a very simple method. The surfaces of the primary standards and the gage-blocks to be compared with them are first cleaned chemically by using ether; then, all of the blocks are immersed in highly refined and filtered kerosene mixed with a small amount of sperm oil, so that the surfaces are covered by an oil film when they are placed between the anvils of the comparator.

The block to be tested is held by pincers made of a non-conducting material (see Fig. 5), since the temperature of the hands would make it impossible to obtain accurate tests. When the block is first placed between the anvils, the end of the holder is moved up and down and tapped lightly, thus turning the block somewhat. This is necessary in order to reduce the oil film to a final thickness. This reduction, which is a very interesting phenomenon, is indicated by decided jumps in the position of the shadow relative to the scale. When the shadow settles to a point where there is no further movement as a result of the tapping on the holder, the very slight oil film remaining can be relied upon, as it is absolutely uniform for a given oil, as far as can be determined by repeated tests. To safeguard against any changes in the zero position, the primary standard is frequently inserted, assuming that a number of other standards or gage-blocks are being compared with it. This comparator has proved to be of great value, as it provides an exceedingly accurate, dependable, and comparatively rapid method of checking the accuracy of precision gage-blocks.

* * *

The Bureau of Standards has recently conducted an investigation of the operation, efficiency, and safety of oxy-acetylene welding and cutting blow-pipes. Apparatus from fourteen different makers was submitted to tests, developed jointly by the bureau in cooperation with makers. The blow-pipes were tested in a standard manner to minimize the personal equation. It developed that the principles upon which the design of such blow-pipes should be based were not well understood, and the conclusions reached should be useful to the industry. The results of the tests have been published in Technologic Paper No. 200 of the Bureau of Standards.

A Shuttle-type Drill Jig

A DRILL jig of unusual and interesting design is used for boring and drilling holes in rotary pump cases and covers in the plant of the Goulds Mfg. Co., Seneca Falls, N. Y. The jig is of a shuttle type. The chucking carriages or shuttles are started at one end of a box and pass the work through to successive spindle centers for machining, until they emerge at the opposite end with the work finished. This long shuttle box is fastened to the table of a four-spindle Barnes multiple drilling machine, as illustrated in Fig. 1. A track is provided for the shuttles, on which they slide as they are advanced from station to station.

Three views of the shuttle are shown in Fig. 2, as well as detailed views of the pump case. The shuttle is made of cast iron, open at the ends, and has a steel rack attached to the bottom so that it may be advanced by pinions, operated by handwheels at the front of the shuttle box. A sufficient number of these shuttles is provided so that the four spindles can be kept constantly in operation, and an extra shuttle permits work to be loaded in readiness to be advanced into the first spindle position as soon as this is free. The pump cases are loaded in the shuttles on a bench, and are located by four 5/16-inch pins in the top plate, as indicated in Fig. 2. They are then secured against the top plate by four jack-screws carried in bosses in the baseplate of the shuttle. Two steel-bushed tapered index-holes are located to correspond with the pitch centers of the rotary pump gears, so that by the use of a spring index-pin at the front of the shuttle box opposite each spindle, the shuttle may be correctly located while the two holes in the casting are machined. The same type of jig is used for machining the covers, the holes in which must correspond and align with those in the case, the only difference being that longer jack-screws are used.

When the loaded shuttle is placed on the extending track at the left-hand end of the shuttle box, the rack on the under side is engaged by the pinion on the first handwheel and the shuttle is advanced until the index-pin engages the first bushed hole in the shuttle box. At this station a four-lipped combination drill and countersink is employed to rough-bore one of the 1 1/16-inch holes and relieve the edge of the hole slightly with the countersink. The index-pin is then removed and the shuttle advanced to the second hole, where the operation is repeated. The work on each spindle is so timed that there is no delay in the advance of the shuttle from spindle to spindle. At the second spindle station these holes are finish-reamed, and at the third station the 4 3/16-inch holes are rough-bored with a boring-bar having a long pilot which extends into the previously finished holes. There are two of these large holes in which the rotary pump gears operate, and as they overlap, the use of a pilot for the boring-bars is essential in order to overcome the tendency of the tools to run out. At the fourth spindle station these two holes are finish-bored with a tool of the same type as that employed in the third spindle.

All drill, reamer, and boring-bar holes in the box are bronze-bushed, and the last bushing plate has four knurled feeler screws which are screwed down on the top of the shuttle to steady it and remove all likelihood of its moving while the hole is being finish-bored. Stop-collars are provided on the boring-bars to obtain the correct depth, which is held to gage limits. A plug gage, such as is shown resting on the top of the shuttle box, is also employed to check the diameters of these holes.

Jigs of this type are used for machining cases of various sizes, and when a different depth of bore is required, separate collars are used on the boring-bars under the regular stop-collars. It was stated that the shuttles are open at both ends, which makes them easily accessible for loading. It will also be noticed that the tracks on which the shuttles rest are high so that a pan can be placed between them to catch the chips from the tools and prevent the passageway of the shuttles from being clogged up. At the right in Fig. 1 may be seen another machine equipped similarly to the one

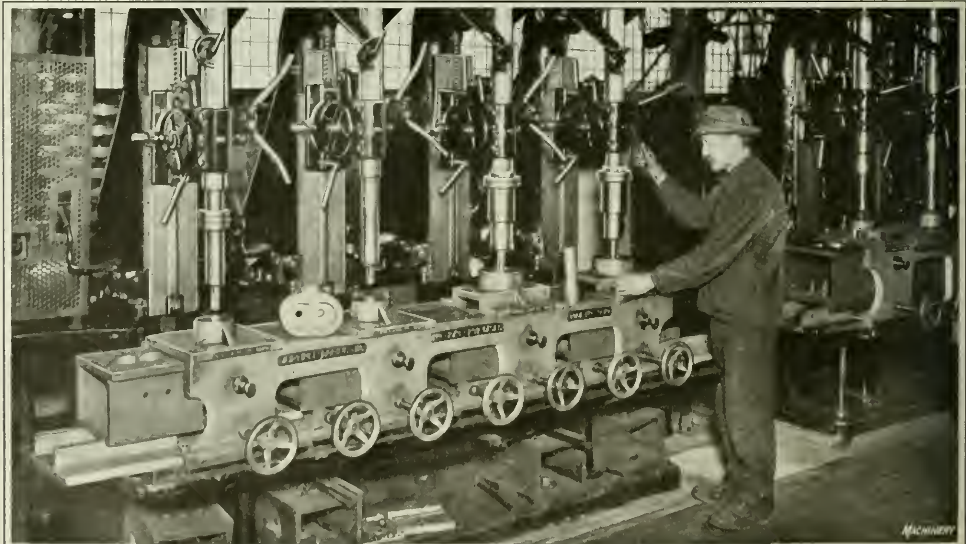

Fig. 1. Four-spindle Gang Drilling Machine with Box Jig and Work-holding Shuttles which travel from Station to Station

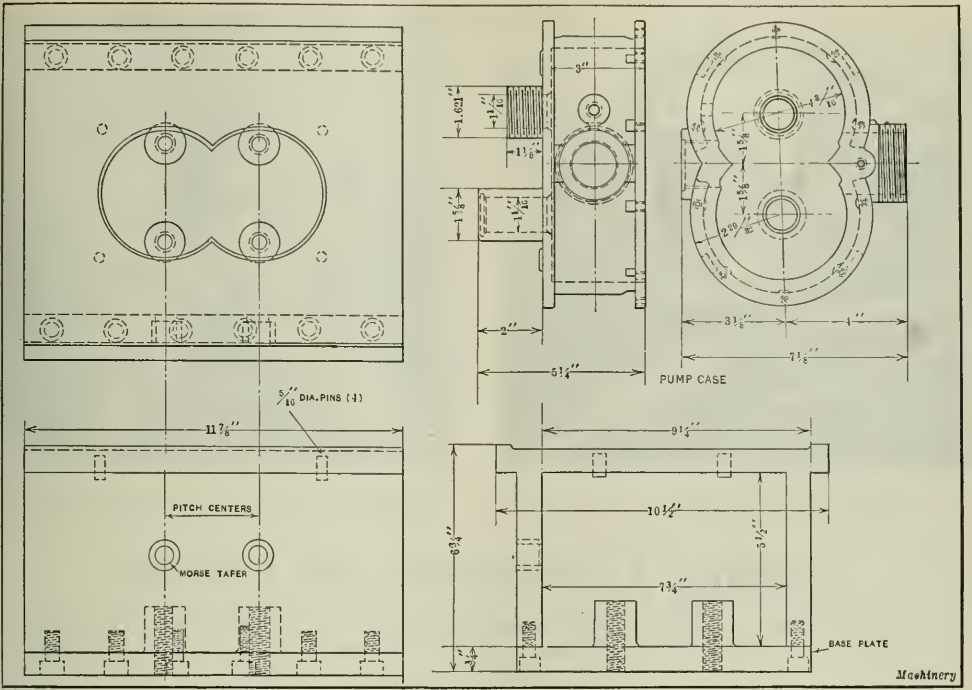

Fig. 2. Rotary Pump Case and Shuttle Jig in which it is bored

to which reference has been made, and here the covers for the cases are machined. Both machines are attended by one operator who thus produces one complete case and cover when the last shuttle is unloaded from each machine.

WORK OF THE AMERICAN ENGINEERING STANDARDS COMMITTEE

The American Engineering Standards Committee, which consists of representatives from five departments of the Federal Government, nine national engineering societies and fourteen national industrial associations, has recently issued a report which sets forth in detail the activities of the committee during 1921 in national standardization in the engineering field. This committee, which was organized January 17, 1917, at a meeting of a special committee appointed jointly by the American Society of Mechanical Engineers, the American Institute of Mining Engineers, the American Society of Civil Engineers, the American Institute of Electrical Engineers, and the American Society for Testing Materials, now has the cooperation of one hundred and sixty bodies of national importance. These cooperative bodies have designated more than five hundred persons as official representatives to serve on sectional committees working under the auspices of the American Engineering Standards Committee.

The object of the American Engineering Standards Committee is primarily to serve as a national clearing house for engineering and industrial standardization, to act as the official channel of cooperation in international standardization, and to provide an information service on engineering and industrial standardization matters. Since the committee functions as a clearing house rather than as a creator of standards, its work necessarily centers in bringing about systematic cooperation of the organized bodies—technical, industrial and governmental—which speak for industry.

During the past year a good foundation has been laid for a really effective information service on standardization. It is planned that a complete file of all American and foreign standards of significance shall be maintained for the free use, not only of the committees working under the auspices of the American Engineering Standards Committee, but of all American industries generally. The file now includes complete sets of standards approved by all national standardizing bodies, and a majority of the standards issued by the important organizations in this country.

During the year, seventeen standards have been approved by the committee, while seventy-nine projects have reached an official status. In the mechanical division specifications for pipe threads have been approved. In the metal divisions, specifications for Bessemer and open-hearth steel for cold-drawn automatic screw stock have also been approved. Of more general interest is the substantial progress reported on safety codes. The safety code program now includes twenty-nine codes for which definite arrangements have been made. The three following codes have been approved: the national electric code, the safety code for industrial lighting, and the code for the protection of the heads and eyes of industrial workers. The National Safety Code Committee serves as a committee for the general program, delimiting specific projects to be advantageously handled as distinct codes, recommending sponsors, assisting in caring for overlaps, and reporting on the progress of the program.

A general scheme for the plan and arrangement for safety codes has been developed and published for the guidance of those interested in the formulation of such codes, in order that there may be as great a degree of uniformity between the various codes as possible.

Copies of the national standards that have been approved by the committee as well as copies of foreign specifications and standards are available to American industries through the headquarters of the committee at 29 West 39th St., New York City.

Tooling Equipments for Pistons

Use of Automatic Machines and Special Equipment for Machining Lynite Pistons at a High Rate of Production

By EDWARD K. HAMMOND

THERE are few industries in which production methods are more carefully scrutinized than in the manufacture of automobiles. In this industry the methods are constantly being checked over and improved, with the result that standards of efficiency and rates of production are steadily being brought closer to the maximum. The use of automatic lathes and turret lathes provided with special tooling equipments for machining pistons in a large automobile factory offers an interesting example of high-production methods. The pistons are made from lynite die-castings, and the high cutting speeds employed are possible because of the use of this material. This article explains, step by step, the procedure in manufacturing these parts, and the accompanying table gives the cutting speed and production for each operation.

As the castings are delivered to the piston department, the first step is to subject them to a visual inspection, after which the work is transferred to a Warner & Swasey turret lathe equipped as shown in Fig. 1. This machine bores, faces and chamfers the open end *a* of the piston casting, Fig. 4, and centers the opposite end at *b*. It will be seen in Fig. 1 that there is a block *A* on the turret at the first station, which pushes the work back into the chuck while it is being clamped in place. On the second face of the turret there is a combination rough-boring and rough-facing tool *B*; and on the third face there is a combination finish-boring, finish-facing, and chamfering tool *C*. The center drill *D*, which produces a hole in the boss *b* cast at the closed end of the piston for that purpose, is mounted on a spindle extending through the hollow main spindle and connected to the bar feed mechanism. The spindle on which drill *D* is mounted rotates in the opposite direction from the main spindle. As the work is rotated by the chuck, the drill can be fed through the spindle into contact with the boss.

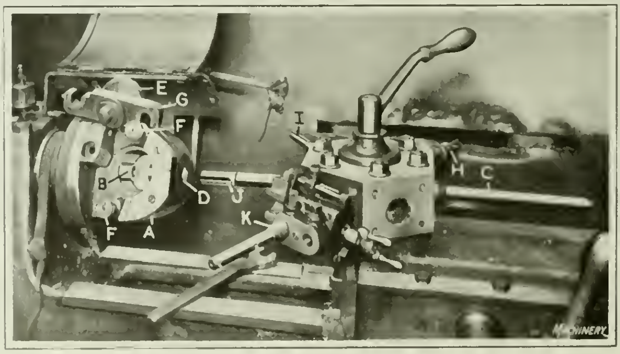

Fig. 3. Turret Lathe equipped for drilling, boring and reaming the Wrist-pin Holes and cutting the Locking Ring Grooves

Finish-facing the Closed End, Turning the Outside Diameter, and Roughing and Finishing the Ring Grooves

Next, the piston castings are sent to a Fay automatic lathe which is tooled up for finish-facing the top end *c*, Fig. 4, turning the outside diameter *d*, and roughing and finishing the piston ring grooves *e*. The front slide feeds from right to left, for turning the outside diameter with tool *A*, Fig. 2, and then moves inward to rough out the piston ring grooves with the three tools *B*. Meanwhile, the rear head swings down to face the top end of the piston with tool *C* and to finish-turn the grooves with the three tools *D*. The work is held between a center *E*, which enters the chamfered open end of the piston and another center *F*, which enters the hole drilled in the boss at the closed end. Driving is accomplished by means of a plug *G* on the spindle, which fits into the space in the piston between the inner ends of the wrist-pin bosses.

Machinery

*For notation see Fig. 4.

Machining the Wrist-pin Holes

After the Fay automatic has completed its work, the piston castings are transferred to a Warner & Swasey No. 4 turret lathe to have the wrist-pin holes *f*, Fig. 4, drilled, bored and reamed, and to cut the locking ring grooves in these holes. A machine tooled up for this work is shown in Fig. 3. A pot fixture *A* is carried on the spindle nose. Into this fixture the piston casting *B* is inserted, being located by means of a pilot bar *C* on the first turret face, which extends through bushing *D* in the fixture and through the wrist-pin hole in the work. The work is then clamped in place by means of a plug *E*, which enters the chamfered open end of the casting and is secured by means of bolts. The ends of strap *G* are slotted to slip under the heads of two bolts *F* after they have been loosened slightly.

Having secured the casting in place, the wrist-pin hole is first roughed out with a core-drill *H*, on the second turret face, and then bored and reamed with the usual types of boring-bar *I* and reamer *J* on the third and fourth turret faces. The locking ring grooves are next cut in the wrist-pin hole by a tool *K* on the fifth face of the turret. This tool is mounted on a cross-slide, which is fed transversely to sink the two grooving tools into the work to the required depth. It is known as a cross-slide under-cutting tool, and is made by the Warner & Swasey Co. for use on turret lathes of its manufacture. To maintain the required accuracy of alignment, bushings are provided in the pot fixture *A* at each side of the work, to receive guiding pilots on the tools.

Facing the Wrist-pin Bosses

The next step in machining these pistons is to face the ends *g*, Fig. 4, of the wrist-pin bosses perpendicular to the finished holes *f*. This is done on a Gooley & Edlund, Briggs type of milling machine, which is shown in Fig. 5 equipped with a work-holding fixture *A* and a special offset cutter-head *B*. The piston casting *C* is slipped into the split cylindrical fixture and located by a plug *D* which enters the wrist-pin hole. The work is clamped by tightening a screw *E*, which passes through threaded bosses at each side of the split top of the fixture. By traversing the table, the work is fed up to the offset milling cutter *B*, which is held in such a way that it can enter the open end of the piston. The cutter is driven by gears to which motion is transmitted by a gear *F* carried on an arbor held in the milling machine spindle. The entire fixture is suspended from the over-arm.

Milling Chamfers on the Middle Piston-ring Groove

It is necessary to mill a chamfer *h*, Fig. 4, on the lower side of the middle piston-ring groove, directly above each end of the wrist-pin holes *f*. This is done on a Burke hand milling machine, equipped with a fixture, as shown in Fig. 6. The piston is located on a pilot *A* carried by the bed of the fixture, and is held down by a clamp *B* having a hand-lever *C*, by means of which the necessary pressure is exerted. Very little time is required to set up the job in this way. The work is traversed past an end-mill *D*, which cuts the chamfer on the middle piston-ring groove.

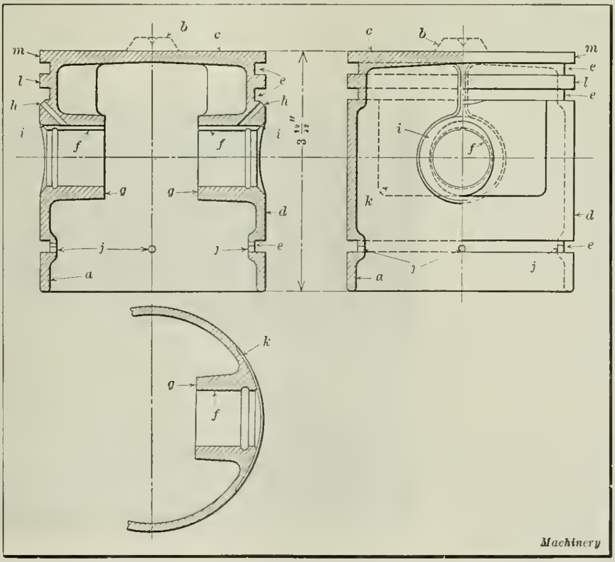

Fig 4. Piston on which Machining Operations listed in Accompanying Table are performed

Drilling Oil-holes

Next in the order of machining operations comes the drilling of two oil-holes *h*, Fig. 4, which extend diagonally from the middle piston-ring groove in to bearing holes *f* for the wrist-pin. Fig. 7 shows a Leland-Gifford sensitive drilling machine, equipped for this operation. A pilot extension on disk *A* fits into the bored skirt, and a smaller pilot extends up into the piston, which has a hole in it through which pin *B* can be slipped. This pin also extends through the wrist-pin holes in the piston and provides for clamping the work by tightening screw *C*,

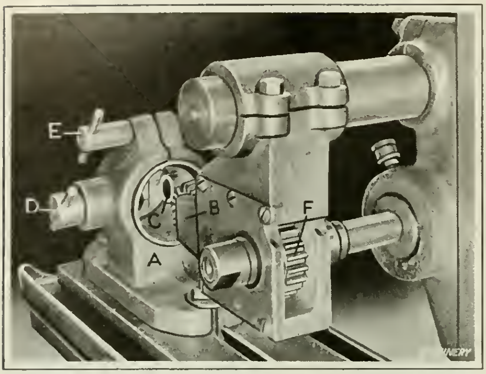

Fig. 5. Milling Machine equipped for facing Inner Ends of Wrist-pin Bearing Bosses

which draws the small pilot and pin *B* in toward the base of the fixture. The pilot is splined so that it cannot turn, and pin *B* serves the additional purpose of locating the oil-

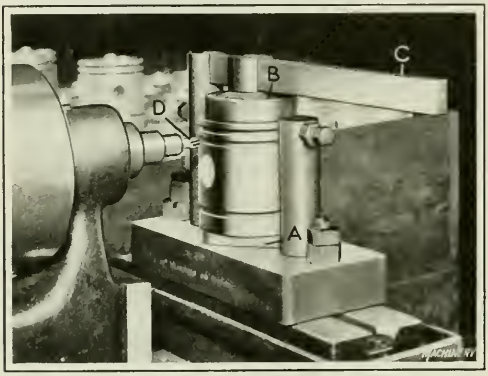

Fig. 6. Hand Milling Machine equipped for chamfering the Lower Side of the Middle Piston-ring Groove

holes in the proper relation to the wrist-pin bearings. The drill bushing is located at *D*, and after one of the two holes *h*, Fig. 4, has been drilled, the work is released from the fixture and reset 180 degrees from its first position. for drilling the second hole.

Next, the outer ends *i*, Fig. 4, of the wrist-pin holes *f*, are chamfered with a cutter *A* on a Sipp upright drilling machine, the work being held in a V-block *B* as shown at the left-hand side of Fig. 8. Then the casting is transferred to a similar fixture shown at the right-hand side of the illustration. The spindle in this machine carries a twist drill *C*, which is used to drill four oil-holes *j*, Fig. 4, in the lower piston-ring groove, distributed equally around the circumference of the work. Oil-grooves are then milled in the wrist-pin holes with a cutter carried in the spindle of a Sipp drilling machine.

Grinding Clearance at Ends of Wrist-pin Holes

It is required to grind a clearance of from 0.010 to 0.015 inch under the sliding surface of the piston over an area adjacent to each end of the wrist-pin bearings, and for this operation a Landis cylindrical grinding machine is used. The form of the clearance to be ground is clearly indicated at *k* in Fig. 4. The work is held at one end by an ordinary center *G*, Fig. 9, while a special center *F* at the other end enters the finished opening *a*, Fig. 4, at the base of the skirt. The Landis grinder is equipped with a fixture shown on the machine at *A* in Fig. 10, and details of its design are more clearly illustrated in Fig. 9.

The piston is rotated in unison with a cam *B* (see Fig. 9), which is finished to the shape and size of a cross-section of the finished piston, through the centers of the wrist-pin holes *f*, Fig. 4. This cam runs in contact with a fixed roller *C*, and as the entire work-holding fixture is pivoted on the grinding machine, the cam carried by the fixture and the

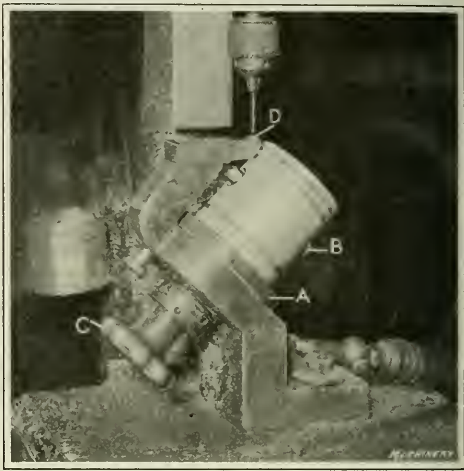

Fig. 7. Jig for drilling Two Inclined Oil-holes leading to Wrist-pin Bearings

roller secured to the frame of the machine oscillate the fixture on its pivotal support *D*, in such a way that the work is swung in contact with the grinding wheel and is ground to the same form as the cam.

The method of operation of the fixture is as follows: The piston *E* is carried between centers *F* and *G*, and a plug *H* extends inward, engaging the ends of the wrist-pin bosses, and thus affording a convenient method of driving. The live center *F* and the cam *B*, which controls the form of clearance ground on the work, are both carried by a spindle which

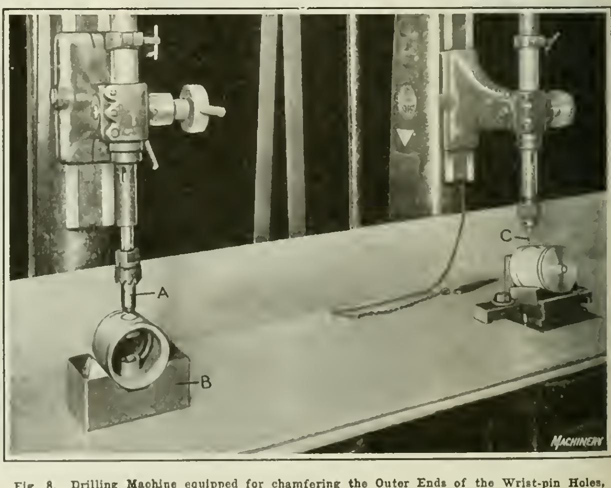

Fig. 8. Drilling Machine equipped for chamfering the Outer Ends of the Wrist-pin Holes, and for drilling Four Oil-holes in the Lower Ring Groove

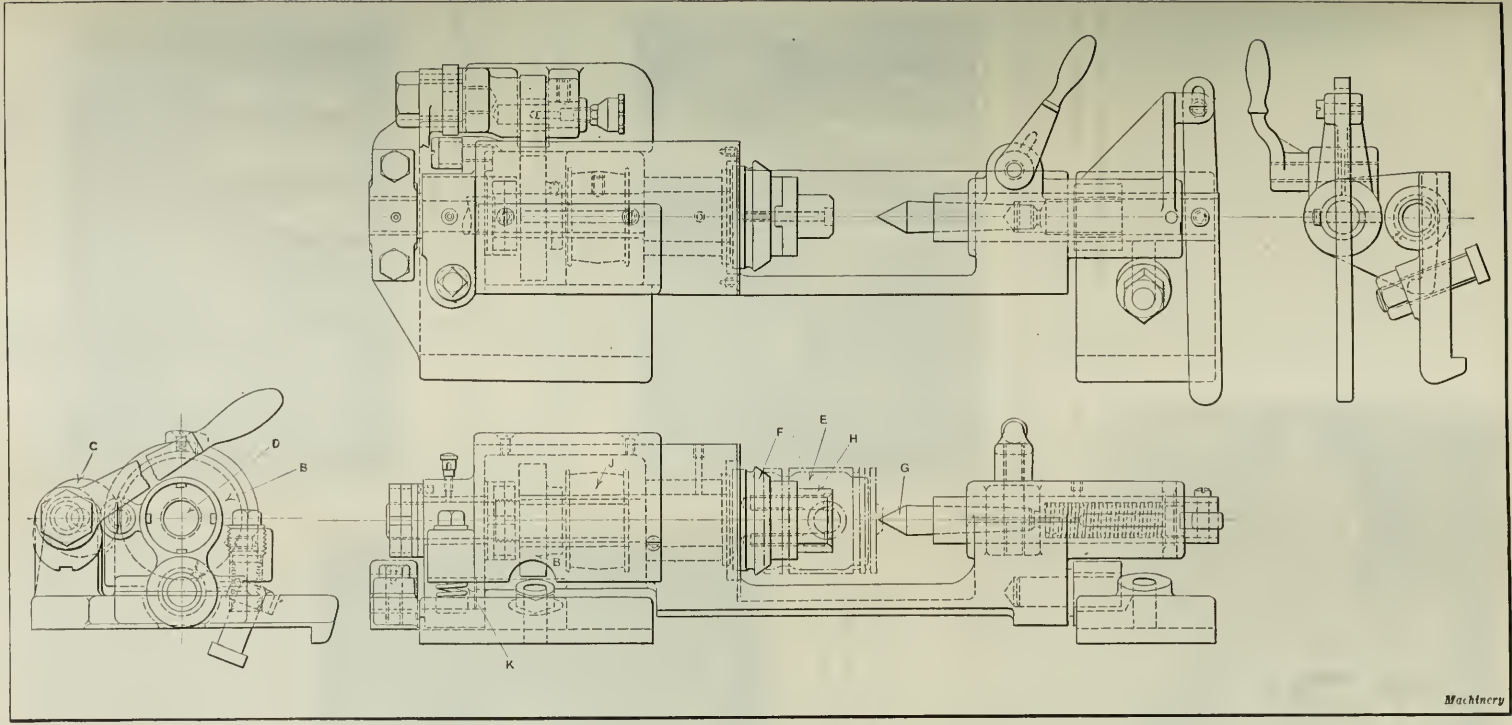

Fig. 9. Details of Design of the Grinding Machine Attachment shown in Operation in Fig. 10

is positively driven from below by means of a Morse silent chain *I*, Fig. 10, running over sprocket *J*, Fig. 9. Uniform contact is maintained between cam *B* and roller *C* by means of two springs *K*, and the action of these springs is supplemented by two additional springs *L*, Fig. 10.

Centering the Open End and Grinding Outside of Piston

After the clearance *k* has been ground, it is necessary to recenter the open end of the piston, as the chamfer formerly machined is not accurate enough to be depended upon for locating the work for rough- and finish-grinding the outside diameter *d*, Fig. 4. For this purpose the pistons are centered on a special machine, after which they are set up on a special cylindrical grinding machine on which the outside diameter *d*, of the work is rough- and finish-ground. Provision is also made at this setting of the work for grinding the clearance on lands *l* and *m* at the top of the piston. The work is shown in Fig. 11 set up for this operation. It is held by a center *A* entering a hole in the closed end of the piston, and a center *B* entering the open end of the work.

Removing the Center Boss at Top of Piston

After the pistons have been rough- and finish-ground, the center boss is no longer needed, and so it is removed by a Sipp drilling machine equipped with a work-holding fixture *A* and end-milling cutter *B* of the type shown in Fig. 12. The piston is located in the fixture by means of a pilot *C* which enters the finished wrist-pin hole, after which handle *D* is turned to raise the supporting table *E* into contact with the bottom of the work. Then the end-mill comes down through a guide bushing *F* at the top of the fixture, and cuts off the boss so that it is flush with the top of the piston.

Next the wrist-pin holes *f*, Fig. 4, are finish-reamed on a special machine. Finally, two lines are scribed across the top of the piston as shown in Fig. 13. The piston is located in a fixture *A* by a pin *B* passing through the finished

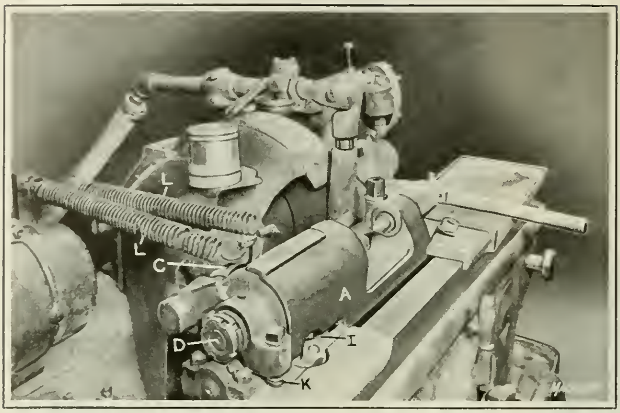

Fig. 10. Special Attachment for grinding Clearance Space at the Outer End of each Wrist-pin Hole

wrist-pin hole, and by a sliding block *C* on the surface plate, on which the work-holding fixture is carried. Block *C* carries two cutting points *D* and *E* which scribe the required lines across the work. The pistons are then washed, wiped, and inspected, and marked for size and weight, after which they are ready to be assembled.

* * *

INDUSTRIAL MACHINERY IN EGYPT

The imports of industrial machinery into Egypt have increased greatly during the last three years. In 1919 the total imports of this class of machinery into Egypt from

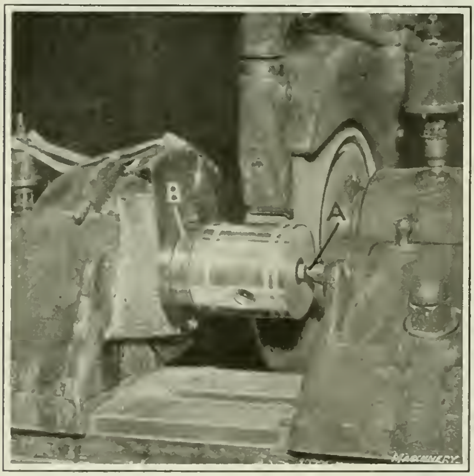

Fig. 11. Cylindrical Grinding Machine equipped for grinding the Outside Diameter and the Clearance on the Two Upper Lands

all countries amounted to about $2,100,000, rising in 1920 to $6,750,000, and in 1921 to nearly $10,000,000. Of these imports 12.3 per cent were from the United States in 1920, and 29.6 per cent in 1921. The imports in the latter year included 49 locomotives built by American firms for the Egyptian state railways. The market for industrial machinery in Egypt is not large, and the largest single item in 1921, outside of locomotives, was stationary internal combustion engines. The countries that contributed to the imports of industrial machinery into Egypt in 1921 in the order of their importance in this trade were: the United Kingdom, France, Germany, the United States, and Switzerland.

MOTOR TRUCK TRANSPORTATION

Although the motor truck is gaining in importance daily as a means of transportation, both for local purposes and in interurban service, there is no danger that it will ever replace the railroads for long distance hauls. An investigation has shown that compared with the tonnage moved by the railroads, the work done by trucks in interurban service is quite small. Between New York and Philadelphia, for example, where there is a highly developed truck service, the trucks do not carry more than one-half per cent of the total amount of freight transported. In the great majority of cases, the trucks handle small package business—a business which at best is not very profitable to the railroads, and which is sometimes even carried at a loss. The transfer of this business to the commercial truck is a logical development of our transportation system. It is economical from every point of view, and it causes no loss to the railroads. The motor truck fills a definite place of great value in the transportation system, and it will undoubtedly be

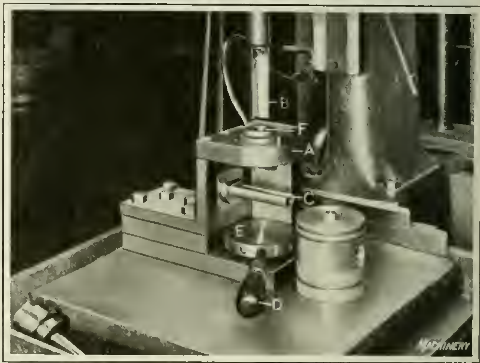

Fig. 12. Drilling Machine equipped with Special Milling Cutter for facing off the Boss on the Closed End of the Piston

used increasingly in certain classes of work, but it will never replace the railroad as the chief hauler of freight.

* * *

There are more than a million wireless receiving sets in use in this country at present, contrasted with 30,000 a year ago, and the number is growing at a rapid rate.

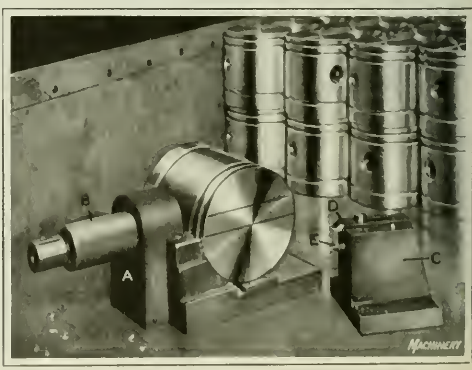

Fig. 13. Tools used for scribing Two Reference Lines across the Closed End of Each Piston for Guidance in assembling

DRIVING CHUCK FOR AUTOMATIC LATHE

By E. M. BIDWELL

Among the various types of lathe drivers or dogs designed for the automatic chucking of cylindrical work, the writer could not find any which seemed to be suitable for the conditions encountered in chucking the automobile clutch or main drive gear illustrated in Fig. 1. Consequently, a special driving chuck was designed, which is quick-operating and which furnishes a positive drive when machining the

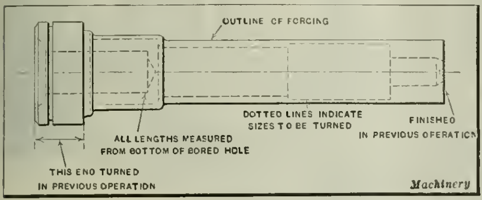

Fig. 1. Automobile Clutch Gear Forging for which Chuck shown in Fig. 2 was designed

forgings in a Fay automatic lathe. This clutch gear is turned down from the rough-forging size to the finished shape shown in dotted lines. Six turning and four facing tools are used in machining this forging, and consequently a very strong and positive drive is required. For this reason it was not thought advisable to use the ordinary set-screw lathe dog. Those familiar with the operation of the Fay automatic lathe know that a large amount of lost time and production will result if a driving dog that slips is used.

Features of Construction

Before the forging goes to the automatic lathe to be turned, the hole in the gear end is bored and the outside diameter of the gear rough-turned, so it is only necessary to provide for a variation of 1/16 inch on the diameter, in designing the driver. This special tool (see Fig. 2) consists of a body *A* which is recessed on one side to fit over the regular faceplate of the lathe, in place of the floating faceplate provided on the machine, and is attached by four fillister-head screws, using the same key as is used in attaching the floating plate. The body is made of machine steel, and is cut out to accommodate the ring *E*, a 1/8-inch floating movement being allowed for the ring. The ring is held in place by a retaining plate *C*, fastened to the body by screws and dowel-pins. The floating ring carries two hardened steels jaws *G*, which are dovetailed and located in the plate in the position indicated.

The top part of the floating ring is cut out on both sides, as is also a section from ring *C*, so that the driving pawl *F* can be assembled by straddling the section in ring *E*, in which position it is held in place by a 7/8-inch nickel-steel pin *D*. The shoulder against which the floating ring bears in the body is also cut away to correspond with the section that is removed from ring *C*, this being necessary on account of the design of the pawl *F*. The sections cut out for the accommodation of the upper end of the pawl are indicated at *K*, these surfaces being those against which the ears of the pawl contact when gripping and releasing the work, as will be explained later. The gripping end of the pawl contains serrated teeth and is hardened, and the surface in which these teeth are cut is eccentric with regard to the center of stud *D* on which the pawl swings when in operation.

The outside of the body of the chuck carries a handwheel which is corrugated to make it easy to grasp by the operator when it is covered with oil. When in operation, the weight of the handwheel rim acts as a flywheel, and its momentum aids in the operation of the chuck. The handwheel carries a finger *H* which is fitted into it and which extends through the body of the chuck and into a slot cut in floating ring *E*; this slot provides sufficient clearance so that the finger does not interfere with the floating movement of the ring. A section of the body of the chuck is also cut out as indicated at *J*, for approximately 90 degrees, which permits the handwheel to revolve nearly a quarter of a turn before its movement is arrested by the finger *H* on the handwheel coming into contact with the surfaces *J*.

Operation of the Driving Chuck

The live stub center of the lathe is made a sliding fit in the end of the clutch gear, and this stub center extends beyond the driver a short distance so that when the work is placed in the machine it is simply necessary to slip the gear over this center and bring the tail-center into engagement with the opposite end of the gear. The work is advanced on the plug center by pushing up the tailstock until the stub center bottoms in the hole in the gear. Jaws *G* are beveled on their inner edge, so that when the work is centered in the position described the floating ring *E* will be moved sufficiently to admit the work readily. The machine is then started, revolving the body *A* and retaining ring *C*, and bringing surface *K* into contact with the pawl, which causes it to swing on pin *D* until the serrated teeth grip the work. The continued rotation of the chuck transmits a rotary movement to the work which is thus positively driven, and any resistance to rotation produced by the cutting action of the tools only tends to tighten the grip of the chuck on the work.

In releasing the work after the machine has stopped, the operator grasps the handwheel and gives it a slight turn, just enough to bring the pawl *F* into contact with the surface *K* at the opposite end of the cut-out section, and thus swing the pawl in the opposite direction. This requires but little effort on the part of the operator on account of the flywheel effect of the handwheel, the momentum of which greatly aids in the disengagement of the pawl. For example, when a finishing cut is taken on this forging, the driver automatically releases itself, due to the momentum of the handwheel, by disengaging the pawl, when the machine comes to a quick stop, as it does when the brake attachment provided on the Fay lathe is used. When the machine comes to a stop, the pawl is swung so as to permit plenty of space for convenience in chucking another forging, so that after each piece is put between centers, all that is necessary is to start the machine.

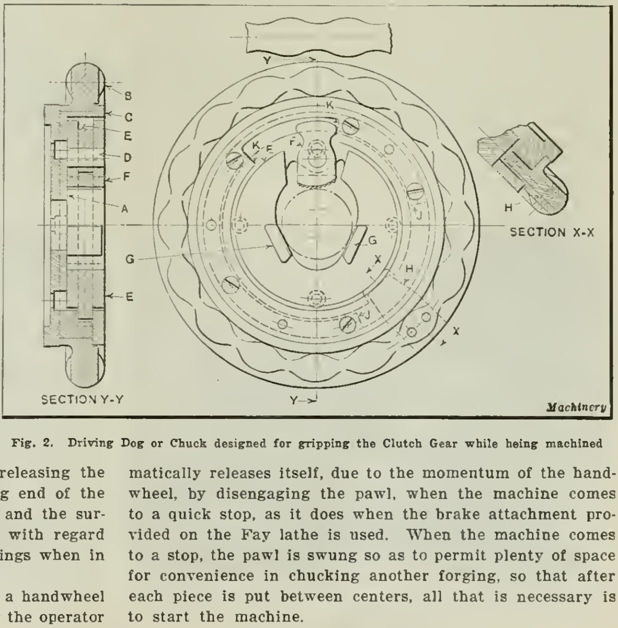

Fig. 2. Driving Dog or Chuck designed for gripping the Clutch Gear while being machined

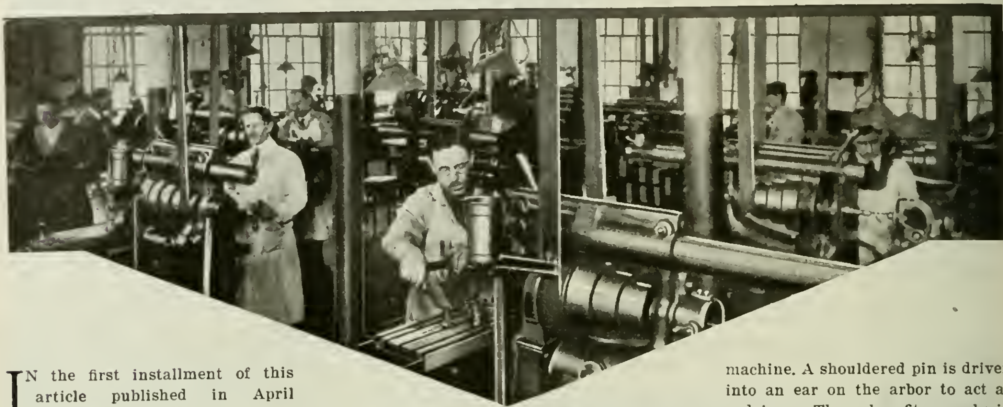
Production Work in a Contract Shop



Manufacturing Methods Employed in the Plant of the Taft-Peirce Mfg. Co. Woonsocket, R. I., in Machining Automobile Parts—Second of Two Articles

IN the first installment of this article published in April MACHINERY, the equipment used by the Taft-Peirce Mfg. Co. for grinding, drilling, reaming, and inspecting the valve followers of the Wills Sainte Claire engine, and methods used in the production of the camshaft drive pinion floating washer were described. The present article deals with operations on the camshaft drive shaft bearing retainer, the motor fan, and the intermediate and fan shafts.

Camshaft Drive Shaft Bearing Retainer

The camshaft drive shaft bearing retainer consists of an upper and a lower member, both iron castings, on which probably the most interesting operation is that of facing one end and the under side of the flange, as shown in Fig. 10. This illustration also gives a good idea of the design of these castings. The two tools are carried in the back-facing attachment of a Porter-Cable lathe. A tolerance of 0.002 inch on the distance from the small end of the casting to the inside wall, through which eight holes are drilled, is allowed, this distance being nearly 3 inches. For finish-facing the flange, a limit of 0.0005 inch is specified between this face and the small end of the casting. Limit length gages are provided to check these distances. The work is mounted on a special arbor, which is shown lying on the carriage of the machine. A shouldered pin is driven into an ear on the arbor to act as a driver. The arbor fits snugly in a brass bushing previously assembled in the casting, with the small end of the pin fitting into one of the previously drilled holes in the flange. The back-facing attachment employs the cam-feed mechanism regularly furnished with this type of lathe.

Fig. 11 shows a special gaging device used for inspecting the concentricity of the two finished diameters of the retainer castings. This consists of a large surface plate to which a stand is bolted. The stand furnishes a bearing for the long bar and centers shown, these being regular Springfield straightening-press equipment applied to this inspecting device. One center has been changed to include a heavy expansion spring and a hand-lever *A* for withdrawing the center against the pressure exerted by this spring. Thus it is possible to center the arbor, over which the work is slipped for inspecting, by simply depressing this lever to withdraw the spring center before locating the arbor in the center at the opposite end of the bar. The lever is then released and the spring center advances into contact with the arbor. This holds the arbor with just enough tension to permit the inspector to revolve the work freely. A dial indicator is used, as shown in the illustration, for determining the amount of error in concentricity of the two diameters.

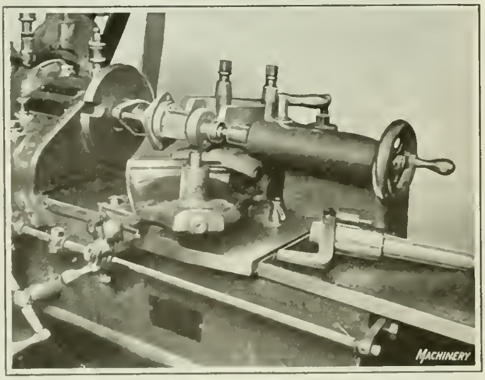


Fig. 10. Multiple Facing Operation on the Drive Shaft Bearing Retainer Casting

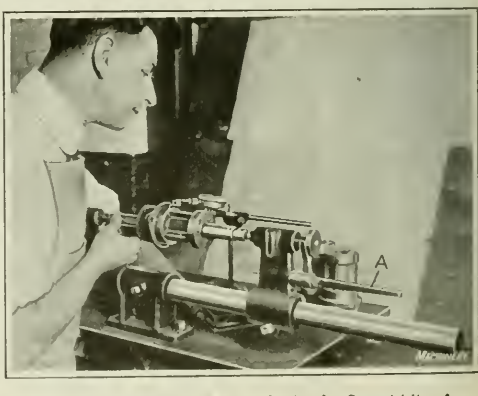

Fig. 11. Inspecting the Retainer Casting for Concentricity of Diameters

Machining the Motor Fan

The motor fan is an aluminum casting, and because of its peculiar shape some interesting machining equipment is employed. A detailed view of the fan is shown in Fig. 12. The first operation to which attention is called is that of chucking, boring, and reaming the hub, squaring face *A*, grooving and chamfering. This work is performed in a 24-inch Gisholt turret lathe equipped with regular Gisholt tools and a facing tool in the cross-slide, which may be seen at *A*, Fig. 13. This view is primarily intended to show the method of chucking the fan rather than the tooling set-up.

so that the blades are gripped at one spot, thus preventing them from being distorted when the nuts are tightened to clamp the straps. The fact that three segment arm studs are provided as fulcrums for operating the chucking mechanism makes it unnecessary to revolve the faceplate when chucking or releasing the work.

Both holes in the fan hub are hand-reamed, using the locating fixture shown in Fig. 15, and a double-expanding Martell reamer. A steel bushing is provided in the fixture as a bearing for the locating plug which is used to locate the fan concentrically when it is first placed in position.

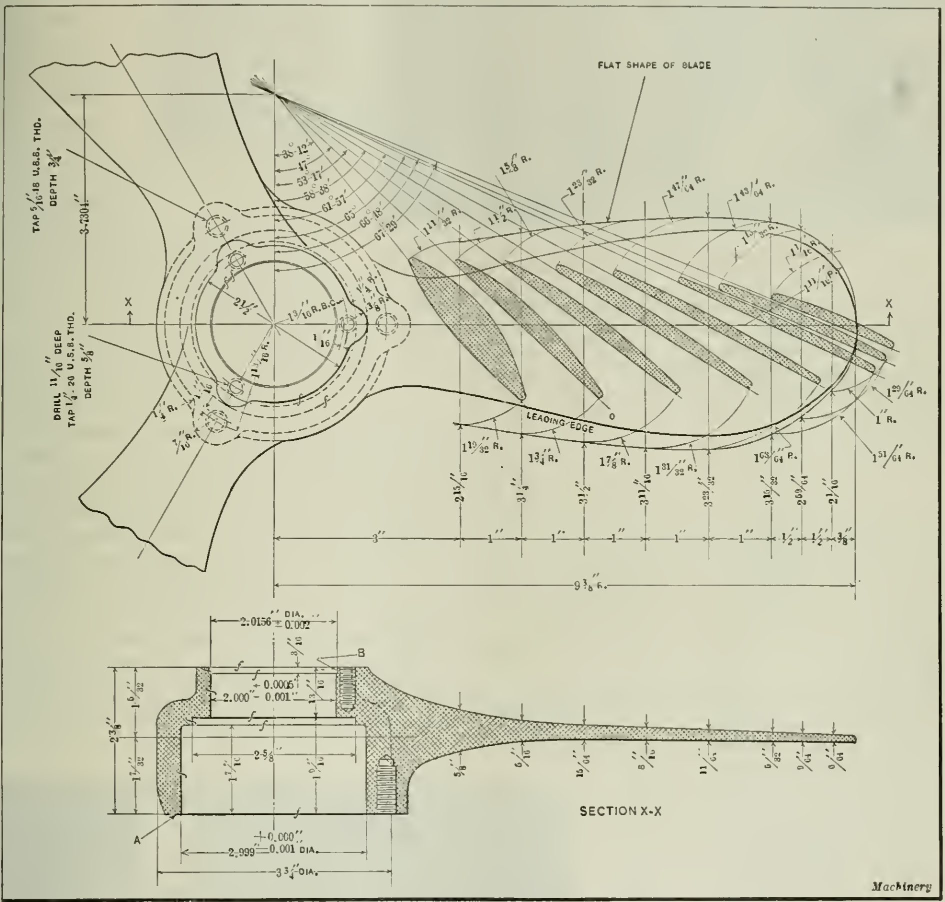

Fig. 12. Detail Views of the Aluminum Motor Fan of a Wills Sainte Claire Engine

A special fixture is bolted to the faceplate of the lathe, having a steel bushing to receive the pilots of the boring-bars and reamers employed in finishing the hole. The front plate of the fixture carries a gear of large diameter, in one side of which there is a cam groove, so that as the gear is turned in chucking the work, three pins are moved axially through the front plate, into engagement with the three bellcrank levers *B*, which causes the levers to swivel and grip the work on the hub between the blades of the fan. The fixture gear is operated by a segment arm *C*, in which there is a hole that fits over one of the three studs *D* extending from the inside of the front plate. The segment teeth engage the gear teeth and rock the bellcrank levers.

The fan is first placed in position for chucking, and given a slight turn forward until the blades enter between blocks *E* and the straps which they carry and are located against stops *F*. The blocks and the straps each carry a steel button,

When the fan has been properly located, a floating clamp at the rear of the fixture is swung around until its end engages a stud in the main casting of the fixture. The illustration shows a fan in this position with the locating plug removed. The body of the Martell reamer is accurately ground to the same diameter as the locating plug, so that when the reamer is placed in the steel bushing, there is absolute assurance of the concentricity of the two holes. At the left of the vise in which this fixture is held, are shown two Taft-Peirce plug gages by means of which the limits on these holes are gaged. Fig. 12 shows that the tolerance on the diameter of the large hole is 0.001 inch, and on the small hole 0.004 inch.

Squaring the Hub, Balancing, etc.

The operation of squaring the hub and counterboring at *B*, Fig. 12, is performed in a Lodge & Shipley lathe, on the faceplate of which the special fixture shown in Fig. 14 is attached.

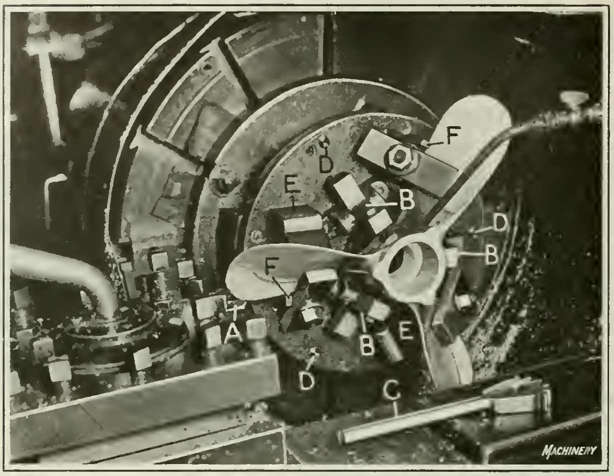

Fig. 13. Turret Lathe equipped with Special Fixture for chucking Motor Fan

This fixture is of the expanding type. Sleeve *A* is made of tool steel, spring-tempered, and has six slots so that when the expanding plug *B* is drawn in against the tapered hole, the fan will be located against shoulder *C* and securely chucked in this position. The end of the shank on plug *B* extends through the opening in arch bracket *D*, and carries a nut which is operated to draw in the plug. The angle of taper for this member is 15 degrees, this having been found a most efficient taper for rapid chucking. Only about one-fifteenth revolution of the nut on plug *B* is required in order to chuck the work securely.

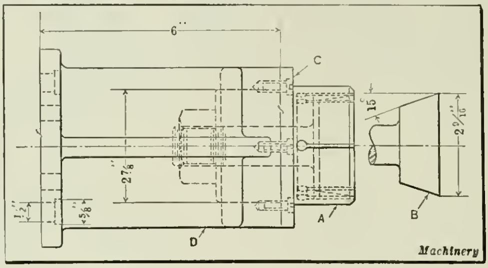

Fig. 14. Draw-in Expanding Fixture for chucking the Fan when squaring the Hub Face

After the fan has been completely machined, it must be balanced, and this is done with the aid of the Rockford balancing machine shown in Fig. 16. The tapered bushing assembled in the fan is engaged by a special tapered arbor, and the fan is placed in suspension between the disks of the balancing machine in the position illustrated. One of the arbors used is shown on the bench. After it has been determined which blade is too heavy to maintain static balance, the fan is clamped on another arbor and held in a bench vise while the metal at the edge of the heavy blade is scraped down or rasped with the square tool shown on the bench at the left of the vise. As in all specialized jobs of this kind, the workman must have a great deal of experience to do this work satisfactorily.

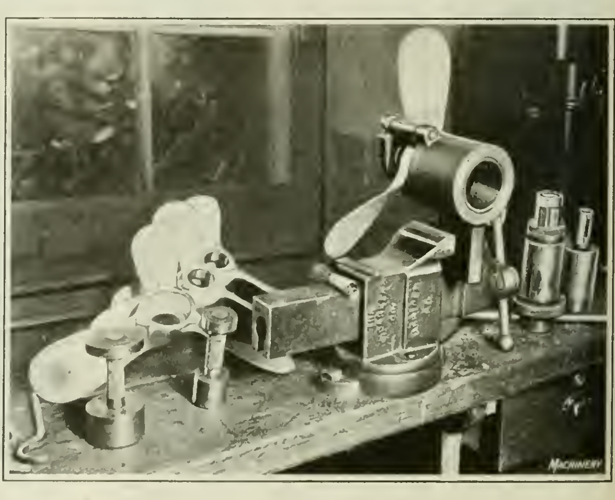

Fig. 15. Equipment used in hand-reaming the Central Holes in the Fan

The bronze bushing previously assembled in the tapered hole of the fan receives a final finish-boring operation; this procedure differs from the usual practice of producing a highly finished surface. The method of finishing consists of using a diamond tool, and this has been found to give the most satisfactory results. Grinding could not be resorted to on account of the possibility of charging the bronze bushing with abrasive. The use of the diamond eliminates all such work as broaching or burnishing for producing the final finish. The fan is chucked against a special base clamped to the lathe faceplate by means of a large-headed bolt which screws into the base and seats against the inner shoulder of the fan. This job is set up in a Lodge & Shipley lathe, the faceplate of which revolves at a rate which gives a cutting speed of 180 feet per minute.

Intermediate and Fan Shafts

All shafts and other steel parts that are subjected to wear and strain are made of a special analysis molybdenum steel, which, on account of its satisfactory service where strength, toughness, and resistance to wear are prime requisites, is admirably adapted for use in automobile construction. The intermediate shaft shown in detail in the upper part of Fig. 17 is forged from this steel and finished in the following manner: After inspecting the forgings and testing them for hardness by the Brinell method, the shafts are straddle-milled to length on a No. 4 Brown & Sharpe milling machine, the length being checked with a limit gage. A Cadillac centering machine is then employed to center both ends, gaging from the opposite side of the large flange in each case.

The next three operations are rough-turning the two sections *A* and *B* at the right of the small flange; rough-turning section *C* and squaring the small flange; and rough-turning end *D*. Each of these operations is performed in a Prentice automatic lathe, a model shaft being used for setting the tools. In machining section *D*. the shaft is not turned down for threading, this end being left one diameter temporarily.

The shafts are then recentered to a uniform depth at each end in a speed lathe, gages being used to check the depth. A Prentice automatic lathe and a model shaft are again used for setting the tools for the next four operations, in which sections *A*, *B*, *E*, *F*, *D*,

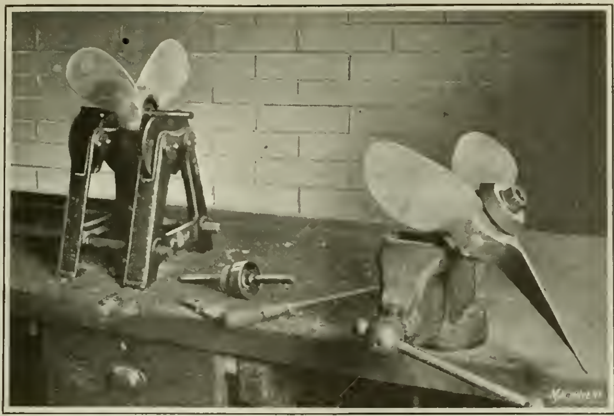

Fig. 16. Bench and Equipment used in producing Static Balance in the Fans

and the small flange are finish-turned. In finish-turning section *D*, 7/64 inch of stock is left at the end where the one-inch thread is later cut, so that the stock will remain soft after hardening. Both flanges are next underscored in a lathe, the shafts are straightened if necessary, and the keyway is cut for the Woodruff key. The latter operation is performed on a Brown & Sharpe milling machine, a gage being provided for checking the central location. The various holes are then drilled, reamed, countersunk, and tapped as indicated in the illustration, after which the threads in sections *B* and *E* are cut on a Pratt & Whitney thread miller, using 18-pitch hobs and limit thread gages.

Before heat-treating, the shafts are copper-plated heavily all over, after which the copper is removed from all surfaces except section *A* and the length on section *C* designated by dimension 7.4687 inches—the two surfaces which are not to be hardened. The shafts are then packed in Houghton's "Pearlite" carburizing material at a temperature of from 1650 to 1700 degrees F., which produces a carbon penetration of about 1/32 inch. The shafts are quenched in oil from a temperature of 1580 degrees, and are then reheated to from 1375 to 1385 degrees and quenched in brine. The higher quenching temperature refines the core and the second heat hardens the carburized exterior. The casehardened shafts are next drawn in oil at a temperature of from 350 to 400 degrees F., for a period of from one to one and one-half hours, and are then permitted to cool in the atmosphere.

There are a number of incidental operations performed before grinding, such as cleaning the centers, straightening, wire-brushing section *C*, cleaning the threads and inspecting. The threaded end of section *D* is then ground, underscored, and chamfered, after which it is ready to have the thread cut. The threading operation is performed on a Pratt & Whitney thread miller by hobbing, holding the threads to gage limits. Sections *A*, *F*, and *G*, diameters *B* and *E*, and the inside of the large flange are then rough- and finish-ground. The final operations are grinding the small shoulder to the 3.0625-inch dimension, grinding the shoulder at the small end of the shaft to the specified length, and grinding surface *H* of the large flange to thickness. The dimensions showing the limits to which the various surfaces are machined are given in the illustration.

The fan shaft shown in the lower part of this illustration is finished in much the same manner and with practically the same equipment as the intermediate shaft. The heat-treating is also substantially the same. There is only one operation of which mention need be made, and that is the cutting of the six-threaded left-hand spiral gear, which is done on a No. 3 Barber-Colman hobbing machine having standard equipment.

* * *

A device developed by the Société Anonyme Adolphe Saurer of Arbon, Switzerland, for the purpose of testing the piston-rings of automobiles, was described in detail in a recent number of *Engineering*. The object of this device is to determine whether the pressure exerted on the walls of the cylinder, when the spring is compressed to its working diameter, is within the allowable limits. The device is actually a comparator, as it indicates whether the ring being tested has the same characteristics of stiffness as some standard ring which is known to be satisfactory.

THE VALUE OF TRADE STATISTICS

A contributing cause of serious business depressions following periods of great prosperity is the lack of complete and accurate trade statistics which would enable manufacturers to form opinions of the industrial future. If such statistics had been available in 1920 our machine tool manufacturers would have been able to anticipate and prepare for the depression, months earlier than was possible when each had to rely on the information he could obtain individually. Signs of a coming depression in the industry were apparent in the spring of 1920, but most factories were then running full on unfinished orders which assured many that the future was secure; consequently large stocks of material were laid in at high prices and more contracted for. When the depression became a certainty many manufacturers continued to produce for stock, expecting it to be of comparatively short duration. Accurate statistics showing the machine tool production in pre-war years, compared with the production in 1917, 1918 and 1919, would have shown that the industry had produced at such a rapid rate as to make a prolonged falling off in demand inevitable. Apart from their value as records and as a guide to production, trade statistics are helpful to manufacturers in kindred industries whose relation is that of a buyer or seller.

Statistics reveal many surprising and encouraging facts bearing on current conditions. For instance, 85 per cent of the working men and women in the United States are employed today and at higher average wages, when compared with the cost of living, than at any time in the past twenty-five years. Savings bank deposits are increasing today more rapidly than at any time in the history of the nation. These are sure indications of returning prosperity, because apparently we have passed the era of reckless spending and entered upon an era of thrift, which is a necessary adjunct of normal industrial conditions.

Sometime there surely will be available complete trade statistics covering all the important industries, which will make the future safer for manufacturers and investors than it has been. Such statistics must be available to both seller and buyer, so that no unfair advantage can be taken of them for the purpose of limiting production or raising prices. Every industry will be benefited thereby, more stable industrial conditions will be made possible, judgment based on accurate facts will replace guesswork, and manufacturers' associations will exercise their highest functions for the benefit, not of one, but of all the industries of the country. It is becoming more clearly understood that no industry can prosper and profit alone. These conditions in any industry will be possible only when all, or nearly all, are prosperous.

* * *

REPAIR SHOPS NEED BETTER METHODS

In most shops where automobile repairing is done there is no uniformity in methods, and consequently the cost of the work varies greatly. In refinishing cylinders, for example, some shops grind, others ream, others simply bore. If the equipment used for making the same repairs on the same type of engine in a dozen shops could be gathered together, it would make a truly miscellaneous collection. When we consider how highly developed and standardized are the methods of manufacturing automobiles, the crude and inefficient practice in repair shops on the same class of machinery is striking. There are a few well equipped repair shops where the equipment has been selected with a view to efficiency and service and where modern methods are applied; but these are the exception.

Even the service stations maintained by the automobile companies themselves frequently are not equipped or organized to produce the most work for the least outlay, and both equipment and methods seldom compare favorably with those employed in the manufacturing plants where the cars are made. The management apparently does not consider that if the equipment and methods are deficient the service cannot do justice to their cars. The reputation of a high-class car may be lost or impaired through the inefficient service stations maintained by the manufacturers, who should devote the same attention to their service stations as to their manufacturing plants. If the former were brought up to the standard of the factory, automobile repair shops generally would be forced to adopt a higher standard, with resulting benefits to all who use them.

During the past two years considerable new equipment has been installed in repair shops which has not always been bought with the best judgment. Machine tool manufacturers can help this branch of the industry generally by educating small repair shop owners in the selection and operation of the best equipment for their purposes, and all concerned will profit thereby.

* * *

STANDARDIZATION SURELY PAYS

According to the statistics furnished by manufacturers and other authorities in the automotive industry, the annual savings resulting from the standardization effected by the Society of Automotive Engineers amount to 15 per cent of the annual turnover in the industry. This turnover is about $5,000,000,000, and the estimated saving therefrom amounts to $750,000,000 a year. No other society or association that we know of has made such great progress in the practical application of standardization. Hundreds of items have been made the subject of investigation and study, and many of the component parts used in automobile construction are now made by all manufacturers according to definite specifications. The marked improvements made in automobiles, without a proportionate increase in price, have been due in large measure to this work.

Other associations and societies that can do so profitably, should follow the example set by the automotive engineers. What has been accomplished by them can be accomplished in other industries, provided there exists the will to cooperate. This is the most important factor; for the success of standardization work in any industry depends upon the extent to which the cooperative spirit is developed and flourishes. In spite of the strenuous competition between automobile manufacturers there has always been a marked cooperative spirit among them. Individual manufacturers always have given freely their figures on production and turnover to their associations—technical and commercial—and as a result there is more information available relating to the automotive industry than to any other industry except iron and steel. This cooperative spirit is extended to the automobile engineering departments, and through them has come about the standardization work which serves as a bright and shining example to other industries.

Very large savings will result to both manufacturers and users of machine shop equipment and appliances, if through cooperation, manufacturers will agree upon certain standards for such parts of their product as need not differ.

National Machine Tool Builders' Convention

THE spring convention of the National Machine Tool Builders' Association was held at the Hotel Traymore, Atlantic City, April 25 and 26. The main business of the meeting was the revision of the constitution and by-laws of the association, and considerable time was devoted to this question. The remainder of the time was devoted mainly to committee meetings. In addition, reports on standardization were presented and such questions were dealt with as various members themselves chose to bring before the meeting in order to have the present problems of the industry discussed.

Address of the President

In his opening address, the president of the association, August H. Tuechter, of the Cincinnati-Bickford Tool Co., Cincinnati, Ohio, called attention to the solid constructive work that has been done in the face of discouraging conditions, and to the wide recognition that this work has received. Some of the vital problems now confronting the machine tool builders were also reviewed. "When the world again needs new machine tools," said Mr. Tuechter, "we will be there with tools so good that the world will have to throw its old ones on the scrap heap. Perseverance and courage have always marked this industry in every depression, and they mark it now as always before."

One of the important points mentioned was the value of reliable forecasts of fluctuations in demand. "With such forecasts, managers in our industry will be able to avoid disaster by learning to keep their finances sound, by learning when to stock and when not to stock, by learning when to run ahead of demands and when to hold operations close to demand. . . . The industry would also be benefited by having reliable forecasts of revival of demand, so that after costs are reduced through the operation of cyclical forces, the industry can again put men to work in advance of the next rise in demand. All equipment cannot be made for stock, and the builder of non-stock machinery always faces the difficulty of building his forces when the labor market is short of men."

It was pointed out that the work of the association and its cost to members should always be regarded strictly as a business proposition. In this connection, the valuable service rendered by the association when its facilities are utilized was emphasized, and some of the important activities were referred to, such as supplying information on business conditions, taxation, etc., and the issuing of special and periodical bulletins in addition to the monthly survey of economic conditions.

Standardization and statistical work covering every branch of the industry were cited as the two big tasks ahead. The importance of standardization and the backwardness of the machine tool industry in this respect, as compared with the automotive industry, was referred to, as well as the increasing demand for the standardization of those elements that are common to all machine tools. The standardization of T-slots was referred to as the first project to be considered, since these slots are found on practically all machine tools. Reference was made to the work of standardization done by the Machine Tool Builders' Association in England in arriving at a standard for milling machine spindles so that in the future face mills, arbors, etc., can be applied interchangeably to English milling machines.

The General Manager's Report

The customary report by the general manager of the association, Ernest F. DuBrul, contained many matters of great importance to the machine tool builders of the country. Mr. DuBrul particularly emphasized the value of an association as an information bureau, when there is the proper spirit of cooperation and the willingness to spend whatever money is required to get results. Attention was called to the fact that information about an industry must come from the industry, and must then be applied by the individual in his own business. By way of illustrating one of the activities along this line, reference was made to the model contracts covering the taking of patents by employes that were procured and distributed as a safeguard against expensive and unnecessary litigation.

That part of the report covering business conditions referred to the gradual increase in shipments and orders for machine tools since July, and also to the encouraging sign that business policies in the industry are being based, on an increasing scale, upon an intelligent study of the necessary cycles that are characteristic of the machine tool industry.

Another timely subject covered by the report pertained to the valuable service of the association in connection with amortization claims. The claims filed as a result of this campaign are claims for money which the law allows a machine tool builder to deduct or to have refunded, if paid. According to Mr. DuBrul, "The total amount of claims that will be presented and allowed as a result of the association's interest in the matter will far exceed the total cost of the association for the last twenty years and for the coming ten years. This is a direct money benefit that the association has returned to some members."

Interesting features of Secretary Hoover's conference of trade association representatives held on April 12 were summarized, and also such important subjects as the study of unemployment and business cycles, the value of adequate cost systems, and the necessity of improving the statistics of the association, especially those needed for a first-class business barometer.

In connection with cost systems, reference was made to the work started last year and carried to the point of establishing a set of uniform principles which association members may use as a basis for cost-finding systems. "It is very desirable," said Mr. DuBrul, "that those who can possibly afford it, revamp their cost systems to bring them in accord with these principles, and this is the best time to make changes. If members wait until faced with a rush of business, they will be unable to do good revision work on cost systems. Now is the time when members should be using the over-earned and unearned burden accounts that were recommended in our cost plan. The man who divides his total expenditures for a month by the number of hours, or other divisor used to arrive at a burden rate, now gets a ridiculously high figure. Such a method has been described as giving merely an exercise in long division, but not giving costs. If, on the other hand, a concern has established a normal burden rate, its costs continue to be comparable during this sort of period. The difference between a normal rate and the actual expenditure is taken into the unearned burden account."

The proposed business barometer merely deals with orders and shipments and not with production and stocks, as do the various group reports. The sole requisite is that the members furnish the information. The fact was emphasized that in order to get a barometer that is worth while, it is necessary to classify orders and shipments in groups covering all classes of machines according to their prices. Six classes were suggested ranging from $250 and less up to and including $4000. The idea is that such a tabulation of orders monthly, covering all kinds of machines within the given classes, would give the entire industry a valuable index of the progress of demand.

The Trade Association Conference

ANOTHER step was taken toward more complete cooperation between industry and the Department of Commerce at the meeting in Washington, April 12, between Secretary Hoover and the executives and secretaries of trade associations. The meeting had been called to consider ways and means of obtaining closer cooperation between the Department and the industries represented by the trade associations, to plan the organization of a comprehensive statistical service, and to arrange for giving publicity to statistics in such a manner as to meet the requirements of the Department of Justice. The meeting was attended by representatives of several hundred trade associations and by the editors of the leading industrial and trade journals. The opening address by Mr. Hoover defined very clearly the status of trade organizations, the possibilities for cooperation with the Department of Commerce, and the service that trade associations can and should render to their members. A clear indication was also given of the practices of trade associations that are not approved by the Government.

Need for Trade Associations

In his opening remarks, Mr. Hoover emphasized the fact that while the efficiency of individual business men engaged in industry and trade is high, there are many questions of general interest that require common action. This was the reason for the organization of trade and industrial associations. Results valuable to the community have been obtained through this cooperation, but one of our national problems is how to obtain the beneficent results of such cooperation without creating influences that will stifle equality of opportunity. Competition among individuals must be maintained as the main impulse toward progress. The legitimate associations in industry and commerce have proved to be in the public interest; one needs only to examine the many functions of the existing 2000 organizations to demonstrate this.

Valuable Activities of the Trade Associations

Among the activities undertaken by trade associations which have been valuable to the country at large, Mr. Hoover mentioned the promotion of foreign trade, with better preparation of goods to meet the necessities of different markets; the securing of credit information in foreign markets; the collection of information relating to demand and supply of goods from competitive countries, custom regulations, transportation of goods, port and warehouse conditions; and the creation of a merchant marine. In the domestic field they have collected domestic credit information, handled insurance in different forms for their members, and standardized qualities and grades of commodities and products so that the public may obtain reliable grades at predetermined specifications.

They have simplified trade terms, eliminated unnecessary varieties, engaged in joint advertising, acted jointly to prevent infringement in trade marks and designs, promoted welfare work among employes, aided employment insurance, created apprenticeship systems, developed trade education, and acted in common for the prevention of industrial accidents. They have also represented the industries and trades in legislation relating to tariff, taxes, and transportation, and have concerned themselves with freight rates, overseas transportation charges, uniform bills of lading, statistics as to production and stocks of goods, rational cost accounting, etc. All these activities, it would be possible to demonstrate, have resulted in great savings in cost of production and distribution for the benefit of both producer and consumer.

General Membership of Trade Associations

There is one generalization in connection with this movement, Mr. Hoover pointed out, that has been mostly overlooked. The membership of the trade association is predominantly made up of the smaller establishments. Big business can employ its own agents in all these matters. It can establish its grades and standards; it can employ its own research laboratories. Little business can hope only to be equally informed and make equal efforts to promote its welfare through trade associations.

The law provides that the Secretary of Commerce shall promote trade, industry, and transportation. In the reorganization of the Department of Commerce that it might become of far greater real service to our whole public, an effort has been made to cooperate with industrial and commercial organizations in the promotion of marketing abroad, in transportation, in elimination of waste, and in the improvement of our industrial technology, statistical services and information, and in many other directions.

These problems must become practical problems of day-to-day contact with commerce and industry, if the Department is to learn the direction in which real service can be accomplished. Such contact can be secured only through trade and industrial organizations, for without organization there can be no representation. Legitimate trade association work, therefore, Mr. Hoover said, is vital and should be encouraged.

Objectionable Activities of Trade Associations

Mr. Hoover made it very clear that trade associations, in order to obtain the cooperation of the Department of Commerce, must conform with the requirements of the law for maintaining our industries on a competitive basis. Certain doubts have been created as to the right purpose of all trade associations during the past year by the exposure of a few groups that have used the benevolent purposes of trade association work as a cloak to create combinations which restrained trade and became centers of corruption. A canvass of nearly two thousand trade associations has showed that only a small number were engaged in those functions that lay the foundations upon which a restraint of trade is suspected.

It is obvious that the Department of Commerce cannot establish cooperative relations with associations who follow practices that have been condemned by the courts. Again there are some two or three activities carried on by a small number of trade associations, the legality of which has been questioned but not yet determined. These are in the main the so-called "open-price associations," which are collecting data on prices and sales of their individual members, and circulating such individual data again to their members, together with certain other information.

"I wish to state frankly and at once that the officers of the Government do not believe that these functions are in the public interest," said Mr. Hoover "whether they are in violation of the law or not. The Department laid down the rule nearly a year ago that it could not cooperate with associations subject to such criticisms and sees no reason to change it."

Cooperation with the Department of Commerce

In regard to cooperation between trade organizations and the Department of Commerce, Secretary Hoover emphasized that all the services of the Department are offered for voluntary acceptance by the trade associations. They are not imposed upon anyone. The Department wishes no arrangement to be established which is not based on the expressed wish of the industry for such cooperation, with a view to aiding the trade associations in their legitimate intentions to serve the industry.

Many of these cooperative services have been developed by the Department of Commerce during the past year. The foreign trade division of the Department has been divided into specialized branches which work in intimate contact with the men in the different industries, and cooperation has already been established with several trade associations who have appointed special committees to advise and direct the Department's agencies abroad on behalf of the whole industry. This has resulted in placing these energies in the channels where the sale of actual goods has been promoted; in dictating the character of information needed for special trades; and in promoting the economic handling and reduction of risks in foreign business.

This cooperation has been very successful. The growth of inquiries from the industries to this division has increased from a few hundred to several thousand daily. Those industries that have not yet taken advantage of this cooperative effort on the part of the Department are invited to make use of the Department's facilities.

Cooperation with the Bureau of Standards

Another field in which the Department has worked jointly with various trade associations is in the advancement of their efforts at simplification of trade terms, in the simplification of general specifications, and in the simplification of dimensions of many and varied products—all of which make for cheaper production and cheaper distribution, which ultimately benefits the consumer as well as the producer.

The Department of Commerce has cooperated with many different industries in carrying out investigations into the technical processes of manufacture, thus taking advantage of the practical experience of men from the trade associations cooperating with the Department's scientific staff. This work of elimination of waste is of the greatest importance to our commercial and industrial development, and can be accomplished only by cooperative effort on scientific lines.

Value and Need of Statistics

The third field in which the Department of Commerce has had much cooperation has been in the development of the government service devoted to publication of statistics on production and distribution of commodities. These services had existed in the Government for many years and the problem was to make the material of greater value to the commerce of the country. In these matters the Department has had the cooperation of many trade associations. These services need further development in the interest of the whole community.

Statistical information as to productivity and national stocks is needed not only by the men in a particular industry, but by men in other industries as well. A study of the trend of production and consumption does not imply restraint of trade. If it does, then the whole statistical basis of commerce that fills one-third of our newspaper space would need to be abolished, and if it were abolished, we would be bankrupt in ten years. "The matter that I am principally interested in" concluded Mr. Hoover, "is that this information should be available to the whole public. It is the old question as to whether a community will succeed better if it acts in ignorance or if it acts in knowledge."

* * *

A general investigation of scrap losses in aluminum alloy foundry practice made by the Pittsburg Experiment Station of the United States Bureau of Mines showed that the annual losses in the United States amount to about $1,200,000, and that universal adoption of methods recommended by the bureau would probably result in a saving of about $600,000 a year. The complete results of the investigation will be published in bulletin form.

INDUSTRIAL CONDITIONS IN FRANCE

By MACHINERY'S Special Correspondent

Paris, April 13

Industrial conditions in France remain unsettled. Considerable variation from day to day in the exchange rates tends to keep manufacturers from undertaking any contracts covering a lengthy period. The only manufacturing plants operating steadily at the present time are those producing woodworking machinery, or machines and materials to be used in developing the water-power resources in the French mountainous regions. Sales are rare in the machine tool field, except by dealers handling machinery of German manufacture. In the northern part of France manufacturers are entirely replacing the equipment destroyed during the war with machinery imported from Germany. However, certain machines of well-known American make are being purchased by French manufacturers in spite of the high prices. Machinery of English manufacture also has a slight but steady sale.

The Wiesbaden agreement, which at first created considerable adverse criticism among French manufacturers, has now been accepted more or less graciously. At one of its meetings the Federation des Industriels et des Commercants Francais recognized the agreement, holding that the payment by Germany of her indebtedness with manufactured goods was in accordance with the terms of the treaty of Versailles and that it facilitates the actual delivery of the material.

Most of the orders which French manufacturers counted on receiving in connection with the reconstruction of the devastated sections will be placed in Germany. As a result, German industries will occupy an important and definite position in France. The introduction of German goods into France is one of the surest ways of obtaining the proper reparation, if precautions are taken to see that Germany does not send materials that French manufacturers produce in sufficient quantities to meet the needs of the country. It seems that this attitude of mind toward the arrangement is being generally adopted.

During the month of January there was a reduction in the imports of raw materials and manufactured articles which amounted to 836,067,000 francs (about $77,503,400, present exchange) and a reduction in the exports of such merchandise of 127,877,000 francs (about $11,854,200). Present imports are now lower than exports.

A great number of the articles included in the recent tariff laws are insufficiently protected. Since the end of the war a general revision of the tariff rates has been contemplated, but such a revision could not actually be undertaken so long as exchange rates remain unstable and business unsteady. It was, therefore, decided that until such a revision could be made, rates would be based on a system of coefficients. The coefficients established were often arbitrary. Besides being complicated, this system cannot take into consideration the fluctuation and prices of materials. Various propositions on the tariff, including the tariff on machine tools, are now before the Chamber of Deputies.

* * *

TERMS USED FOR CASTINGS

At the American Gear Manufacturers' Association's annual meeting in Buffalo, the metallurgical committee proposed that, in designating castings made from steel, the expression "steel casting" always be used instead of the term "cast steel," in order to prevent confusion with the many so-called cast-steel tool steels on the market. It was also recommended that the term "cast iron" be dropped for the more explicit terms "gray iron" or "white iron" as the case may be, and that the term "semi-steel" be dropped in favor of the more specific term "gray iron with a certain percentage of steel scrap." The association accepted the recommendations with regard to steel castings and gray iron and white iron, but deferred action in regard to semi-steel.

THE RADIO EQUIPMENT INDUSTRY

"Broadcasting" has caused a phenomenal growth of the wireless industry. There are hundreds, if not thousands, of newly formed organizations in the radio field, and many others are constantly being formed to meet the abnormal demand. Most of these concerns, however, are producers in name only. The majority of the so-called manufacturers of radio equipment are little more than assemblers who have no manufacturing facilities. They purchase their metal parts from outside manufacturers, most of whom are unable to fill promptly the orders which are flooding their shops.

The contract shops that are actually doing the manufacturing are not rated as radio equipment manufacturers, while, on the other hand, those assemblers who are so rated often have no factories, or at least none that contain machinery. The entire production facilities in such shops often consist, perhaps, of a bench or two, with a few girls to assemble the units. One electrical engineer who has been connected with radio development since 1905 and is the originator of a certain type of wireless apparatus states that there are not more than twenty actual manufacturers of radio equipment in the United States, who have facilities for producing radio apparatus complete from start to finish. It is the parts manufacturing business that has assumed such large proportions.

Screw machine products molded into some insulating material, or otherwise attached, and sheet-metal stampings constitute the greater part of the metal units that enter into the construction of radio receiving sets. The flood of orders for these metal parts has surpassed the production facilities of shops regularly engaged in the manufacture of this class of work. The overflow will be taken care of by those machine shops that are properly equipped and in a position to handle additional orders. There is an opportunity for metal-working plants having small screw machine and power press equipment available to handle some of the present overflow. The radio industry promises to be active for a considerable period, as there are at present but a comparatively small number of receiving sets in use. It has been recently estimated that about 600,000 receiving sets have been distributed.

Classification of Manufacturers of Radio Equipment

In the early development of any industry there is lack of standardization and efficiency in manufacturing methods. An analysis of the present manufacturing conditions in the radio industry places the manufacturers in three groups: The first class is made up of operating plants that have previously been engaged exclusively in the manufacture of telephone and telegraph equipment. These manufacturers are well equipped for turning out radio apparatus in large quantities, and the methods found in these shops are well systematized. The second class consists of manufacturers who, through a lack of activity in their own industry and because they possess suitable machining equipment, have undertaken to manufacture wireless apparatus and furnish the parts to others engaged in the assembling of the units; manufacturers in this class sometimes build some of the more simple equipment completely. The third group comprises assemblers, who turn out receiving sets, trademark them and place them on the market. It is probable that at present more radio equipment is produced by this means than the combined products of the other two classes.

Machine Tool Equipment Used in Making Radio Apparatus

Molded insulator parts of bakelite, condensite, formica, and other compositions are largely used in radio receiving sets, and glass parts for vacuum tubes and lightning arresters are also extensively used; but neither of these products would be manufactured in a shop primarily engaged in metal-working. For that reason nearly all the molded composition articles are obtained from companies specializing in molded insulator materials; similarly, the glass detector and amplifying tubes and the lightning arresters are generally furnished by manufacturers specializing in those lines.

Comparatively few types of machine tools are employed for making the metal-working parts of radio equipment, fully 75 per cent of the parts being produced on screw machines and power presses. There is considerable use for certain light bench equipment such as bench lathes, and drilling and tapping machines are, of course, required. The hand screw machine or turret lathe also finds considerable use. Although a comparatively large amount of wire is used, most of the winding is done by means of special attachments either on a bench lathe or a speed lathe, so that single-purpose machines are rarely needed.

In the regenerative type of receiving set, the rotor and stator of the variometer are usually made of wood (although these parts are sometimes molded from bakelite), consequently woodworking machines are required for this work. The sets are usually furnished in a wooden cabinet with a suitable panel, made either of wood or of some molded material, on which the controls, dials and connection sockets are arranged. It is not the usual practice, however, for the instrument manufacturers to build their own cabinets, but they often finish the panels, and this requires certain woodworking machines. If the panels are to be grained, a sanding belt is usually employed.

An engraving machine is necessary for cutting the manufacturer's name and all notations pertaining to switches, capacity, and certain other specifications on the panels. A great many of the metal parts are made of nickel-plated brass; therefore plating equipment and polishing machines are in common use. Among the other machine tools that find varied application may be mentioned hand milling machines, nut tappers, arbor and foot presses, power saws, and riveting machines.

PRODUCTION OF MILLING MACHINES IN 1919

On page 467 of February MACHINERY a table was published giving the production of machine tools in the United States as compiled by the Bureau of Census for 1919. The figures covering milling machines have been corrected by the Bureau because of an error that appeared in the returns given by one of the manufacturers. The corrected figures, as sent by the manufacturer to the Bureau in a revised return, are given in the accompanying table.

MILLING MACHINES MANUFACTURED IN THE UNITED STATES IN 1919

	Number of Establishments	Number of Machines	Value
Milling Machines			
Plain	34	7433	7,088,120
Ohio	10	3246	2,979,301
Wisconsin	3	924	1,536,666
New York	4	646	479,937
Connecticut	3	274	176,986
All other states	14	2343	1,915,230
Universal	17	3201	5,635,758
Wisconsin	4	914	1,710,317
Ohio	4	1155	1,860,215
All other states	9	1132	2,065,226
Vertical	14	1316	2,761,737
Automatic	12	822	1,232,048
Other Types	22	1760	3,000,593

Machinery

The Soviet Government, about a year ago, placed an order for 1000 locomotives with the Trollhättan Locomotive Works in Sweden, with the stipulation that deliveries be made during a period of five years. The locomotives are of the improved type based on a model developed at one of the leading Russian locomotive works in 1912. During 1921, 50 locomotives were delivered and 200 are scheduled for shipment this year, while during the next three years 250 locomotives will be completed annually until the entire order is filled.

Gear Manufacturers' Annual Meeting

THE sixth annual meeting of the American Gear Manufacturers' Association, held in Buffalo, April 20 to 22, was characterized by the activity always displayed by the association. Many reports on standardization were presented at the meeting, some of which were acted upon and adopted either as standards or as recommended practices. Progress reports were also presented by several committees, although final action was not taken at this meeting. A number of addresses on subjects closely allied to practice in the gear-cutting field were read, the meetings occupying the entire time of the three days set aside for the convention.

The President's Address

In his address at the first general session, F. W. Sinram, president of the association, referred to the present trend in the industry and to some of the important activities of the association. These activities were classified as twofold—commercial and technical. It was pointed out that commercial matters should receive greater consideration, especially as regards concerted constructive effort, and that, regardless of initiative, progress in any direction can be achieved only when a fair proportion of the industry is receptive and ready to cooperate. The discussion of commercial subjects in connection with the association meetings was advocated because "the present demands constructive effort that we may stabilize our industry and do our part in giving stability to business in general." In connection with this topic, the attention of the members was directed to the two group meetings for considering industrial conditions. In view of the fact that there are problems peculiar to each of the main groups comprising the gear industry as a whole, separate meetings for each were arranged to facilitate the deliberations, and in order to accomplish as much as possible. In commenting briefly on the technical side of the association's work, what has been accomplished, especially toward standardization, was referred to as a decided step forward, and as a phase of the work that has attracted the attention of the entire mechanical world.

Papers Read before the Meeting

The papers read before the convention covered a wide range of subjects. H. E. Harris of the Harris Engineering Co., Bridgeport, Conn., read a paper on "Good Practice for Cutting the Faces and Clearance of the Teeth of Hobs, Gear Cutters, and Form Cutters." In this paper Mr. Harris emphasized the necessity for proper rake of hob and gear cutter teeth. Ralph E. Flanders of the Jones & Lamson Machine Co., Springfield, Vt., read a paper on "The Use of the Projection Comparator in Testing Gear and Gear Cutter Teeth," in which he pointed out the advantages of the Hartness comparator for the visual inspection of tooth profiles. G. E. Katzenmeyer, of the R. D. Nuttall Co., Pittsburg, Pa., presented a paper on "The Proportions of Industrial Gears," containing valuable formulas and charts which enable the designer to readily proportion gears according to requirements and to place this work upon a standardized basis. R. S. Drummond of the Gear Grinding Machine Co., Detroit, Mich., dealt with the subject "The Grinding of Gear Teeth and its Future in the Industry." F. E. McMullen and T. M. Durkan presented a paper on "The Gleason Works System of Bevel Gears" in which the principles underlying the system were thoroughly explained.

Hartness Comparator Applied to Gear Testing

The application of the Hartness comparator as a thread-testing apparatus is dealt with in the first part of Mr. Flanders' paper, and then the use of this apparatus for the inspection of gears and gear-cutters is considered. For gear work the comparator is entirely rearranged. The microscope must have a large aperture to take in a whole tooth, and in order to get the required degree of magnification at a distance of five feet (so that the operator can readily observe and manipulate the work) the image is reflected against a mirror, because the angle of projection is so wide that no lens system can be devised to prevent distortion and interference from color bands. The accuracy of the results may be judged from the fact that with a magnification of 100 times, differences of 0.0001 inch can be detected.

As applied to a form cutter, the apparatus is applicable for testing the regularity of the teeth one with another; the tooth of a cutter giving satisfactory results may be compared with one which is not satisfactory and the reasons for the unsatisfactory results determined. The projection of cutter outlines is a comparatively simple problem, owing to the sharp, definite character of the cutting edges. In the case of gears, however, the problem is complicated because of the lack of clearly defined lines both at the entering side of the cut and at the opposite side. Furthermore, many gears used in the automotive field have the teeth chamfered.

An ingenious and interesting part of the apparatus is that used for projecting and tracing a tooth outline representing any section throughout the length of the tooth. This is done accurately and simply, by using a needle that is mounted and focused in the plane of the tooth to be inspected. The tooth outline is traced by this point, the junction of the point and its reflection providing a location for the surface which is measurably accurate within 0.0001 inch; it is also possible to draw the outline rapidly with nearly this degree of accuracy.

Gleason Bevel Gear System

The bevel gear system developed at the Gleason Works, as explained in the paper by McMullen and Durkan, is the result of a need for a definite system of designing bevel gear teeth based on the most desirable tooth form for use under average conditions. It has been common practice in the past to use spur gear formulas, such as those of Brown & Sharpe and Fellows, in figuring bevel gears. These formulas were worked out for an interchangeable spur gear system, which necessarily required some compromise, so that when they are applied to bevel gears, where interchangeability is not a factor, the possibilities of the involute curve are not fully utilized. The Gleason 0.3 and 0.7 long and short addendum tooth was brought out to improve this condition, and various other alterations of the standard spur gear design have been used, but for the most part these can be applied to certain combinations only, and therefore, are not universal. Recent applications of bevel gearing covering a wide range of ratios have made it imperative that a progressive system, embracing all ratios and any number of teeth in common use, be worked out.

An investigation has been conducted by the Gleason Works with the idea of developing a practical system of designing the quietest form of tooth consistent with strength and wear considerations, and the results of this research have been incorporated in a simple table. This system applies to any pair of generated spiral or straight-tooth bevel gears, operating at right angles, where the pinion is the driver and has ten or more teeth. Bevel gears cut on planers of the former type are the subject of a special study, as certain practical limitations prevent the application of the system to this class of gearing without modification.

The principal qualities considered in arriving at this system, arranged in the order of their importance, are quietness, strength, and durability. In regard to quietness, experience shows that bevel gears cut with a lower pressure angle will operate more quietly than those with a higher one, other conditions being equal. There are several reasons for this: With the lower pressure angle, a greater arc of action is obtained, any eccentricity has less effect, and the radial component of the tooth load is minimized. Thrust forces also make it desirable to avoid the higher angle, not only because of the introduction of an axial or cone thrust not present in spur gears, but also because the majority of bevel gears are overhung from their supports so that the total load should be kept as low as possible. For these reasons the basis of the system is the use of the lowest pressure angle that can be employed without sacrificing strength by introducing excessive under-cut.

The limitation of under-cut has been fixed by a study of successful automobile practice where both strength and silence are paramount. Strength, as governed by the pressure angle, is not sacrificed to any great extent when a low pressure angle is selected in the interests of quietness, because the stronger tooth section of a higher angle is nearly offset by the greater arc of action of the lower angle. The effect of this increased arc of action is to keep the load nearer the pitch line when only one tooth is in contact. Durability has been taken account of in the system by proportioning the teeth so that the sliding action, which is always present in gears, is approximately balanced between approach and recess. The various factors that go to make up the system have been arrived at by an examination of the considerations already outlined, and have been arranged in a simple practical form. The Gleason Works system will be fully described in June MACHINERY.

Reports of Committees

Among the committees that presented reports were the Sectional Committee of the association working in conjunction with the American Engineering Standards Committee; the General Standardization Committee; and the Spur Gear, Bevel Gear, Spiral Gear, Herringbone Gear, Electric Railway and Mine Gear and Pinion, Nomenclature, Worm Gear, Inspection, Composition Gearing, Keyway, Sprocket, Metallurgical, Transmission, Differential Gearing, Tooth Form, Uniform Cost Accounting, and Library Committees.

Companies Elected to Membership

The convention also included two special group meetings, one of the Industrial Gearing Group and one of the Automotive Gearing Group to consider the conditions in the industry. The American Gear Manufacturers Association now has 94 member companies, 110 executive members, and 55 associate members. The Automotive Gear Works, Atlanta, Ga., was elected to membership at this meeting, with C. G. Hamilton as executive member. The Willys-Morrow Co., Elmira, N. Y., was also elected to membership, with F. H. Higgins and T. W. Tidd as executive members. E. H. Ott of the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., and D. L. Boyle of the General Electric Co., Schenectady, N. Y., were elected associate members.

Executive Committee and Officers

The following members were elected to serve on the executive committee of the association: E. J. Frost, Frost Gear & Forge Co., Jackson, Mich.; J. B. Foote, Foote Bros. Gear & Machine Co., Chicago, Ill.; C. F. Goedke, William Ganschow Co., Chicago, Ill.; W. H. Phillips, R. D. Nuttall Co., Pittsburg, Pa.

The officers were all re-elected to serve for the coming year and are: President, F. W. Sinram, Van Dorn & Dutton Co., Cleveland, Ohio; first vice-president, R. Johnson, Warner Gear Co., Muncie, Ind.; second vice-president, B. F. Waterman, Brown & Sharpe Mfg. Co., Providence, R. I.; secretary and treasurer, F. D. Hamlin, Earle Gear & Machine Co., Philadelphia, Pa.

CONVENTION OF THE NATIONAL METAL TRADES ASSOCIATION

The twenty-fourth annual convention of the National Metal Trades Association was held at the Hotel Astor, New York City, April 19 and 20. The first session, in addition to the usual preliminaries, included the appointment of convention committees and the reports of W. W. Coleman, president; Frank C. Caldwell, treasurer; Homer D. Sayre, commissioner; and L. W. Fischer, secretary. During the sessions following, many subjects of vital importance to the metal trades were presented by prominent speakers. Professor Harold G. Moulton of the University of Chicago spoke on "American Industry and the Stabilization of Europe." A clear analysis of the factors affecting business conditions both here and abroad was presented, as well as the important points to be considered in building up export trade. "Facts and Fancies about Wages in Basic American Industries" was the subject of an address by Magnus W. Alexander, managing director of the National Industrial Conference Board, New York City. A. M. Loomis, from the Washington office of the National Grange, spoke on "The Farmer as a Balance Wheel"; and James A. Emery, counsel for the National Association of Manufacturers, spoke on "Industrial Courts." E. L. Greever, whose subject was "West Virginia Fights for Freedom" gave first-hand information on this critical situation, Mr. Greever having been counsel for the non-union mine operators.

Report of Apprenticeship Committee

Another subject of vital importance to the metal trades, which was discussed at the convention, was that of training apprentices to be skilled all-around workmen. The committee on apprenticeship examined various apprenticeship systems in order to incorporate their virtues and eliminate their defects in the training course advocated. The report which the committee presented laid down courses of shop work of the apprentice and included suggestions for a standard diploma, for an interchange of apprentices among the smaller or specialty shops, and dealt with other aspects of the apprenticeship problem on the basis of the best American practice. Harold C. Smith, chairman of the Industrial Training Committee is president of the Illinois Tool Works and also of the Chicago branch of the National Metal Trades Association. The other members of the committee are William Taylor, president of the Chandler & Taylor Co., of Indianapolis, and John C. Spence, works manager of the Grinding Machine Division of the Norton Co.

The officers of the association for the coming year are as follows: President, W. W. Coleman, Bucyrus Co., South Milwaukee, Wis.; first vice-president, J. B. Doan, American Tool Works Co., Cincinnati; second vice-president, Paul C. DeWolf, Brown & Sharpe Mfg. Co., Providence; treasurer, J. W. O'Leary, Arthur J. O'Leary & Son Co., Chicago; commissioner, Homer D. Sayre; and secretary, L. W. Fischer.

MEETING OF AMERICAN WELDING SOCIETY

The American Welding Society held its annual meeting in the Engineering Societies Bldg., New York, on April 26 to 29. At the morning session on April 26 there was a conference, at which a number of tank manufacturers were present, for the purpose of considering the subject of the welding of unfired pressure vessels. At the technical session, held on the evening of April 27, a number of interesting papers were presented, among which were "Welding of Heavy Copper Plate," by A. S. Kinsey; "Electric Welding of Dredge Pipes," by J. H. Nead and R. L. Kenyon; and "Thermit Welding," by J. H. Deppeler. The reports of the various committees were presented at the different sessions, covering welding wire specifications, resistance welding, specifications for steel to be welded, electric arc welding, gas welding, training of operators, and welding of storage tanks.

Tool Design Standards

Development of Standard Instruction Sheets for the Use of Tool Designers

By H. P. LOSELY, Industrial Engineer, Detroit, Mich.

ANYONE who has worked in different tool designing offices must have noticed the large amount of time usually spent in looking up machine dimensions, how other jigs or fixtures are made, and other miscellaneous information. Somewhat less obvious, but none the less substantial, is the amount of time spent in designing certain elements of tools again and again which could be worked out carefully once, and after that simply copied when required. In addition, extra time is taken in checking the drawings each time to see that all parts of the design are correct. It is the purpose of this article to show how the principle of permanent standard practice instructions may be profitably applied to tool designing.

Developing Standard Practice Instructions

The first thing to be considered in developing such standard instructions is what shall be covered by them. No hard-and-fast rule can be laid down to cover all cases, but the following will serve as a general guide:

1. General instructions should be issued on office practice, covering every phase of the work, including the organization of the office and its relation to other departments, and the methods to be followed in ordering and routing work. The practice to be followed in making designs and drawings should also be written down. When a new man comes into the organization, he can read over these instructions and readily acquaint himself with customs, so that he can work in harmony with the organization.

2. Data should be accumulated of all machines on which jigs and fixtures are employed.

3. All elements of construction which recur with great frequency in jigs and fixtures, such as spring plungers, U-lugs, eyebolts, etc., should be carefully studied, and standard practice instructions issued concerning them. In many cases it will be found practical to draw up the element in question to scale, and dimension it so that when it is required in a design it can be readily copied. Not only does this save time otherwise spent in designing that element, but it also enables the designer, in making the first lay-out, to know how much space he will need for the element. Furthermore, the completed design will be known to be correct.

4. Certain detail parts can be so drawn on standard instruction sheets that special drawings will be unnecessary in the making of tooling equipment. This does not mean that the parts must be carried in stock; they may be catalogued by a classification number and ordered by that number when required. Examples of detail parts that can be handled in this way are as follows: Drill bushings, tool bits, locating keys and pins, jig feet, adapter plugs, and gage handles.

5. There are many details such as hand-knobs, hand-wheels, stops for jig lids, baseplates, angle-plates, and handles, which vary in the dimensions required on an individual tool, but which can readily be made from a standard pattern. This method reduces pattern costs as well as the time required to obtain the casting. In many cases it may be feasible to keep rough castings in stock, thus still further reducing costs.

In making up standard practice instructions, the neatest and handlest arrangement is to use one size of sheet. A size that has given satisfaction is 8½ by 11 inches, leaving at least a ¾-inch margin at the left side so that holes may be punched for placing the sheets in a three-ring loose-leaf binder or so that they may be bound together. When only a few copies of the instructions are required, they may be typed with a black ribbon on a good bond paper, preferably without a watermark. Black carbon paper should be placed with the carbon side to the back of the sheet thus producing a negative from which blueprints may be made. If many copies of the instructions are needed, some manifolding process may be employed. In larger offices it is worth while to have blank sheets printed and carried in stock ready for use.

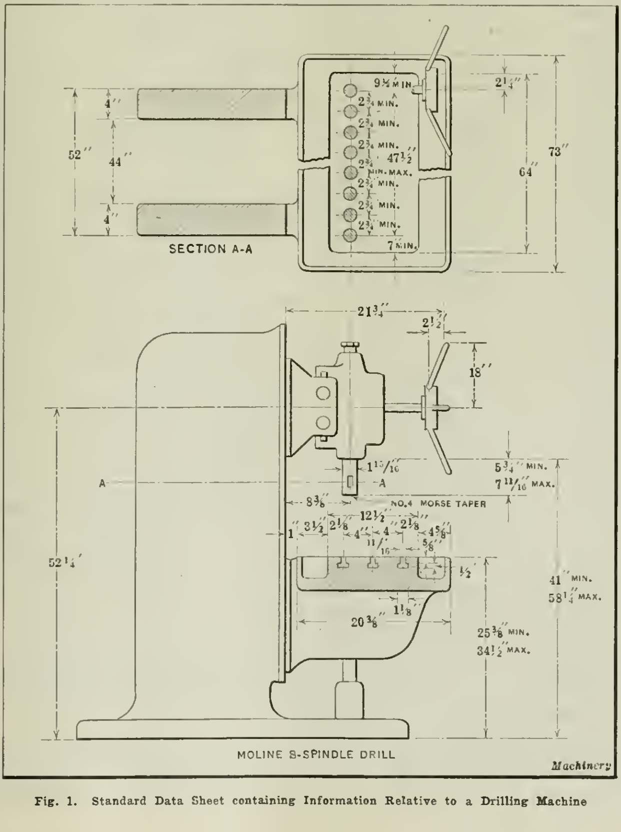

Fig. 1. Standard Data Sheet containing Information Relative to a Drilling Machine

Collection of Machine Data

The subject of machine data is somewhat controversial. In the opinion of the writer it is not worth while, as a rule, to make elaborate drawings of each machine; whenever data is required it should be obtained and arranged conveniently for reference. This end may be attained by not allowing any draftsman to go into the shop to sketch a machine without permisson from the chief draftsman who has charge of the standards. This scheme makes the men use the sheets in existence, and whenever any material is at fault or missing, they must bring the matter to the attention of the chief draftsman. The latter can keep notes of such work and see that data obtained are turned in to him. A sketch can then be drawn on a standard sheet, and the latter can then be indexed and placed in the file.

When work is slack and it is desirable to keep the force together, it may be a good thing to have sketches of all machines drawn up. The data for a machine much used may, of course, be worked up elaborately, and an ink tracing made. In any case, all dimensions should be checked by a second man before a sheet is put in the reference file. Fig. 1 gives an idea of the manner in which useful data of a machine may be arranged. In drawing up standards for units, parts, or patterns, there will be a choice between tabulating and showing each size drawn to scale. If the space is limited so that tabulation is necessary, care should be taken to do this with due regard to proportion. In fact, it is generally advisable to sketch each size roughly to scale before tabulating dimensions in order to be sure that no errors are made. It is preferable to draw each size separately on data sheets, as it eliminates referring to a tabulation for dimensions and in many cases allows a designer to make a direct comparison between sizes, enabling him to decide readily which size is best for the work in hand.

TABLE I. INDEX TO MACHINE TOOL DATA SHEETS

General Classification

Group No.	Type of Machine
1- 9	Drilling and tapping machines
10-19	Milling machines
20-29	Lathes and screw machines
30-39	Grinders
40-49	Shapers, planers, and slotters
50-59	Boring machines
60-69	Punching machines
70-79	Gear-cutting, thread-milling, profiling and broaching machines
80-89	Bench equipment
90-99	Miscellaneous

Note: For automatic and semi-automatic machines, see Section A

Detailed Classification

Group No.	Type of Machine
1	Upright drilling machines
2	Radial drilling machines
3	Multiple - spindle drilling machines
4	Bench drilling machines
5	Electric drills (hand)
6	Gun drills
7	Tapping machines
10	Plain milling machines
11	Universal milling machines
12	Hand milling machines
13	Vertical milling machines
14	Multiple - head milling machines
15	Lincoln milling machines
16	Briggs milling machines
17	Automatic milling machines
18	Keyway milling machines
20	Engine lathes
21	Turret lathes
22	Bench lathes
23	Centering machines
30	Plain cylindrical grinders
31	Universal grinders
32	Surface grinders
33	Internal grinders
34	Cylindrical grinders
35	Disk grinders
36	Cutter grinders
37	Portable grinders
40	Shapers
41	Planers
42	Slotting machines
50	Vertical boring mills
51	Horizontal boring mills
60	Plain power presses
61	Back-geared presses
62	Toggle presses
63	Foot presses
70	Gear-cutting machines
71	Thread milling machines
72	Profiling machines
73	Broaching machines
80	Arbor presses
81	Bench straighteners
82	Vises
90	Shears
91	Saws
92	Furnaces
99	Special machines

Machinery

Indexing and Cataloguing Instruction Sheets

It is most important that a proper indexing and cataloguing system be used in connection with instruction sheets. One of the chief reasons that unsatisfactory results are sometimes obtained in making up standards is that they are incompletely indexed and badly kept so that when information is wanted it cannot be found. Considerable forethought is necessary in deciding upon any numbering system, since if it is done haphazardly, a renumbering may soon be required, causing great annoyance and some expense. Before deciding on a system, it is advisable to ascertain what other numbering systems are being used by the concern so that the one used for standard sheets and parts will not be confused with others. The writer uses a symbol consisting of a letter indicating the class of data, a prefix number indicating a group in that class, and a suffix number for each sheet of the group.

Suppose, for instance, a sketch is made of a Whitney No. 6 hand milling machine. The letter "M" may be used for all machine tool data, and upon referring to the classification list in Table 1, it will be seen that 12 is the group number. Looking under the detailed list of sheets it might be found that two other hand milling machine sheets had been previously issued so the number assigned to the new sheet would be 12-M-3. Then, if a draftsman requires data on this machine he can find it on the list of hand milling machines and get the sheet from the supply room.

In numbering special tools the part number method may be used, in which a symbol is added to the part number consisting of a letter which designates the kind of tool and a distinguishing number. Then when two fixtures are required for part No. 529, for example, they are numbered 529-F-1 and 529-F-2.

Various letters may also be used for identifying the standard sheets. The letters used for these purposes must receive consideration when making the standard sheets, and the following arrangement is suggested:

SPECIAL TOOLS

(B) Boring and reamer bars
(C) Cutters
(D) Punches and dies
(F) Fixtures
(G) Gages (special)
(H) Multiple heads
(K) Tool-blocks
(L) Arbors
(R) Reamers
(T) Tool bits
(Y) Special machines
(Z) Form tools

STANDARD SHEETS

(A) Automatic lathe data
(E) Construction elements for general use
(M) Machine tool data
(N) Small tool and equipment data
(O) Organization and office system
(P) Pattern drawings
(Q) Gages (standard)
(S) Stock lists
(V) Thread gages (s't'd.)

The reason for subdividing the standard data sheets into nine classes is that this allows the group numbers generally to be kept down to two digits, and should a renumbering of any class become necessary, probably only that one class would be affected. Table 1, to which reference has previously been made, shows an index for data on machines generally used in a large shop, and indicates how the various groups may be arranged.

Accessibility and Maintenance of Data

In the distribution of standard data, the two main requirements are to make the information accessible and to keep it up to date. The following suggestions may be of value in securing these ends:

1. Place the responsibility of upkeep on the chief draftsman who can appoint an assistant if necessary.
2. File all original data sheets in the supply-room drawing files.
3. Keep a visible card index of all data sheets in an accessible place so that anyone can find the number of any required sheet.
4. Have the supply clerk maintain a separate file of blueprints of the standard sheets. The number of copies in existence should be recorded on the left-hand margin of the original, or in a large establishment, a separate card index may be kept for this purpose.
5. Require a receipt for each blueprint lent, this receipt to be given back only when the blueprint is returned to the file.
6. When changes or additions are made, require the chief draftsman to obtain the original and all blueprints from the supply clerk and have them all changed together, or the old prints destroyed and replaced by new ones.
7. Select sheets which are frequently required, and make up special standard books. These books should be firmly bound, properly recorded, and charged to the men receiving the books; loose-leaf binders should not be used.
8. Keep complete sets of prints for open reference, in small shops; where more than four men use a set, it is difficult to maintain them in this way, and it is better to keep them in a file room.

Standard Feet for Jigs and Fixtures

As a rule, it is preferable to make a jig or fixture with feet, rather than to have the under side of the base machined all over. This is particularly so when a jig is to be slid around and turned on the machine table, as it lessens the chance of chips getting between the jig and table contact surfaces. Incidentally, the cost of machining and scraping the feet is less than when a solid base is used. If a fixture is clamped to the table or not pushed around much, the most economical design is to make the feet integral with the fixture casting. The feet should be located in such a way as to prevent distortion of the casting by clamping or cutting strains, and they must be far enough apart to prevent rocking or upsetting of the fixture. Fig. 2 shows a fixture used in drilling a hole in a long bar; the bar is supported by a button *A* close to the drilling point, and an extra foot *B* is placed beneath this point of pressure to prevent the whole casting from sagging. This makes it possible to use a lighter design than could otherwise be employed.

Where cast feet are in the form of pads, they should be 1-inch square, and when finished there should be a 1/4-inch

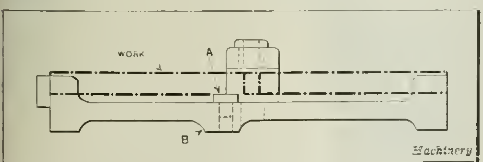

Fig. 2. Drill Jig with Extra Foot located close to Drilling Point to prevent Distortion

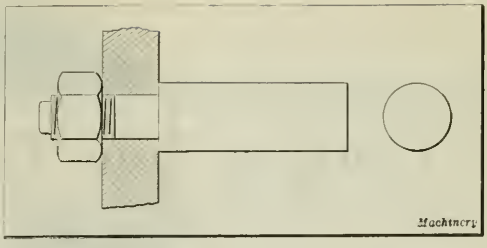

Fig. 3. Type of Foot commonly used on Reversible Jigs

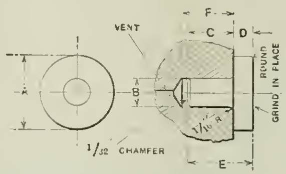
clearance between the table and the rough surface of the base. If the feet are formed by an extension of a wall, they will naturally be made the same thickness as the wall and should generally be not less than 1½ inches long. The practice with milling machine fixtures is usually to make a solid base; however, if the base is over 8 by 10 inches, it is advisable to relieve it, but care must be taken to see that all pressures are transmitted directly to the machine table.

TABLE 2. DIMENSIONS OF STANDARD INSERTED JIG AND FIXTURE FEET



All dimensions in inches

A	B	C	D	E	F
¾	0.3758 0.3755	⅝	¼	⅞	¾
1	0.3758 0.3755	⅝	¼	⅞	¾
1¼	0.5010 0.5005	¾	5/16	1 1/16	⅞

Machinery

When a jig is to be slid around, or if great accuracy is required, it is best to use inserted hardened tool-steel feet. These can be carried in stock by the tool-room in sizes such as shown in Table 2, of which the 1-inch size is best adapted for general use. These stock feet are pressed fits in standard reamed holes, and the working surface of each foot is ground after all the feet of a jig have been assembled. As with any pressed-fit plug, an air vent must be provided and provision made for removal. If the air vent is so placed that a pin cannot be used to drive out a foot, then the pad supplied for the foot on the casting should be smaller in diameter than the large diameter of the foot, so that the latter may be pried out. Fig. 3 illustrates the type of foot construction commonly used on reversible fixtures, both ends of the plug being ground.

COMPENSATION FOR SKILLED WORK

By CHARLES W. LEE

The kind of encouragement often accorded skilled mechanics, especially in small towns, is well illustrated by the following incident. A hurry call on the 'phone was received recently from a neighboring manufacturer requesting the writer to come and see if he could tell what was the matter with one of the machines. The writer, not wishing to be unneighborly, left what eventually proved to be far more important business to comply with the request. On arriving at the plant a whole group of machines was found idle. Something had gone wrong with one of the machines, causing the production of the entire group to be suspended. In spite of all efforts, no one had been able to locate the trouble.

The matter was soon straightened out however, and production resumed. The writer began mentally to convert about $24.99 into terms of gasoline, supposing of course, that the manufacturer would at least suggest that a bill be sent in for the service rendered. But instead, he looked at his watch, and said: "Now let's see—you've been here about half an hour, would fifty cents be about right?"

Cutting Spur Gears by Hobbing

Setting up Gear-hobbing Machines—Examples from Practice—Application of Multiple-threaded Hobs—Cutting Small Pinions

Fourth Article of a Series on the Use of Different Types of Gear-cutting Machines for Cutting Various Classes of Gearing

GEAR teeth cut by the hobbing process are given the required shape or curvature by a generating action resulting from the rotation of the gear blank relative to a cutter of the hob form. Gear-hobbing machines are commonly applied to the cutting of spur, helical, and worm gearing, and hobbing is the most rapid method of cutting gears by a generating process. This article will be confined to spur gears.

In the practical application of the generating principle to gear-hobbing machines, the hob used has cutting teeth of the same cross-sectional shape as teeth of a rack of corresponding pitch, except for minor variations such, for example, as increasing the length of the hob teeth to provide for clearance at the bottom of the tooth spaces. As the hob teeth lie along a helical path (like a screw thread) the hob is set at an angle to align the teeth on the cutting side with the axis of the gear blank. When the hob is inclined an amount depending upon the helix angle of its teeth, the latter represent a rack on the cutting side.

When a hobbing machine is in operation, the gear blank and hob revolve together, the ratio depending upon the number of teeth in the gear and the number of threads on the hob—that is, whether the hob has a single or a multiple thread. This rotation of the hob causes successive teeth to occupy positions corresponding to the teeth of a rack, assuming that the latter were in mesh with the revolving gear and moving tangentially. In conjunction with the rotary movement of the hob, the slide on which it is carried is given a feeding movement parallel to the axis of the gear blank. As this feeding movement continues across the gear blank (or blanks when several are cut together) all of the gear teeth are completely formed. In other words, hobbing is a continuous operation, since the teeth around the entire circumference of the gear are finished together (instead of one tooth being cut at a time) and ordinarily by one passage of the hob.

A front view of an Adams-Farwell gear hobber, built by the Adams Co., Dubuque, Iowa, is shown in Fig. 1. The slide carrying the hob-spindle feeds downward or vertically as on most gear-hobbing machines. As the illustration shows, the gear on this machine is about half finished. It is made of cast iron, has 90 teeth of 3 diametral pitch, and a 3¼-inch face width. A particularly smooth finish was obtained by using a feed of 0.050 inch per gear revolution, and a hob speed of 80 revolutions per minute. This gear was completed in one hour and twenty minutes.

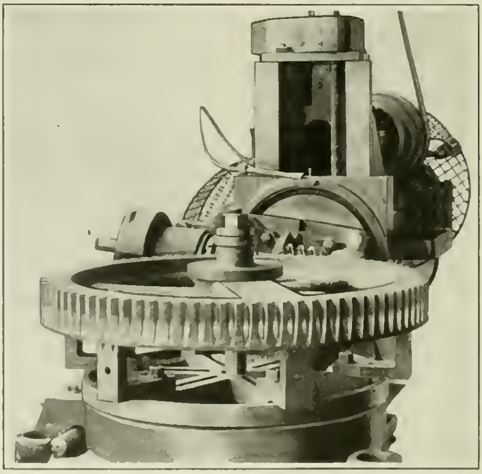

Fig. 1. Hobbing a 90-tooth Spur Gear of 3 Diametral Pitch

Another Adams-Farwell machine is shown in Fig. 2. In this instance five gears were clamped in a stack on the work-table, and were cut at one passage of the hob. This is common practice when the shape of the gear blanks will permit placing one on the other. The operation is roughing differential ring gears for a tractor. These gears have 100 teeth of 4 diametral pitch, and a 2¼-inch face width.

The hobbing machine or generator shown in Fig. 3 differs entirely in its design from the vertical-cutting type of machine. The head or slide which supports the hob is adjusted along the bed to suit the diameters of the gears to be cut, but remains in one position when the machine is in operation. The feeding movement is in a horizontal direction and is applied to the slide carrying the work. This illustration shows a 19-inch generator, made by the Lees-Bradner Co., Cleveland, Ohio, arranged for cutting tractor gears.

The gear-hobbing machine shown in Fig. 4 is so designed that the slide carrying the hob is mounted on the horizontal ways of the machine bed, and the horizontal work-spindle is supported by a slide adjustable along the vertical face of the column, to suit the diameter of the work. This machine is made by the Barber-Colman Co., Rockford, Ill., and in the illustration it is shown cutting a stack of six gears, having 37 teeth of 5–7 pitch.

The hobbing process is used extensively for cutting helical as well as spur gears, and its application to the former will be considered in a succeeding article. Hobbing machines are also used for cutting worm-gears and even for cutting worm threads.

Setting up Machine for Hobbing Spur Gears

While the exact method of adjusting or setting up a gear-hobbing machine varies somewhat with different designs and makes, there are certain general adjustments common to different machines.

No attempt will be made to cover the details of various designs, the idea being to deal with the more important general features.

In arranging a machine for cutting spur gears, there are several important adjustments to be made. The hob must be set to the correct angle, and an axial adjustment for centering a tooth relative to the gear blank may be considered desirable. The machine must be so geared that the hob and work revolve at the proper speed ratio. This is taken care of by means of change-gears.

The rate at which the hob feeds across the gear blank must be varied to suit the quality of finish required on the teeth and the cutting qualities of the material. Change-gears in some form, are also used for this purpose. This feeding movement, as previously mentioned, is parallel to the axis of the gear being cut, and the amount per revolution of the gear blank or work-table may vary from 0.015 to 0.030 inch on some jobs and from 0.100 to 0.200 on others.

The method of holding or chucking the gear blank (or blanks) is very important, and there are two essential points to consider: First, the blanks must be supported rigidly to prevent any decided springing action when the hob is at work; second, the gear blanks must be concentric with the axis of the work-spindle or table and not be sprung out of shape by clamping. It is well to test the concentricity of the blanks after they are placed on the machine and before cutting, by the use of a dial indicator.

The next step is to adjust the blank relative to the cutter, or vice versa, so that gear teeth of the correct depth will be cut. This may be done on most machines, by adjusting the cutter-slide until the hob is opposite the uncut blank; then the work-table is moved until the teeth of the hob, which should be revolving, just graze the blank. The hob is next moved far enough to clear the rim of the blank, and the work-slide is adjusted toward the hob an amount equal to the whole depth of the tooth. Gear hobbers have graduated dials on the feed-screws or special gaging devices to facilitate making these adjustments. When the hob is set for the depth of cut, as just described, the teeth should be correct provided the outside diameter of the gear blank is the right size.

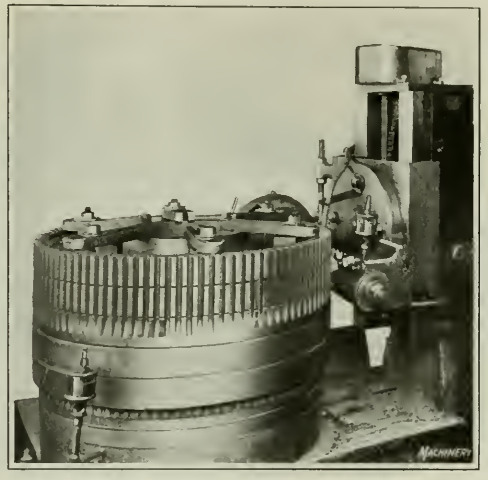

Fig. 2. Hobbing a Stack of Five Spur Gears

A reliable method of checking the accuracy of the teeth is to measure the chordal thickness, using a vernier gear tooth caliper. This chordal thickness should be checked just as soon as the hob has been fed into the gear blank far enough to produce completely formed teeth. Before the cut is started, the work-holding table or slide should be secured rigidly to the ways on which it is mounted, by means of clamping screws provided for this purpose.

The stop which serves either to automatically disengage the feed or stop the entire machine after the gear teeth are cut, is set before starting the machine, so that it will come into action after the center of the hob clears the edge of the gear blank. Spur gears are usually finished at one passage of the hob, although sometimes a roughing cut is taken with the hob set slightly less than full depth, and this is followed by a finishing cut in order to obtain greater refinement. According to one rule, two cuts should be taken when cutting gears of 3 diametral pitch and coarser, assuming that gears of the best grade are required. The important adjustments referred to briefly in the foregoing will now be dealt with more completely.

Determining Angular Position of Hob when Cutting Spur Gears

Although a hob must conform to the diametral pitch and pressure angle of the gear to be cut (the pitch being stamped on the hob), it is not necessary to consider the number of teeth in the gear, as when using formed cutters. In other words, a hob of given pitch is applicable to gears having any number of teeth, and this is also true of cutters used on any machine of the molding-generating type.

The angle at which the hob-spindle or swivel slide is set depends upon the lead of the hob thread and its diameter, since the object of inclining the hob is to bring the teeth on the cutting side into alignment with the axis of the gear blank. This angle is equal to the helix angle of the hob thread at the pitch line, measured from a plane perpendicular to the hob axis, and is often called the "end angle." To avoid the necessity of making calculations, this angle is usually stamped on the hob. If the angle is not known, its tangent may be determined simply by dividing the lead of the hob thread by the pitch circumference.

Gears may be cut with left-hand hobs, although hobs threaded right-hand are used ordinarily. The hob is inclined from the horizontal position in one direction when it is right-hand, and in the opposite direction when it is left-hand. The proper direction may be determined readily by simply considering which way it is necessary to turn the swivel slide, to bring the teeth on the cutting side parallel with the work-spindle.

Centering the Hob

In many shops it is the general practice to locate one tooth of the hob central in relation to the gear blank before setting the hob at the required angle; that is, the hob is adjusted in a lengthwise direction until the center of one tooth lies in the same plane as the axis of the gear blank. The object of centering a tooth is to avoid slight errors which are sometimes caused by using a hob that is not centered, and to insure that the teeth will be cut the full depth.

The effect of hob-centering was analyzed in an article by John Edgar, published in June, 1914, MACHINERY, page 862. It was pointed out that there are hob defects that cannot be compensated for by centering, such as distortion due to hardening and unequal tooth thickness due to springing of the tool when forming. The defect that centering favors is that of any slight eccentricity which causes the teeth to run out of true, as when the arbor is not concentric with the spindle; the inaccuracy resulting from the use of an untrue arbor when backing off the teeth may be another cause of eccentricity.

The three conditions considered included (1) a hob with the low tooth and high space centered; (2) a hob with the high tooth and low space centered; (3) a hob not centered but half way between the conditions represented by the two preceding cases. Mr. Edgar's general conclusions are as follows: With an unground hob in which the eccentricity is an unknown quantity, but may be taken as sure to be existent, it is well to center the high tooth; and with an accurate hob, such as would be obtained by an accurate method of grinding, it is unnecessary to center the hob, if the hob has been carefully sharpened and the hob arbor runs true on its axis.

According to Gould & Eberhardt, it is important to center a hob tooth when cutting gears having less than thirty teeth. The centering gage on the Gould & Eberhardt machines is permanently attached to the slide at the rear of the hob. The hob is adjusted until the gage, which may be moved forward by turning a small knurled knob, coincides with a tooth space on the rear side; then a tooth at the front side is in a central position, as the hobs have an even number of flutes. The hob is adjusted lengthwise for centering by loosening nuts on the spindle bearings, which permits adjusting the bearings in a lengthwise direction by means of a small screw. When a tooth space matches the gage, the spindle bearing bolts are tightened and the gage withdrawn.

According to the Newark Gear Cutting Machine Co., the subject of hob-centering may be summarized as follows:

1. For roughing operations, where the prime object is the removal of metal, without especial regard to the accuracy of the tooth contour, the centering of a hob tooth is not necessary.

2. The best gear shops today commonly use ground hobs for finishing the better grades of gears, so they are not concerned with the errors due to distortion in hardening. It is not possible to get the best production if the hob arbor runs out of true or if the hob has a high tooth, as either of these conditions causes a few teeth to do all the work, which makes them become dull very rapidly.

3. If hobs were made with a vast number of teeth, centering a tooth would be unnecessary. Since hobs are made with from about four to twenty flutes, or rows of cutting teeth, it will be seen that the gear tooth contour is composed of a large number of small flats produced by the hob teeth. To illustrate, if a gear tooth were found with a contour made up of only six flats which did not match each other on the two sides of the tooth, the tooth would be unsymmetrical. This would be an extreme case, as a gear tooth contour should be composed of from fourteen to twenty flats or more.

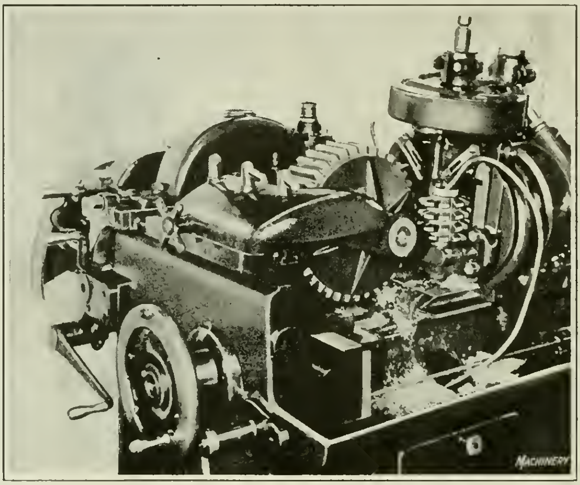

Fig. 3. Cutting Tractor Gears on Hobbing Machine having Horizontal Work-spindle

4. A hob should be centered when it is found that unsymmetrical gear teeth are being cut. If centering does not correct this fault, the trouble is in the hob teeth or the machine itself. To prevent unsymmetrical tooth contours, a hob tooth should be centered if the hob has less than twelve flutes, especially when hobbing gears of less than thirty teeth, for extra fine work, or eighteen teeth for ordinary work.

Adjustment of Hob to Distribute Wear

In order to distribute wear, it is good practice to set different teeth in the central position when resetting the hob. A hobbing machine has been designed to give the hob an axial movement in conjunction with the required feeding movement, the idea being to insure a more uniform distribution of wear. To compensate for this lengthwise motion of the hob, the rotary speed of the gear blank differs from the normal speed required when a hob remains in the same axial position. This change in the rotation of the work is just enough to compensate for the lengthwise motion of the hob. This refinement makes the machine more complicated, and such a design is not likely to supersede a simpler one, especially in view of the fact that wear on the hob teeth can be distributed satisfactorily if care is taken to set the hob each time so that different parts are in the cutting position.

Rotating Hob and Gear Blank at Correct Speed Ratio

When cutting spur gears with a single-threaded hob, which is the kind generally used, the number of revolutions made by the hob per revolution of the gear is equal to the number of teeth to be cut. For example, if a gear is to have forty teeth, the machine would be geared to revolve the hob forty times during one revolution of the gear or work-table. The combination of gears required for cutting any gear would ordinarily be determined simply by referring to a table or chart accompanying the machine.

When calculating these gears, it is necessary to consider the fact that in all gear-hobbing machines there are certain gears that form a permanent part of the machine and serve to transmit motion from the main driving shaft to the hob-spindle and to the work-table. Since the ratios of these permanent gears vary in machines of different makes, these ratios enter into change-gear calculations: In the equation given below, which may be used to calculate change-gears on machines of different makes, there is a constant or fixed value for each machine. These fixed numbers are based on the ratio of the permanent gearing in each machine, and serve to allow for this ratio. In the equation n equals the number of threads on hob (that is, n equals 1 for a single-threaded hob, 2 for a double-threaded hob, etc.), N equals number of teeth to be cut in gear, and the constants for different machines are: Adams-Farwell, 30; Barber-Colman, 30; Gould & Eberhardt, 60; Lees-Bradner, 24 on some machines, 32 on others; Newark Gear Cutting Machine Co., 16, except for special machines.

$$\frac{\text{Product of No. of Teeth in Driving Gears}}{\text{Product of No. of Teeth in Driven Gears}} = \frac{\text{Constant} \times n}{N}$$

To illustrate how change-gears are calculated, assume as an example that the gears to be hobbed have 45 teeth, a single-threaded hob is to be used, and the constant of the machine is 60.

Then

$$\frac{\text{Product of Driving Gears}}{\text{Product of Driven Gears}} = \frac{60 \times 1}{45} = \frac{5 \times 12}{5 \times 9}$$

The numbers in this expression are now raised to higher values by multiplying with trial numbers in the usual manner, thus obtaining larger numbers corresponding to the numbers of teeth in available change-gears. Thus,

$$\frac{5 \times 12}{5 \times 9} \quad \frac{(5 \times 16) \times (12 \times 5)}{(5 \times 16) \times (9 \times 5)} = \frac{80 \times 60}{80 \times 45}$$

The numbers above the line represent the driving gears which have 80 and 60 teeth, respectively, and the numbers below the line the driven gears, with 80 and 45 teeth, respectively. Of course there are other combinations that would give the same ratio, and it might be necessary to calculate them by selecting other trial numbers, assuming, for example, that it were not possible to find change-gears corresponding to one or more of the numbers obtained by the calculation.

Hobs Used for Spur Gears

Hobs for spur gears are made by cutter manufacturers for cutting gears of various diametral pitches, the pitch being stamped on the end of the hob. The normal pitch of the hob should be the same as the circular pitch of the gear. The "normal pitch" is the shortest distance from one thread to the next, the pitch being measured at right angles to the thread. If the pitch of the hob, as measured parallel to its axis, were made equal to the circular pitch of the gear, an error would be introduced owing to the fact that the hob must be inclined to locate it in the working position. However, the difference between the normal pitch and the pitch measured parallel with the axis may be so small as to be negligible when there is little inclination of the hob teeth relative to the axis.

While ordinary hobs must be inclined to align the teeth with the gear on the cutting side, some hobs are so made that they can be set at right angles to the axis of the gear. The included tooth angle on these hobs is reduced in order to obtain the effect of a rack-shaped cutter when the hob is in the right-angle position.

Using Multiple-threaded Hobs

While hobs that have a single thread or row of teeth are generally used for cutting spur gears, multiple-threaded hobs are sometimes employed. An example of spur gear cutting on a Lees-Bradner generator, equipped with a triple-threaded hob is shown in Fig. 5. The operation is that of cutting teeth on the rims of automobile flywheels. A number of these flywheels may be seen at the right-hand side of the illustration. There are 128 teeth of 8-10 pitch. The face width is 1 inch, and the rate of production 125 gears in nine hours, or nearly 14 per hour.

When using a multiple-threaded hob, it is necessary, of course, to change the ratio of the gearing controlling the relative speeds of the hob and the work, in proportion to the number of threads in the hob. For instance, when using the machine shown in Fig. 5, driving and driven change-gears of 3 to 4 ratio are used for a triple-threaded hob, whereas for a single-threaded hob the ratio is 1 to 4. In view of the fact that a single-threaded hob must revolve 128 times to one revolution of the gear for the particular operation referred to, whereas a triple-threaded hob revolves only one-third that number of times, it is evident that much greater production is obtained with multiple-threaded hobs, assuming that the same rate of feed is maintained.

To illustrate, suppose that a single-threaded hob is used for cutting a gear having 128 teeth; the hob diameter is 3 inches, and the speed 80 revolutions per minute, thus giving a cutting speed of about 63 feet per minute. Now, assuming that the feeding movement of the hob per revolution of the gear is 0.160 inch, and that the hob has to travel 2 inches for cutting the teeth, then the gear will make 12.5 revolutions while the teeth are being milled ($2 \div 0.160 = 12.5$), and the total number of hob revolutions will equal $12.5 \times 128 = 1600$, since the hob makes 128 revolutions to one of the gear. Hence, the actual cutting time will equal $1600 \div 80 = 20$ minutes when using a single-threaded hob.

Now suppose that the same gear is cut with a triple-threaded hob having the same diameter as in the preceding case and that the same cutting speed and feed per revolution of the gear are employed. Since the triple-threaded hob makes 42 2/3 revolutions to one of the gear, the total number of hob revolutions during 12.5 revolutions of the gear will equal $42\ 2/3 \times 12\frac{1}{2} = 533\ 1/3$. Therefore, the cutting time equals $533\ 1/3 \div 80 = 6\ 2/3$ minutes, or one-third of the time required when using a single-threaded hob for the same work.

Notwithstanding the relatively high production obtained with multiple-threaded hobs, the single-threaded type is preferable for hobbing spur gears, as a general rule, because it generates more accurate teeth. This is due to the fact that a multiple-threaded hob has a larger helix angle than one with a single thread, unless the diameter of the multiple-threaded hob is increased in proportion to the number of threads. Because of this difference in the angle of the helix along which the teeth are located, the cutting action and the form produced are different, assuming that the teeth are the straight-sided rack-shaped form commonly used. The general practice of the Lees-Bradner Co. is to use triple-threaded hobs for cutting cast-iron gears, which need not be very accurate. The use of the multiple-threaded hob for cutting steel gears is usually limited to the double-threaded form, and this is only applied to work that does not require the same degree of accuracy that is possible with a single-threaded hob.

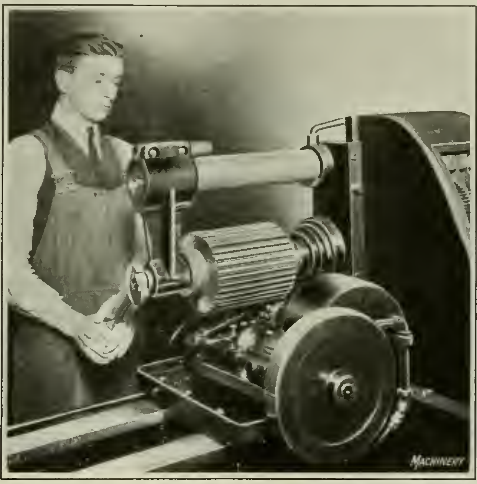

Fig. 4. Another Horizontal Type of Hobbing Machine

It has been shown that a multiple-threaded hob of given size will reduce the actual cutting time in direct proportion to its number of threads, as compared with a single-threaded hob of the same size rotating at equal speed and having an equal amount of feed per gear revolution. The metal is removed at a faster rate by the multiple-threaded hob, because it has, in effect, two or more tools or hob threads working instead of one. Now each tooth of a multiple-threaded hob has to remove more metal per hob revolution than a single-threaded hob, unless the hob diameter and number of flutes are increased in proportion to the number of threads on the hob. This is due to the fact that a single-threaded hob, because of its smaller helix angle, has more turns or thread convolutions, and, consequently, more teeth in contact with the gear being cut or a larger number of cutting edges working constantly, than a multiple-threaded hob of the same size. This point is brought out in connection with the following comment on the use of multiple-threaded hobs by Fred Ross Eberhardt, of the Newark Gear Cutting Machine Co., Newark, N. J.

When using a hob, the amount of feed possible per revolution of the work depends upon (1) the hardness of the material; (2) the revolutions per minute of the hob; (3) the degree of finish desired. The number of revolutions per minute of the hob depends upon the hardness of the material and the feed, which, to be exact, means the thickness of chip for each hob tooth actually working. With a certain hardness of material and a finish requirement permitting only 0.125 inch feed per revolution of the work, the following examples will be considered:

A gear having 90 teeth of 12 diametral pitch and a pressure angle of 14½ degrees was cut with a single-threaded hob, 2¾ inches outside diameter, having 14 flutes. The hob speed was 100 revolutions per minute, and the feed 0.125 inch per gear revolution. In this instance, about four convolutions of the hob teeth were cutting, and each tooth of the hob removed about 0.002 inch of metal per hob revolution. The finish requirements would not permit a greater feed. If the hob were run at a higher speed (revolutions per minute) it would have dulled too quickly. The limit of production, therefore, seems to have been reached with this hob.

With all other conditions the same as in the preceding example, but using a triple-threaded hob, only about one and one-third convolutions of the hob teeth were cutting in each tooth space. Therefore, each hob tooth removed about 0.006 inch of metal per hob revolution. The feed per revolution of the work remaining the same, this triple-threaded hob would leave feed marks of the same appearance as the single-threaded hob previously referred to, but the cutting time would be one-third that of the single-threaded hob.

While these are actual examples of work done in the Newark Gear Cutting Machine Co.'s shop, there might be different cases. Each tooth of a multiple-threaded hob does so much more work than each tooth of a single-threaded hob of the same diameter, using the same feed, that the hardness of the material might necessitate reducing the feed per revolution of the work to reduce the chip thickness per hob tooth; however, according to the experience of the company just referred to it is seldom possible to feed single-threaded hobs as much as the teeth will stand, because such coarse feeds would cause unsightly feed marks. As the appearance of the cut usually determines the maximum feed, the use of a multiple-threaded hob makes it possible for each hob tooth to take as large a chip as it can efficiently. It is assumed that the hob has a sufficient number of flutes to give the required generating action. Another point worthy of consideration is that when the number of teeth to be cut is prime to the number of hob threads, the generating flats are the same as for a single-threaded hob of the same diameter, although usually the flats are not noticeable.

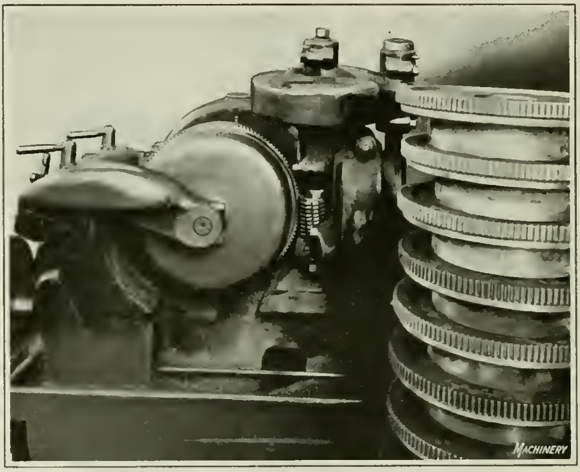

Fig. 5. Cutting Spur Gears with a Multiple-threaded Hob

Hobbing Pinions Having a Small Number of Teeth

Sometimes it is desirable to use pinions having a very small number of teeth in order to obtain a certain velocity ratio and at the same time a relatively small center distance between pinion and gear. When an ordinary pinion is used (having a pressure angle of 14½ degrees) 12 teeth is generally considered the minimum number. Even with a pinion of this size, the flanks of the teeth must be under-cut somewhat to avoid interference, provided the mating gear has more than twelve teeth, and this interference and the need for under-cutting increases if the pinion is to run with larger gears.

A method of improving the shape of the pinion tooth that has long been employed consists in enlarging the pinion blank and reducing the gear blank a corresponding amount. Another method is to increase the pressure angle of the gearing, and a third method consists in modifying both the pressure angle and the blank diameters in order to obtain a tooth shape giving the best results.

Enlarging the pinion blank and decreasing the gear blank a corresponding amount is applied not only to spur gears but also to bevel gears, worm-gearing and herringbone gears. When cutting an enlarged pinion or a reduced gear (whether by hobbing or on a generating shaper or planer) the procedure is the same as when cutting standard gear teeth, and any generating type of machine may be used. The teeth are cut to the full depth on both pinion and gear, and in the usual manner, but if the position of the cutter relative to the gear blank is checked by measuring the tooth thickness, then the change in the height of the pinion and gear addendum must be taken into account, the tooth thickness being measured where the pitch circle crosses the tooth in each case.

For instance, when using a gear tooth caliper for measuring the tooth thickness of the pinion at the pitch line, it must be set with reference to the long addendum. This tooth thickness will exceed one-half the circular pitch, because the same number of teeth have been formed on a blank of larger circumference than standard for that pitch. On the contrary, when measuring the mating gear, the caliper should be set with reference to the short addendum to check the thickness at the pitch line, and the gear teeth are thinner than one-half the circular pitch, because the blank diameter has been decreased.

On account of these changes, the formulas used for determining the chordal thickness and corrected addendum of standard spur gears must be modified. When the blank diameter is changed, the following formulas may be used, in which T = chordal thickness at pitch circle; D = pitch diameter; X = circular thickness of tooth on pitch circle; R = pitch radius; and H = height of tooth arc or amount to add to long or short addendum to obtain corrected addendum.

$$T = D \times \sin \frac{90\,X}{R \times 3.1416}$$

$$H = R\left(1 - \cos \frac{90\,X}{R \times 3.1416}\right)$$

To obtain the value of X, first find the difference between the normal and the modified addenda and multiply this difference by the tangent of the pressure angle of the gear. For a pinion *add* twice this product to one-half the circular pitch to find the value of X; for a gear, *subtract* twice the product instead of adding.

When the pinion blank is enlarged and the gear blank reduced, as described, without changing the pressure angle, the practical effect is to move the pinion teeth outward radially and the gear teeth inward a corresponding amount relative to the pitch circles as well as to the base circles from which the tooth curves are derived. In order to understand why the shape of the pinion teeth is improved by enlarging the blank, it must be remembered that the base circle of the pinion is much closer to the pitch circle than the base circle of a comparatively large gear. This is due to the fact that the diameters of the base circles for the gear and pinion must be in the same ratio as the diameters of the pitch circles or as the numbers of teeth. For instance, if the gear is four times as large as the pinion, the base circle of the gear must also be four times as large as that of the pinion, and the pinion base circle will be proportionately closer to its pitch circle.

In this connection it is important to note that an involute curve cannot extend below the base circle from which it is derived. Now, unless prevented in some way, the part of the tooth below the base circle of a small pinion of standard proportions will be under-cut if generated in the usual manner, thus showing that the teeth of a gear, and especially the teeth of a straight-sided involute rack, would interfere unless this under-cutting had taken place. This explains why standard 14½-degree pinions in small sizes are not recommended.

When the pinion blank is enlarged, as described, the base circle diameters remain the same and the pitch circle and base circle of the pinion cross the tooth near the root; consequently, the involute curve extends over a larger part of the tooth since the latter has been moved outward, thus increasing the amount extending beyond the base circle. As the length of the involute is increased, that part below the base circle where under-cutting occurs, is correspondingly decreased. It should be remembered, however, that this improvement in the shape of the pinion tooth is at the expense of the gear tooth, which is moved inward relative to its pitch circle and base circle. The extent to which the shape of the gear teeth is sacrificed decreases as the size of the gear increases and is considered negligible for gears having, say, 40 teeth or more.

Changing the blank diameters as described does not affect the velocity ratio of the gearing, since this depends upon the relative diameters of the pitch circles, or the number of teeth in the gear and pinion. The center distance also remains the same, provided the gear is reduced an amount equal to the pinion enlargement. An enlarged pinion does not necessarily have to be used with a gear of reduced size, as it will mesh with any gear in an interchangeable series, but if the mating gear is standard, the center distance will be increased an amount equal to one-half the increase in the pinion blank diameter.

Determining Diameter of Enlarged Pinion Blank

When a pinion blank is enlarged to avoid under-cutting, the increase of diameter may be determined by the following formula, in which O = outside diameter of blank; B = pressure angle; D = pitch diameter; and W = working depth.

$$O = \cos^2 BD + 2W$$

To maintain the same center distance between the gear and the pinion, the gear is reduced by the same amount that the pinion blank is increased.

HOSPITAL FOR INDUSTRIAL INJURIES

The first hospital intended specifically for industrial workers who have been injured in the course of their employment, is the Reconstruction Hospital at 100th St. and Central Park West, New York City. Here patients have been treated from every industrial state east of the Mississippi, and a new eleven-story addition is now under way, to provide room for additional patients who have been injured or contracted diseases as a direct result of their industrial employment. The aim of those in charge of the Reconstruction Hospital is to make it an institution upon which hospitals all over the country can be modeled, and to give instruction to medical students and post-graduates in the modern science of industrial medicine and surgery, as well as to train nurses in industrial plants.

CHECKING DIAMETER OF TAPER PLUG GAGE

By W. G. HOLMES

In checking the diameter at the small end of a taper plug gage, the gage is first mounted on a sine-bar as indicated in Fig. 1 so that the top of the gage is parallel with the surface plate. A disk of known radius r is then placed in the corner formed by the end of the plug gage and the top side of the sine-bar. Now by determining the difference in height between the top of the gage and the top edge of the disk, the accuracy of the diameter B can be readily checked.

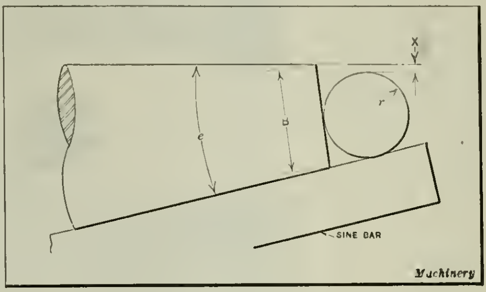

Fig. 1. Gage in Position for checking Diameter B

The known dimensions are:

e = angle of taper;

r = radius of disk; and

B = required diameter at end of plug gage.

With the dimensions given, it is required to find the difference X between the height of the top of the gage and the upper edge of the disk. Referring to Fig. 2 we have,

$$g = 90 \text{ degrees} - \tfrac{1}{2} e \quad \text{and} \quad k = \tfrac{1}{2} g$$

By trigonometry,

$$F = \frac{r}{\tan k}; \; E = B - F; \text{ and } \tan m = \frac{r}{E}$$

Also

$$P = \frac{r}{\sin m}; \; n = g - m; \text{ and } H = P \sin n$$

Therefore, $X = H - r$ or $r - H$, depending on whether or not the top edge of the disk is above or below the top of

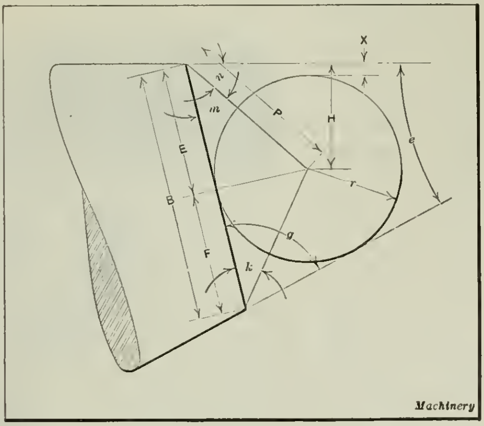

Fig. 2. Diagram used in calculating Dimension X

the plug gage. In the illustration the top of the disk is below the top surface of the plug gage so that it is evident that $X = H - r$.

Sine-bar Fixture for Accurately Checking Thread Angles

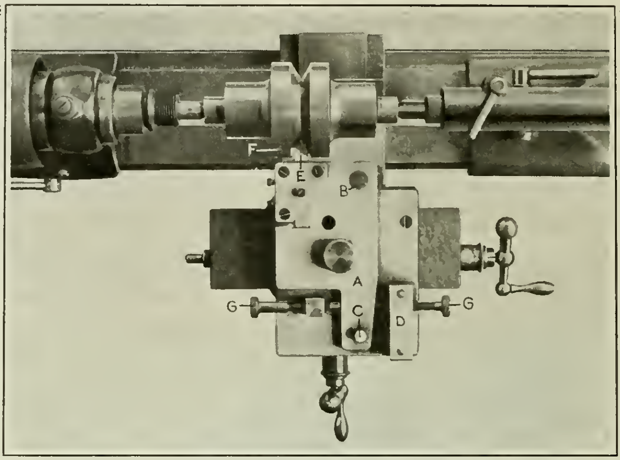

Fig. 1. Adjusting Sine-bar Fixture by Means of a Master Plug

In making screw thread plug gages, hobs, taps, etc., the thread or tooth angles may be tested by means of the sine-bar fixture described in the following. This fixture is simple in design, but very accurate as a means of checking angles, and is used by the Pratt & Whitney Co. whenever such a test is required in connection with work of the classes referred to. The fixture is used in conjunction with a bench lathe. It is held on the tool-slide, and the gage or other piece to be tested is placed between the lathe centers. If the angle is not standard, the error may be readily determined.

This fixture has a plate *A*, Fig. 1, which is free to swivel about pivot *B*. This plate, which is used like a sine bar, has a projecting plug at *C*, opposite block *D*, from which measurements are taken with an ordinary micrometer. A gaging or contact point *E*, having an accurately ground V-shaped end, is secured to the sine-bar plate by the set-screw and holder shown. Before using the fixture, one side of this V-shaped end is set in alignment with the conical surface of master gage *F*, which has the standard angle required. In making this adjustment, screws *G* are used for shifting the sine-bar plate as required.

The master gage is next replaced by whatever gage, hob, or tap is to be tested. When the V-shaped gaging point *E* is brought into contact with the side of the thread or tooth, even a slight lack of alignment may be detected without the aid of a magnifying glass. Assuming that there is an error in the angle, a measurement is first taken, in the manner illustrated in Fig. 2; the sine-bar plate is then adjusted as shown in Fig. 3 until the gaging point is in perfect contact, as nearly as can be observed. The magnitude of the error is indicated by the difference between these two micrometer readings. The length of the sine bar or the distance between the centers of pivot *B* and plug *C* is such that a difference of 0.0001 inch in the micrometer readings is equivalent to an angular error of 5 seconds. This general rule, which makes it very convenient to determine errors without calculation, is accurate enough for practical purposes unless the errors are larger than those ordinarily encountered. If the bar were moved more than, say, 2 degrees, because of angular error, it would be advisable to calculate the error instead of using the rule referred to.

There are two general methods of using this fixture. One is to test one side of a thread at a time, the work being reversed between the centers for testing the opposite side. The other method is to test both sides at the same time by adjusting the V-shaped point until it makes contact with both sides instead of one side only. The second method is sufficiently accurate for most work, because the V-shaped points are carefully ground to standard angles, and they have clearance like a thread tool, so that the lines of contact are along the upper edges only.

Accuracy of Readings Obtained with the Sine-bar Fixture

It might be supposed that accurate results would be impossible with this fixture, inasmuch as its use depends entirely on the alignment of the V-shaped point, which, in turn, is a matter of judgment and vision. In this connection it is interesting to know that three men not particularly skilled in using such a device, each tested a thread of ⅛-inch pitch, and all came within 10 seconds of the same reading. A fourth man varied by 20 seconds. A skilled inspector is able to repeat readings within 5 seconds on plugs having eight threads per inch, and within 15 seconds when the threads are as fine as twenty per inch.

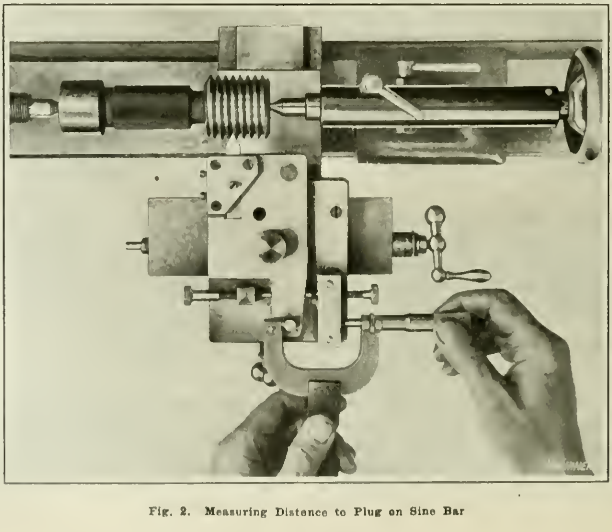

Fig. 2. Measuring Distance to Plug on Sine Bar

EQUIPMENT OF UNIVERSITY SHOPS

By WARREN ICHLER

The aim of any technical school is to furnish the broadest possible instruction along engineering lines. In spite of this, however, we find numbers of universities and technical schools equipped with, say, fifteen or twenty engine lathes of one make which are all exactly alike; two or three milling machines from one manufacturer that differ in general features only in that some are plain millers and some universal machines, and so on down through the list, except, of course, for the more bulky and special machines where one unit is sufficient for instruction purposes and where, perforce, there can be no duplication.

Possibly a laudable desire for standardization—that is, laudable in nearly every business except that of instructing engineering students—has led to this standardization of equipment, but it will be plain to anyone familiar with machinery that any school shop so equipped can give only limited instruction in the use and care of machine tools. Lest this be considered as merely destructive criticism, the writer ventures a few suggestions as to how he endeavored to broaden his courses while a machine shop instructor at a state university.

The first and most important step toward overcoming the disadvantages of a limited tool equipment was taken when inspection trips to nearby shops and factories were substituted for one shop or laboratory instruction period each month. Instead of making these trips general in their nature, an effort was made to confine the inspection to one particular machine or class of machine. For example, one trip to a large shop was made to study vertical boring mills since the vertical boring mill was not included in the university's equipment. Of course, this method of instruction is as old as the teaching profession, but too much emphasis cannot be laid upon it, as the students see work being performed under actual manufacturing conditions.

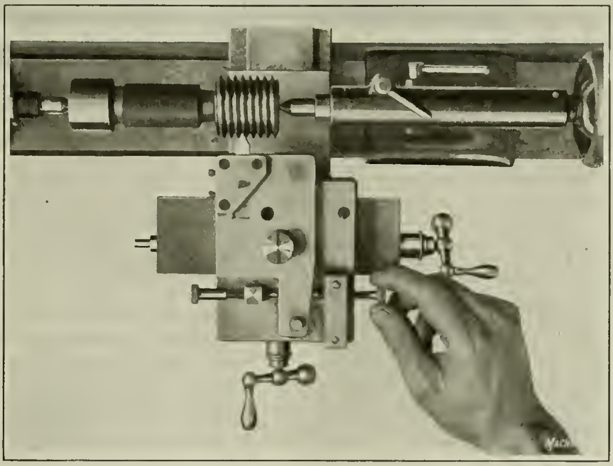

Fig. 3. Adjusting Sine Bar to align V-shaped Point with Gage Thread

Use of Pictures for Instruction Purposes

A second method of supplementing the regular university course was by the use of pictures of machine tools, and in this connection the writer would mention that the machine tool industry in general responded generously to requests for such pictures. Many instructors spend hours in producing fine blackboard lay-outs of novel or special machines, but it is a question whether these have any more value for instruction purposes than a large well posed picture of the same tool would have.

When not in use for instruction purposes the pictures of machine tools were employed to transform the shop into what may be termed a machinists' art gallery. This was valuable in making what would otherwise have been rather dingy surroundings more attractive. Catalogues, and descriptive matter were secured along with the pictures, and brought to the attention of the students, and finally a quiz on each particular machine that had been made the subject of a lecture was held. One gratifying result of such instruction was the fact that students were often able to explain, while on inspection trips, many novel features in machines that puzzled the mechanics operating the machines.

School Equipment Used for Actual Manufacturing

A third measure for broadening the course was the somewhat radical innovation of inviting the owners of certain small garages and machine shops to send to the university shop such work as could not be handled on their equipment, but was still within the capabilities of the university shop. It must be understood that this work was performed by the mechanics of the shop sending the work, and was paid for on a basis of hourly rental for machines and power, so that in no sense were the students used on contract labor, and the hourly rental basis was fixed at a figure that was attractive to the average manufacturer. In this way, students became familiar with the methods of setting up for more intricate work than that of their regular course and were able to see the little indefinable distinctions that differentiate the work of the skilled mechanic from that of the student. Of course, the methods of the skilled mechanic were studied on inspection trips as well, but of necessity, under less favorable conditions than in the school shops. The school was thus made of real benefit to the community and the money realized from the rental of its machines was available for new equipment. Another plan that was employed was that of asking certain large manufacturers to lend the services of their salesmen or service men for short talks to the classes.

The writer has noted one exception to the usual method of equipping an engineering school shop. In this school which is located in the Middle West, one can search the machine shop through and through without finding two machines that are duplicates of each other. This shop was fortunate in having for its founder a man of wide practical experience, as well as thorough technical training. In a conversation with the writer this man remarked: "Standardization is yet in its infancy, and the boys we are training will not be likely to secure employment in factories standardized as they should be, so why try to surround them with ideal conditions in that respect? Furthermore, no two students are reached by the same methods in the class or shop. We have built up quite a little healthy rivalry with our varied equipment by reason of this principle. That boy over there running that lathe is quite convinced that his is a better machine than the lathe next to it on which his chum is working, because his lathe has a little handier quick-change-gear mechanism than that provided on the other machine. Conversely, the boy on the other lathe is firmly convinced that he can secure a finer finish on his work, and at higher speeds, than his chum because the bed of his lathe is braced differently from that of the other machine and is a little deeper. Just as long as manufacturers strive to outdo each other in producing machines of the highest development, just so long should we strive to bring before engineering students, everywhere, the results of the manufacturers' experiments and experience."

Planning in Large Contract Plants

Problems Relative to the Installation of Planning Departments

By GEORGE H. SHEPARD, Professor of Industrial Engineering and Management, Purdue University

EFFICIENT planning means not only the giving of instructions for performing work in the most economical manner, but also the scheduling of the various jobs to insure their completion on the desired dates. In the machine shop using the cards and records shown in the previous article on this subject, which appeared in March MACHINERY, the percentage of jobs completed on time increased greatly immediately after the installation of the planning system. The chart in Fig. 1 illustrates diagrammatically the results obtained in this shop during a period of over six months. At the time the system was installed, only about 45 per cent of the jobs were completed according to schedule. The percentage line gradually rises until it reaches the 100 line one month from the installation date. From then on, the percentage of jobs completed on time is never less than 89.

In connection with planning, it may be found that some jobs run in a sufficient volume to warrant their segregation and a standardized manufacture. Such jobs should be placed on a manufacturing basis as soon as possible.

Personnel of a Planning Department

In building up a planning organization, care must be taken to select a competent personnel. This is especially important in contract or jobbing shops, because the continual variation in the work handled makes it necessary to rely on the skill and good judgment of the planners. Hence, only skilled mechanics with a good local knowledge of the shop should be employed. Planners should have an opportunity to advance. The departmental chief planner should have a foreman's rank, and the nature of his job makes him, provided he has executive ability, the logical understudy and prospective successor to the general foreman.

Some executives think that the work of the planning office is an addition to that of the shop and that the employment of mechanics as planners results in a corresponding reduction in productive capacity. But this is not the case. The purpose of a planning department is to increase production. Whether there is a planning department or not, it is necessary to determine the priority of jobs, to see that preparations are made for the work, to combine different jobs in order to obtain the most efficient use of machine set-ups, and to record the progress and completion of jobs. These things can be done more effectively by fewer persons in an office with a specialized organization and records, where there is an opportunity to develop special skill, than on the shop floor in the midst of the distractions of manufacturing. Shop men who are employed in the planning department, no matter how skilled they may be as mechanics, must be trained for the work and be guided until they have acquired the special skill necessary for planning.

Functionalizing Planning and Dispatching

Functionalizing planning and dispatching along the general lines of methods, materials, and progress, has been found advantageous. Another common method is to assign separate sections of a planning office to different work, such as customers' orders, stock, plant maintenance, repair, etc. The method followed must, of course, depend largely on local conditions, but the experience of the writer has been that functionalizing by methods, materials, and progress is preferable for the following reasons: (1) This is a definite classification of specially skilled men who can be used on any job on which their services would be of value. (2) Planners develop higher skill by specializing along these lines than they otherwise would, and a smaller personnel is capable of doing the work. (3) Better coordination of the work as a whole is obtained when all the jobs are handled by the personnel along the special lines outlined, than when the various jobs are handled independently by different people.

When planning and dispatching are first started, a daily priority list may be the only dated schedule for the guidance of the shop, but as the application of these principles proceeds, the amount of scheduled work increases rapidly. For example, soon after a planning organization is functioning, it may be necessary to repair part of the shop equipment. The method man of the planning office foresees the necessity of having this equipment ready for use on some order. The completion date of this order on the priority list establishes the date when the equipment will be needed and therefore determines the completion date for the repairs. Again, as planning and dispatching are installed in the stores department, the planning office begins to issue requisitions for the manufacture of stock parts with completion dates based on the date when the parts will be needed to keep the stock from falling below the minimum limit. In such ways as these the majority of the job orders will gradually come to have completion dates. In contract or jobbing plants usually from 70 to 75 per cent of the job orders finally are scheduled in this way.

Need for Filler Orders

The remaining 25 or 30 per cent of job orders have no definite priority, and this is of considerable advantage. Under contract or jobbing conditions it is impossible for a planning department to see ahead far enough always to provide a definite job for every machine or group of men. In order that supervisors on the shop floor may be able to fill such gaps, it is necessary for them to have some filler work, which can be run to suit conditions; jobs without a definite priority meet this need. A certain amount of filler work should be provided also to stabilize the load on the shops, so as to keep them busy when customers' orders are unavailable.

One means of providing filler work is to manufacture parts for stock when there is a large enough demand to warrant this. In such cases the overhead costs to be distributed over the parts, the cost of carrying the parts in stock, and the comparative cost of shop manufacture relative to tne market price of the article should be carefully considered. Parts for which there is a large and steady demand and which can be made profitably, instead of providing filler work, are suitable for production by manufacturing methods. Some stock orders, also, require a too definite and immediate completion date to allow them to be run as fillers.

Notwithstanding these facts, the manufacture of stock parts is the source of the largest volume of filler work in contract plants. Another convenient source of filler work is the maintenance of shop equipment. This should properly be the responsibility of a separate department, specially organized for the purpose, but the variety of such work in a contract plant makes the expense of a completely equipped maintenance department prohibitive. In order to use plant maintenance jobs as filler work, ample notice must be given of the needed repairs. This requires the installation of a system of constant and thorough inspection of equipment, which will make the need for repairs apparent well in advance of the time when immediate repairs are necessary.

Centralization and Decentralization of Planning

The question of centralization and decentralization comes up continually in the installation of planning systems. A correct balance must be maintained between the two if the work of the planning department is to be successful. While it has been found desirable to install a central planning office to deal with the plant as a whole, it has been found equally desirable to leave the details of departmental planning to the departmental offices. The function of the central planning office should be to make the first analysis of orders, determine in general the methods to be followed in filling the orders, decide what materials are to be used, order the stores department to provide and reserve these materials, place in general terms the orders on the shops for the work to be done, determine the final delivery date of a job and the completion date for every shop on all but filler work, follow up the progress of work from shop to shop, and settle questions of conflicting priorities referred to it by the shop or departmental planning offices.

Extent of Decentralization

A point requiring attention in the installation of a departmental planning office is the relation between the general foreman and the departmental chief planner. The former is likely to think that the latter is placed over him and to resent the whole planning scheme, considering it an attempt to undermine his authority. It should be made plain, therefore, at the beginning of a planning installation that the departmental chief planner is a subordinate of the general foreman and that his duty is simply to relieve the general foreman of details, in the same way that the other foremen do. The responsibility for meeting completion dates rests on the general foreman, and he has the authority to give the departmental chief planner whatever orders his judgment dictates. In fact, the general foreman and the chief planner should meet every day for that purpose.

After a departmental planning office has been installed, it is sometimes necessary to decentralize further by installing a sub-departmental office in some section. This second sub-division is likely to be needed in connection with a service section. For example, the tool section of a certain machine shop worked largely on orders from other sections of the shop. It was found impossible for the departmental planning office to foresee much of this work in connection with its analysis of orders, and so this section was finally given a small sub-planning office of its own. The foremen of other sections sent their orders directly to the tool foreman by means of the inter-shop order, described in the March article. These orders were handled by the tool foreman and his planning office without reference to higher authorities, except in case of conflicting priorities and similar questions.

One of the problems of a contract plant, as compared with a manufacturing plant, is the difficulty of assembling data into general summaries, which will give those in control an idea of the relative amount of work in the different departments, and other conditions. It is common for a jobbing plant to pass quickly from a greatly overloaded to an underloaded condition, notwithstanding the fact that the plant has plenty of filler work. This is due to a lack of planning. Some preparation is always necessary for filler work, and if the falling off in customers' orders is not foreseen, the plant will be without this class of work or will be unprepared to take up filler work. One of the main values of a daily prior-

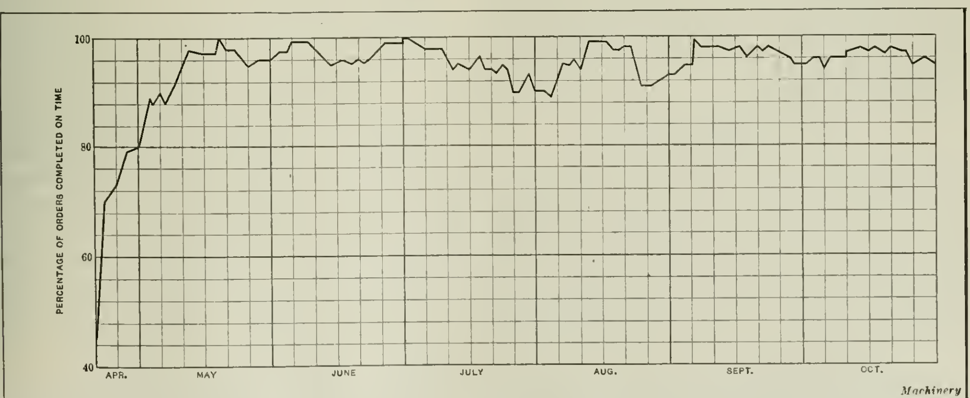

Fig. 1. Graphic Representation of Results obtained by the Installation of a Planning Department in a Contract Machine Shop

ity list is that its regular consideration can hardly fail to bring to the attention of the chief officers of the plant a prospective falling off in the amount of work on the main orders. Besides this, continual attention by planners and shop foremen to schedules and progress of jobs will cause them to notice a prospective falling off in the amount of work and indicate the necessity of looking for filler work and of preparing for it.

A good cost accounting system and frequent balance sheets are particularly necessary in a contract shop so that estimates and bids can be compared with actual costs. The industrial engineer should be continually on the watch for chances to install periodic summaries which will show to the officials the general tendency of matters under their control. Local conditions cause this matter to vary so much that it is useless to go into details; however, as an example, a summarized graphic record of tool loss and damage per man per day in a certain shop is shown in Fig. 2. As soon as general tool-room practice and records had been improved to the point where it became possible to obtain summarized records with substantial accuracy, this monthly summary was made. In the illustration, line *A* indicates the cost of wear; line *B* the cost of tools damaged; line *C*, the sum of the costs of tools worn and damaged; and line *D*, the average total cost. The results for the first three months showed the loss and damage to be going up at an alarming rate. Every month the summary was reported to the works manager, and every foreman concerned was informed of the loss and damage chargeable to his section. Beginning with the fourth month a gratifying reduction in waste was shown.

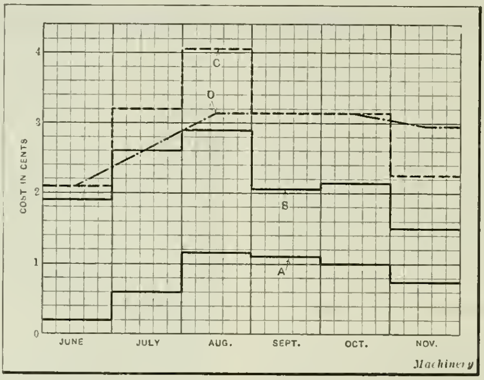

Fig. 2. Monthly Record showing Average Daily Cost of Tool Wear and Damage per Man

If teamwork is to be obtained under the unstandardizable conditions of a contract plant, all means of communication and transportation must be made as convenient as possible. The principal means of communication are the plant mail and the telephone. The former is generally used effectively, but often there is not an equal appreciation of the latter. Every plant official down to, and including the grade of foreman, and in special cases, the assistant foreman, should have a desk telephone. A planning office of any size should have several, and every shop shipping and receiving clerk should have one. These telephones should be connected to a private exchange, and the service should be the best obtainable. Anyone who has experienced the convenience of automatic service in private exchanges will prefer it to a manual exchange on account of the delays and errors customary with the latter system.

Transportation within the Plant

Transportation can be divided into two distinct classes inter-shop and intra-shop. In a large plant inter-shop transportation should be controlled by a separate department, under its own head, who should report directly to the works manager. The work of this department should be planned and dispatched in detail by its own departmental office. The question of equipment for transportation is important. For intra-shop transportation, the overhead traveling crane is in general use for heavy articles, and the elevating truck (propelled by storage batteries for long hauls) for light loads. For inter-shop transportation, the equipment should consist of a standard gage plant railway, locomotive traveling cranes, and automobile trucks. The latter should be provided with various auxiliary devices for hoisting and quick loading and unloading. During the last few years there has been a great development of conveyors; for the contract plant, the small portable types are the most promising. There seem to be considerable possibilities for effecting economy in the handling of materials by the judicious use of conveyor equipment.

Problems Connected with Transportation

Closely connected with transportation are the problems of locating responsibility for parts during their movement, of preserving their identity, and of securing a proper sorting of materials for convenient handling in the receiving shop. The plant delivery tag for inter-shop movement and the route tag for intra-shop movement are the means of locating responsibility and preserving identity. These tags were discussed in the article previously referred to. Preserving the identity of parts is no small problem when you have in process of manufacture, for example, hundreds of small valves, which are too nearly alike to be identified by casual inspection, but which are not interchangeable. The greatest trouble experienced in the use of tags is that they are likely to become detached.

This is especially true with castings and forgings, and for such parts, a satisfactory solution is to have an identifying symbol painted in black or colored shellac on each part by the shop which produces it. This method could not be followed, of course, if the parts were to be annealed. In such cases identification tags should be provided for all articles, all tags should be removed and kept during the annealing process, all work should be looked over just prior to being placed in the annealing oven, all articles should be re-identified after being annealed and, finally, all tags should be correctly re-affixed immediately after annealing. It is sometimes necessary to have special memoranda or sketches on the tags to insure correct identification. The work outlined may seem considerable, but anyone who has experienced the troubles incident to the loss of identity of steel castings, for example, in and after annealing, in a plant handling large numbers of such parts, will realize that the care necessary to prevent occurrences of this kind is the lesser by far of the two evils.

Storage of Equipment and Large Numbers of Parts

The delivering shop should be responsible for sending its product out properly sorted. If the shop is insufficiently supplied with containers, its shipping force will put the product into the containers on hand, which will result in mixing the orders and will cause confusion in the receiving shop. In order to insure a sufficient supply of containers, there should be a central place for their storage, manufacture, and repair. Then the general foremen may send to the central point all skids for elevating trucks, containers, and tote boxes for which there is no immediate use. This equipment can be looked over, repaired if necessary, inventoried, and stored. When the general foremen need these articles again, they can obtain them through a requisition on the central storage department. The storekeeper of the central storage department should be responsible for keeping a sufficient stock of skids, containers and tote boxes on hand to meet any demand that might arise.

Closely connected with the preservation of identity of parts and the placing of responsibility for them, is the problem of assembling and storing large numbers of parts, such as are often needed for construction or repair jobs. Failure to solve this problem is serious, because parts are likely to be lost, and even if they are only mislaid temporarily, considerable delay and expense result. On some large jobs, which were expected to require months of work, so that parts would need to be stored for a long time, it proved desirable to establish a complete storehouse with its own force of storekeepers, to receive and store such parts, and to issue them correctly on requisition as needed. The parts were sent to this storehouse at all stages of manufacture, whenever they were not actually being worked on in the shops.

Other troubles are those due to partial deliveries. For example, when a foundry delivers directly to a machine shop, it is almost impossible to keep up such a steady flow of castings that work in the machine shop will not be interrupted. The machines must then either stand idle, or their set-ups must be broken down and later remade. The use of a store-room enables the machine shop to accumulate castings, until it can start an order with a reasonable assurance that there will be a sufficient supply of work to insure that the operation will be continuous, thus eliminating costly delays.

Attention to the progress of jobs through the plant results in cleaning up dead jobs, in preventing their occurrence, and in improving the appearance of the shop. It is common to find a shop with a large accumulation of junk, a great number of dead orders, and tools stored at random. In one instance a clean-up revealed several tons of old tools, the purpose of which in many cases was unknown. In another instance, carloads of valuable scrap metal were unearthed and immediately sold at a good price.

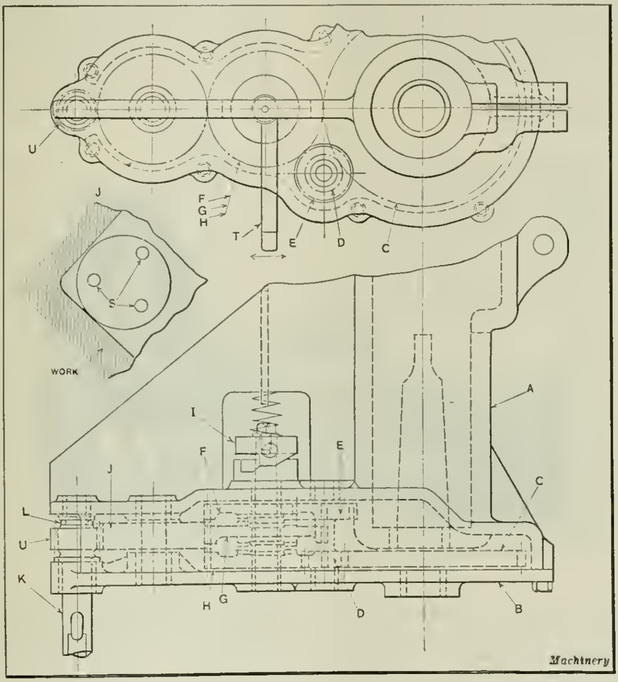
FOREIGN TRADE CONVENTION

The program for the ninth national foreign trade convention to be held in Philadelphia, May 10 to 12, includes a number of both general and group sessions devoted to important problems in the foreign trade field. Among the many questions that will be discussed are the following: "A Foreign Loan Policy that will Enable Idle Factories to get to Work"; "A Practical Method of Putting Our Surplus Gold to Work in Financing Foreign Trade"; "The Effect of High Taxation on the Exchanges"; "The Factor of Depreciated Currency in Competition"; "Protection Against Exchange Losses"; "Uniform Commercial Credit Instruments"; "The Merchant Marine—an International Problem"; "Inland Waterways as Developers of Traffic"; "Marine Insurance"; "Free Ports"; "Meeting Preferential Tariffs"; "Sales Promotion through Advertising"; and "The Essentials of a Market Survey." Further information may be obtained from the National Foreign Trade Council, New York City.

DRILLING AND TAPPING HEAD

By HAROLD A. PETERS

The drilling and tapping head illustrated was designed for use in drilling and tapping three small holes in an engine crankcase. The holes were located in a corner as indicated at *S* and could not be drilled satisfactorily in a regular drilling machine or with any of the small air or electrically driven portable drills available. The drilling head shown differs from the usual type in that it is adapted for tapping as well as drilling. The drilling and tapping head consists of two steel castings *A* and *B*, and a train of gears enclosed by the castings. The top casting *A* is designed to be clamped to the drilling machine spindle housing, and the lower casting serves as a cap to enclose the gear train. The gear train is so arranged that the small auxiliary tapping spindle *K* can be revolved in either direction, or stopped by simply manipulating lever *T*. Although the illustration is diagrammatic, it will serve to show the location of the various gears comprising the gear train and give a good idea of the general construction of the device.



Drilling and Tapping Head for Use in drilling Three Inaccessible Holes

A Morse taper shank, turned integral with gear *C*, fits into the drilling machine spindle after the head is clamped in place on the spindle housing. Gear *C* is always in mesh with gear *D*. Above gear *D* on the same shaft is a slightly larger gear *E*, which is in mesh with the upper clutch gear *F* while the taper shank gear *C* is in mesh with the lower clutch gear *H*. The center clutch gear *G* slides up and down on the shaft, but gears *F* and *H* are kept in the position shown by the stationary bushings on which they revolve.

Clutch gear *G* is raised until its clutch jaws grip those of gear *F*, or lowered until they grip those of gear *H*, by means of the clutch *I*, which can be rotated on its axis by lever *T*. Drill socket *K* can thus be revolved to the right or left, or stopped, by manipulating lever *T*, as previously mentioned. When lever *T* is in the position shown, gear *G* is held in a neutral position and no movement is imparted to socket *K*. Gear *G* is always in mesh with the idler gear *J* as shown, and gear *J* is constantly in mesh with the drill socket gear *U*. A small ball thrust bearing *L* takes the thrust of the drill or tap. The gears are all heat-treated to insure long wearing qualities. A drilling head of this type which has been in constant use for about eight months is giving excellent service, although it has been subjected to unusually severe service.

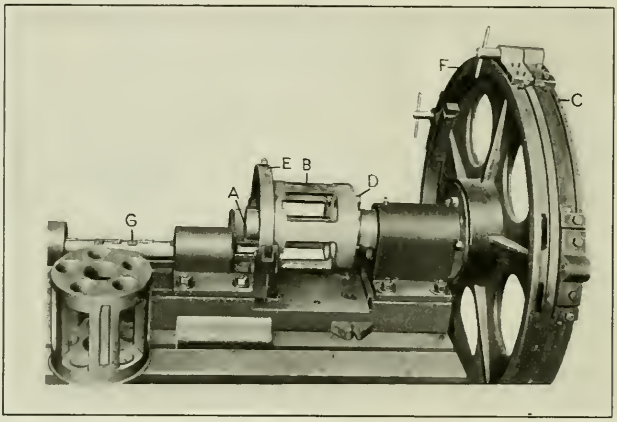
Exports of automobiles during 1921, according to the Department of Commerce, totaled 41,392 cars, of which approximately 14,000 cars went to Latin America and about 6000 cars to Canada.

BORING AND MILLING FIXTURE

Two drum-shaped cast-iron heads are provided on the Davenport multiple-spindle screw machine; one of these revolves and carries the five work-spindles, and the other is stationary and carries the tool-spindles. The revolving head has five longitudinal slots machined in it to receive the steel blocks by means of which it is indexed. The boring of the five holes in each of these cast-iron members, as well as the milling of the five index-block slots, is pérformed by the use of the special boring and milling fixture illustrated. Accuracy was the chief consideration in designing this fixture, as it is essential that all spindles be equally spaced, that they be parallel and that the radial distance from the center of the castings be the same for all holes. The milling of the slots in the revolving head must also be done with the same degree of accuracy.

For boring the holes, the fixture is placed on a Rockford horizontal boring and drilling machine. The fixture has a solid base machined for attaching three bearings, the foremost of which carries the spindle *A* on which the work *B* and the index-wheel *C* are mounted. The other two bearings, which are in line with the spindle bearing, carry the boring tool. All three bearings are bushed with steel. The work is driven by finger *D* which extends into a hole machined in the end of the casting, and is secured by a collar which screws on the end of the spindle. An outboard support is furnished in the form of a cradle having a hinged cover *E* which secures the work in position during a boring or milling operation and which must be released while indexing the work to the next position.



Boring and Milling Fixture of the Indexing Type

At the outer extremity of the spindle bearing is attached a flange to which a stationary wheel *F* is bolted. This wheel carries two locating plug blocks which are fitted to the periphery by means of a tongue and groove and which are located so that the plugs may be properly aligned with similar blocks attached to the periphery of the index-wheel. Five of these index plug blocks are attached to the periphery of the index-wheel, and they are set to the correct chordal distance by the use of plugs and verniers. These wheels are 40 inches in diameter, and the pitch circle on which the holes are bored in the work is 6 inches in diameter, so that an error of 0.001 inch in the setting of the plugs is reduced to less than 0.00015 inch in the spacing of the holes. After these locations have been accurately obtained, the two blocks on the stationary wheel are set by the use of the knurled handle plugs shown, and during the indexing of the work it is necessary that both of these plugs enter corresponding holes in the blocks on the revolving wheel. The plugs are made of hardened steel, and the blocks are furnished with steel bushings.

A special Kelly reamer *G* is used in boring the holes. This bar carries six blades, three for finishing the holes in the front wall of the castings and three for the holes in the rear wall. The first cutter-blade stocks out the holes, while the second is a fly cutter for finish-boring, and the third is a double blade for reaming. Corresponding cutters in each set of three feed through the work before the next cutter starts operating so that there is no tendency for the boring-bar to become cramped and cause inaccuracies or misalignment of the holes. The boring-bar is driven by a floating holder or chuck; thus it is free to adjust itself so as to maintain its parallelism with the work-carrying spindle, established by the alignment of the boring-bar bearings.

The revolving head is shown resting on the base of the fixture. The axial hole of this casting is larger in diameter than the hole in the stationary head, so that it is necessary to use a sleeve to fit in this hole in order that the same work-holding spindle can be used. For milling the parallel grooves in the revolving head the fixture is attached to a Milwaukee milling machine.

INSPECTING THERMIT WELDS

Progress in welding methods has been retarded by the fact that the actual strength of a weld cannot be determined without destroying the weld itself. An examination of the surface of a weld does not reveal its strength. For this reason, technical societies and associations accepting the responsibility of setting standards have naturally been severe in their restrictions regarding specifications for and the allowable application of welding. According to the Metal & Thermit Corporation, however, definite conclusions as to the strength of a thermit weld may be drawn from a careful interior inspection of the collar or reinforcement section of the weld.

In thermit welding, it is said to be impossible for defects such as lack of fusion or oxide inclusion to exist, if the proper amount of thermit is used and if instructions are carefully followed. Oxide inclusions (due, for example, to the failure to clean scale properly from wrought-iron sections before welding), if present at all, will always be in the thermit steel collars due to the natural tendency of the gases to rise in the molten mass. An examination of the interior of the collar can be made without materially affecting the strength of the weld. Thus unsound welds can be found and condemned.

In practice, this examination is made by gouging deep grooves in the thermit steel collars parallel with the axis of the piece. These grooves may reach almost to the original section itself. Two grooves on each of the four sides of a thermit weld have been found sufficient. If these grooves are observed to be clean and free from blow-hole defects, the inspector may be assured that the weld itself is sound.

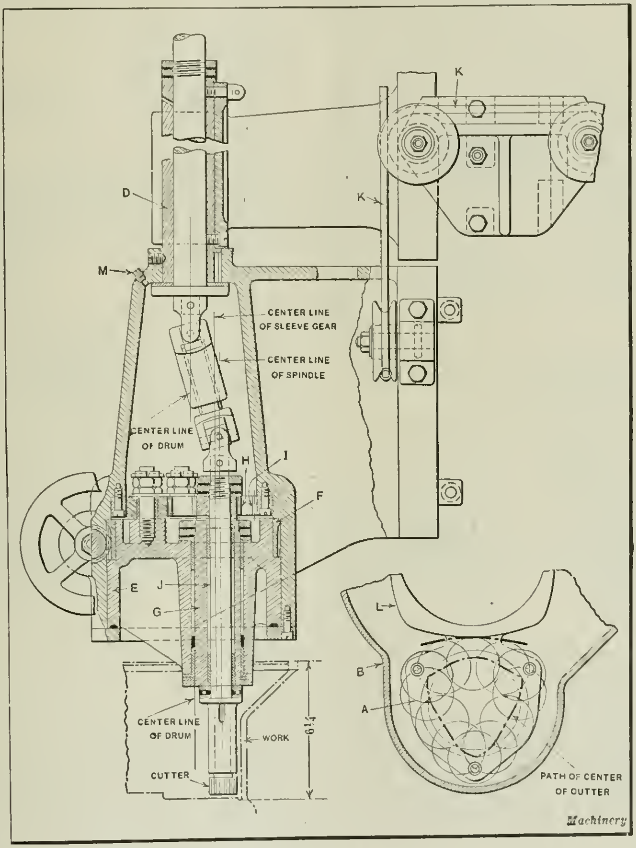
A new chromium-nickel steel is said to have been developed by the Armstrong-Whitworth Works in England, which, it is claimed, does not have the brittleness present in nickel-chromium steels when subjected to certain heat-treatments. The new steel is said to be highly resistant to torsion and shock, which makes it particularly adaptable for use in turbine rotors and for crankshafts and other shafts subject to high stresses when running at high speeds. It has been given the trade name "Vibrac," and is understood to be the result of researches carried on at the company's Openshaw Works in Manchester, England.

Geared Milling Head for Profile Work

By A. B. BASSOFF

THE special geared milling attachment here illustrated was designed for end-milling a flat pad in a transmission gear-case casting. This surface *A* is triangular in shape, and located within the casting 6¼ inches from the end. The circular wall *B* merges into the bell-shaped casting proper and produces a very restricted area within which to work, requiring the use of long slender spindles if the work is produced in a milling machine in conjunction with former plates. The use of former plates is usually objectionable, because they introduce the human element, and often result in rejected work due to the failure of the operator to follow the outline of the profile plate. There is a raised surface *L*, approximately rectangular in shape, which is adjacent to one side of this triangular pad, so that it was impossible to face the surface in a lathe. At the point where the rectangular boss joins the pad the casting has a draft, and it was necessary to cut into this metal along the contour shown by the heavy dot-and-dash line, in order to accommodate the plate which was to be attached to the finished surface of the pad.

The problem of machining the surface and of following the desired contour was solved by the use of a head which is shown in section in the illustration. This attachment was designed to be used on a 24-inch Cincinnati drilling machine, to which it was applied in place of the regular quill and spindle, the quill *D* of the attachment being inserted into the spindle bracket, in place of the regular construction. The milling head consists of a body casting or case which was designed to fit the regular slide on the column of the machine. This casting has attached to it, at the top, a quill *D* for accommodating the special spindle of the milling head. Within the lower end of the case a drum *E* is contained, and this drum has a spiral ring gear *F* keyed to it so that it may be revolved by means of the handwheel shown and a small spiral pinion meshing with the ring gear. The drum has an eccentrically located neck extending down through the retainer plate that holds the drum in position, and that carries within it a sleeve *G* in which there is cut a gear *H* at the upper end. This gear rotates the sleeve through the internal ring gear *I*, which is attached to the inside of the case, and a train of two gears. The spindle *J* that carries the cutter at the lower end is located eccentrically relative to the center line of the sleeve, and runs in bearings. It will be seen that the upper end of the spindle is connected, through universal joints and a telescopic sliding shaft, to the upper vertical spindle which has its bearings in the quill, and which is driven similarly to the regular drilling machine spindle.



Geared Cutter-head used for end-milling Inaccessible Flat Surface

Operation of the Head

With each half revolution of sleeve *G* the cutter-spindle *J* is alternately advanced toward the center of the drum and receded from it, due to the eccentricity of the spindle relative to the center of the sleeve gear *H*. The ratio between the sleeve gear and the large stationary ring gear *I* is 3 to 1, so that when the large drum has made one complete revolution, the cutter-spindle will have advanced and receded radially three times, and in so doing the path of the cutter will follow a regular figure having three high points and three low points midway between them, corresponding to the general triangular shape of the pad to be machined.

The partial view of the interior of the transmission case in the lower right-hand corner of the illustration indicates, by broken outline, the path that the center of the cutter-spindle takes during one revolution of the drum. From this view it will be seen that the course of the cutter corresponds very nearly to the contour of the pad. It will be noticed that the movement of the spindle is not an abrupt rise and drop, but a curve very nearly parallel to that of the outline of the surface to be milled.

The cutter is fed to the work in the same manner that a drill spindle is fed, the vertical location being established by the use of stop-collars such as are regularly furnished with the machine. After the head has been fed to the proper depth, it is clamped in place by two clamping bolts which bind the body casting to the column of the machine through the medium of the regular dovetailed slide construction. The operator then turns the handwheel until the drum *E* has made one complete revolution, and as has already been explained, this completes the cut. Only one cut is taken across the surface, the finish produced being sufficiently flat and free from chatter marks.

The position of the work is shown in broken outline in the illustration, with the cutter adjacent to the surface to be machined, and although no fixture is shown, it is understood that any suitable device for holding the work will be adequate. The entire mechanism runs in oil, the top of the case being provided with a filling plug *M* and also a drain plug at the bottom of the casting, thus permitting the oil to be renewed from time to time. Obviously the weight of an attachment of this kind is considerable, necessitating additional counterweights for returning the spindle to its upper position. These are provided at the rear, and a wire rope *K* is connected to them, passing through a series of pulleys in and around the head, so as to equalize the strain produced by the weight of the attachment on the dovetailed slide.

* * *

In "The Transactions" of the American Institute of Mining and Metallurgical Engineers, it is stated that an investigation of the so-called "fatigue of metals under stress," covering a period of a little over a year, has shown more conclusively than has been shown before that steel under repeated applications of stress, reversed from positive to negative, will not fall below some fairly clearly defined limiting stress which, however, so far as can be determined, does not bear any definite relation to the ordinary elastic limit, being as large as the elastic limit in some cases and about one-half the elastic limit in others.

SPRING PLUNGERS FOR FIXTURES

By H. P. LOSELY, Industrial Engineer, Detroit, Mich.

Three supporting points determine the plane in which a given piece of work will lie when clamped in a jig or fixture. However, it is sometimes necessary to provide more than three points of support in order to take up the thrust of the cut and prevent the piece from being distorted and machined out of alignment. When rough or unevenly machined surfaces are being dealt with, these extra supports must be adjustable. The piece may then be laid on the three fixed points and the adjustable supports brought in contact with the piece and locked, so that the work will be firmly held in position.

While there are various other types, the most economical adjustable support to use on a production job is the spring plunger, which consists of a cylindrical plunger pressed against the work by means of a spring. The plunger is held in place by a screw. The simplest way to make a plunger would be to mill a flat on the cylindrical surface and let the clamping screw bear directly on this flat; however, this is not good construction, because the vibration of the cut is likely to make the plunger slip so that it does not support the part properly.

To avoid this trouble, the plunger construction shown in Fig. 1 has been devised. This plunger has a flat milled on the cylindrical surface at an angle of 7 degrees with the axis, and the use of an intermediate plug between the screw and the plunger prevents the latter from being burred and locks it securely in position when the screw is tightened. Both the plug and plunger should be made of drill rod and hardened; the clamping screw may be made from cold-rolled stock, and cyanide-hardened. Either a plain hexagonal-head machine screw may be used or a pin may be driven through the head to assist in rotating the screw. This pin should be at least ¼ inch in diameter, so that it will be heavy enough to withstand hammer blows. The

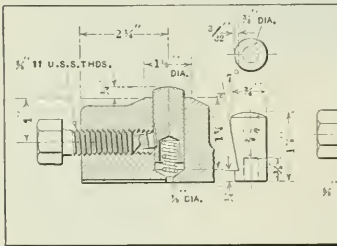

Fig. 3. Plunger with Spring placed in Hole at Lower End

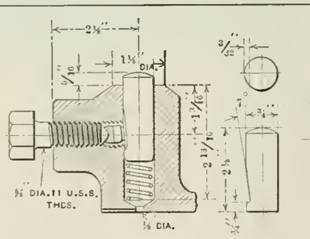

Fig. 4. Size which meets Average Requirements

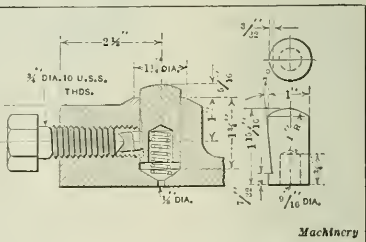

Fig. 5. Especially Heavy Construction for Large Work

plunger hole is reamed to a slip fit for the plunger. The coil spring is made of spring steel, 0.062 inch in diameter, and it has seven coils, an outside diameter of 19/32 inch, and a free length of 1⅜ inches. An air groove is provided from the ⅛-inch diameter vent at the lower end of the plunger hole to the outside of the fixture.

Fig. 3 shows a variant of the standard plunger construction, this being a heavier size, and in order to reduce the head room, the plunger is drilled at the lower end to accommodate the spring. The spring in this case is made of spring steel, 0.054 inch in diameter, and it has six coils, an outside diameter of 11/32 inch, and a free length of ⅞ inch. Fig. 4 shows a good size of plunger for average requirements, the spring being made of spring steel, 0.072 inch in diameter, and having seven coils, an outside diameter of 11/16 inch, and a free length of 1 5/16 inches. A specially heavy construction, intended for jigs and fixtures holding large pieces on which heavy cuts are to be taken, is shown in Fig. 5. The position of the spring here is the same as in Fig. 3. The spring is made of spring steel, 0.062 inch in diameter, and has seven coils, an outside diameter of 17/32 inch, and a free length of 1 5/16 inches.

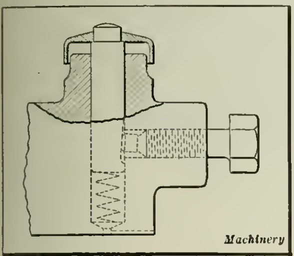

Fig. 6. Method of keeping Chips from Plunger Hole

An arrangement for clamping two plungers at one time is illustrated in Fig. 2. It will be seen that when the screw is first tightened, the clamping plug will be locked against the right-hand plunger; then, as the screw continues to be tightened, shaft *A* will be forced over, also locking the left hand plunger. Care must be taken to make the slots in the shaft of sufficient length to allow the necessary longitudinal movement. At the left-hand slot, enough stock must be milled away at the bottom of the shaft to provide clearance between the latter and the shoulder at the lower end of the flat on the plunger.

Usually the head of the plunger, on account of being under the work, is somewhat protected from chips, so that the provision of a boss, as shown in the various illustrations, is sufficient to prevent chips from working into the plunger hole. Sometimes, however, a condition will arise when chips will be thrown under the work by a cutter at some distance from the point of support, or a heavy stream of lubricant conveys the chips to the plunger. In such cases, additional protection is desirable, and the special design shown in Fig. 6 may be used. The cap on the plunger slides over the machined head of the boss, and if the fixture is so designed that the head of the boss is above the level of lubricant, the plunger cap will effectually keep out chips and prevent having the plunger jammed. If lubricant floods around the boss, its height from the base to the ridge or shoulder half way up on it should be at least ½ inch. In all cases of plunger construction, an air vent must be provided at the bottom of the plunger hole, so that the plunger can move freely. A plunger and spring must be of such dimensions that the plunger will have sufficient travel to meet variations in the work.

* * *

About forty airplane factories having a total production of 2500 machines a week were in operation in Germany at the close of the war. The majority of the firms operating these plants took up other work after the war, although three of the firms decided to manufacture airplanes for commercial use. These were the Sablatnig Co. of Berlin, the Junkers Co. of Dessau, and the Fokker factory of Schwerin.

BURNISHING BOLTS IN QUANTITY

By D. C. OVIATT

A high rate of production can be obtained by finishing the bodies of bolts by burnishing instead of by grinding. As will be seen by referring to the accompanying illustration, the die employed is of simple design, as is also the guide by means of which the bolt is kept in alignment with the center of the opening in the die. The over-all dimensions of the die-block will be suitable for the size of bolt shown in the illustration, that is, ⅝ inch diameter. The length of die neck through which the bolts are forced by the punch should be equal to about half the diameter of the bolt, and should be finished by lapping and have about ⅛ inch radius at the top. Good results will be obtained from "Novo" steel, double heat-treated in the following manner: Pack-harden for three hours at 1700 degrees F., and allow to cool off in the pot; then reheat to 1300 degrees and quench in oil. The diameter of the die opening in this case is such as to reduce the diameter of the bolt 0.005 inch.

Comparison of Results Obtained by Burnishing and by Grinding

Whereas the production rate by grinding will average about 800 bolts per day, it is possible to burnish as many as 4000 bolts per day when a power press equipped with a die of the type described is employed. No trouble will be experienced in maintaining straightness of the bolts up to 4 inches long, and even then the bolts may be successfully finished in this manner. The degree of finish obtained is good, possibly superior to that obtained by grinding, and the structure of the surface, being subjected to the compressive action of the burnishing die, is harder and will wear longer than any surface which has not been treated in this way. The type of press on which this operation has been successfully performed is a No. 84 Bliss reducing press, equipped with a cam-actuated attachment for lifting the bolts out of the die after the operation has been completed. The bolts which were so finished were what is known as spring bolts and king-pin bolts, such as used on the front axles of automobiles, and they were made with an undercut under the head to take care of the metal that might accumulate on the die and prevent the bolts from seating properly.

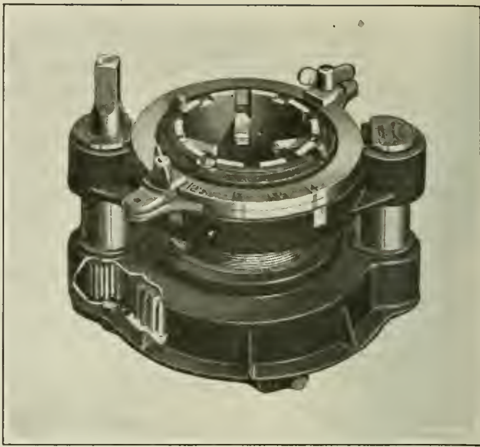

Fig. 2. Geared Die-stock for threading Pipe from 2½ Inches to 4 Inches in Diameter

Pipe Threading Tools and Their Manufacture

Methods Used in Making Beaver Die-stocks and Chasers—First of Two Articles

By FRED R. DANIELS

A MODERN type of pipe-threading die-stock is shown in Fig. 1. The die-stock is secured to the pipe by a universal chuck, tightened and released by the grip-screw *A*. The chuck-holder is threaded into die-head *B* so that as the latter is turned in cutting a thread, the chasers will be advanced at the same rate. This means that the threaded portion of the die-head must correspond in lead with that of the thread to be cut. Since the lead is the same for threads of more than one pipe diameter, it is obvious that by providing a means for opening the chasers independently to suit varying diameters, a number of pipe sizes can be threaded with the same die-stock. This is accomplished by a cam-plate *C*, in which there are slots which are engaged by pins *G* in the chasers, thus opening or closing the dies when plate *C* is turned. The dies are set to the desired pipe diameter, as determined by the graduated plate *D*, and the chasers locked in this position by wing-nut *E*. The chasers start cutting at full thread depth and travel at an angle with the center of the pipe in order to produce the standard taper pipe thread. This angular travel of the cutters is produced in the following way: On plate *D* is a lug which travels in an angular slot in post *F* as the die-head is turned in cutting a thread. The result is that the top plate advances with the die-stock, and being clamped to the cam-plate, turns that member and causes the chasers to travel at the correct angle to produce the desired taper thread, as previously mentioned. The taper-threaded chasers are not usually provided with more than two or three threads; in fact, a single chaser thread might cut a pipe thread satisfactorily under these conditions.

The die-stock shown in Fig. 1 will accommodate the four pipe diameters 1, 1¼, 1½ and 2 inches, these sizes having the same thread pitch. The use of a universal chuck for clamping the die-stock to the pipe does away with the neces-

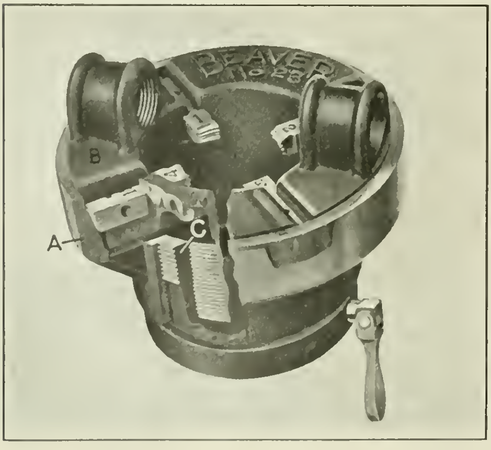

Fig. 3. Die-stock of the Non-adjustable Type

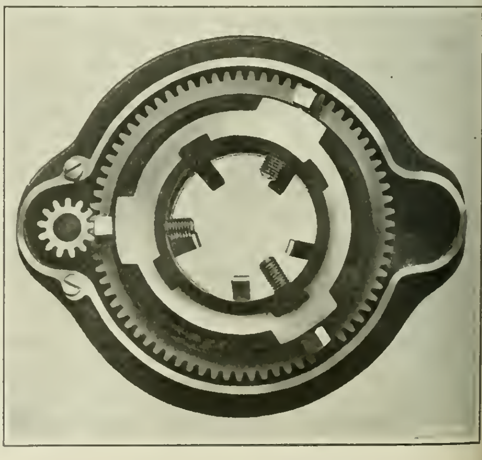

Fig. 4. Interior of Geared Die-stock shown in Fig. 2

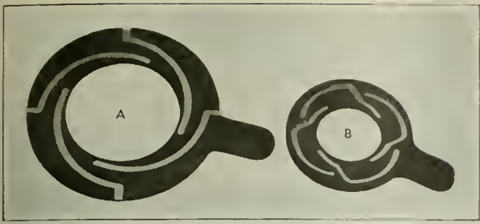

Fig. 5. Types of Chaser Cam-plates

sity of using a separate bushing for each of these sizes. The die-stocks that are described in this article are known as the "Beaver" type, and are manufactured by the Borden Co. of Warren, Ohio.

For pipe diameters of 2½ inches and larger, the die-stocks are operated by a gear and pinion, but the principle is identical with that already described. A tool of this construction that will handle pipe sizes up to 4 inches is illustrated in Fig. 2. Aside from the geared feature and the pillar arrangement for keeping the upper and lower main members in alignment, this die-stock is the same in principle as the one used for the medium sizes of pipe.

Die-stocks with Two Sets of Chasers

For the small sizes of pipe, when it is necessary to handle more than one diameter, the construction previously described must be modified. This is due to the fact that the pitch varies more in the smaller sizes than in the larger sizes. For example, a ¼-inch and a ⅜-inch standard pipe thread have eighteen threads per inch, and a ½ and a ¾ inch thread have fourteen threads per inch, whereas, the thread pitch on larger sizes of pipe would be the same for a number of consecutive sizes. By making provision for accommodating two sets of chasers, these four pipe diameters can be threaded with one tool. A die-stock of this type must be so designed that while one set of chasers is in use the other set can be withdrawn from contact with the pipe. The principal change in design made necessary by this requirement is in the slots of the cam-plates which control the radial adjustment of the chasers.

The difference in cam-slot arrangement is clearly shown in Fig. 5, the cam shown at *A* being the type used when one set of chasers is employed, and that at *B* the type used when more than one set is employed, and it is necessary alternately to advance and withdraw the sets of chasers, as when threading the smaller pipe sizes.

Non-adjustable Type of Die-stock

A die-stock which is not adjustable is illustrated in Fig. 3. This tool is of simpler construction than the cam-plate type, and consists of only three main parts in addition to the die chasers. In this case, the chasers are set to the required pipe diameter when the top edge of the outer housing *A* is flush with the upper surface of the die-head *B*. The barrel of the die-head is threaded externally, the threads having the same pitch as the thread to be cut. The threaded part of the head operates in the leader nut *C*, the outside of which has a coarser thread than that of the die-head barrel so that as the die-stock is turned, the outer housing will advance at a faster rate than the die-head. Consequently, the chasers will be traversed at the required thread angle due to the angularity of the inner wall of the outer housing against which the ends of the chasers bear. With a die-stock of this type it is necessary to use separate sets of chasers and bushings for each size of pipe that is threaded. The principal feature of this stock is its low cost due to the small number of parts entering into its construction.

Examples of Machining Operations

The housings for the operative parts and the slots in which the chasers are seated must be correctly machined, and the surfaces must be in a definite relation to each other if ease of operation and a high quality product is desired. The machining of the leader nut for the type of die-stock shown in Fig. 2 is of interest. This leader nut has gear teeth cut on its periphery, as shown in Fig. 4, which is a view of the bottom of the die-stock, showing the chasers and the construction of the pinion-shaft case in which the pinion and the gear end of the nut are housed. The machining operations to be described are performed on a Potter & Johnston turret lathe, Fig. 6. The work is held in a chuck provided with soft jaws. The tools carried in bar *A* rough-bore the two diameters *B* and *C* of the work. The bar is long enough to enter a guide bushing in the chuck and thus insure concentricity between the two bored diameters. While the second tool is at work, two tools in holder *D* rough-turn the flange of the work. This flange has two diameters separated by recess *E*. Before these two rough-turning operations are completed, tool *F* chamfers the inside of the hole.

The boring-bar used at the second station of the turret also comes into alignment with a bushing in the chuck and carries two finishing tools *G* and *H* for finish-boring the previously rough-machined holes while the shoulder is being squared up by tool *J*. At the same time the outside of the flange is beveled by means of tool *K*. Surfaces *L* and *M* are then rough-faced by a pair of tools mounted at the rear of the cross-slide and finish-faced by another pair of tools at the front of the cross-slide. Recess *E* is turned by tool *N* carried in a tool-block which is attached to the cross-slide in such a position as to turn the recess at the same time that surfaces *L* and *M* are being faced. The final machining operation consists of tapping the hole in the flange with a self-opening die-head *O*, which is mounted in the third station of the turret.

In finishing the outside diameter and the opposite side of the leader nut in another Potter and Johnston machine, the work is held by soft expanding jaws which grip it in the previously tapped hole. The chuck also has a pilot for locating the piece centrally with respect to the turret lathe spindle. The operations performed in this machine are rough- and finish-facing the opposite side of the nut and rough-turning the outside diameter. While these operations are in process, the rough edges are removed by auxiliary tools.

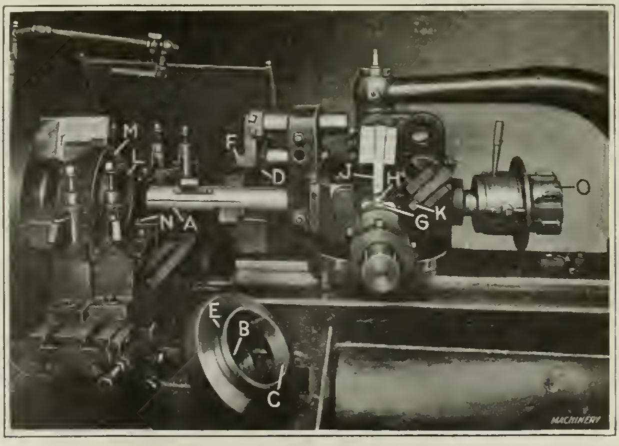

Fig. 6. Turret Lathe equipped with Tooling for machining Leader Nuts for Pipe Thread Chasers

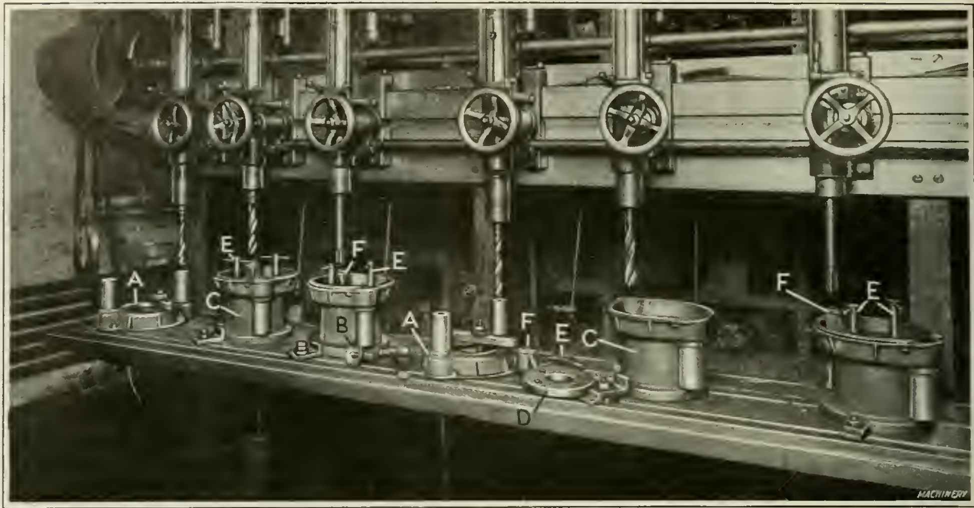

Fig. 7. Multiple-spindle Drilling Machine arranged for drilling Hole in the Pinion-shaft Case

The pinion-rod hole in the pinion-shaft case, Fig. 4, is machined on a Foote-Burt multiple drilling machine, as illustrated in Fig. 7. Two gangs of tools are used, each of which consists of two drills and a reamer, so that steady production can be maintained without undue loss of time by the operator. The work is shown strapped to the machine table at *A*. The outside diameter of the post through which this hole is drilled is previously machined, so that by using the prick-punch *B* for locating the center for the 7/8-inch drill which is used first, it is not necessary to use a fixture for this operation. As soon as this hole has been drilled, the operator unclamps the work and loads it into jig *C*. The jig is of the pot type, with a shoulder for receiving the work. The height of this shoulder is less than the thickness of the casting, leaving a pocket, 1/4 inch deep, in which the jig plate *D* fits, where it is located by dowels and secured by pilot-screws *E*. This brings the bushing *F* into correct relation with the center hole in the case.

The 1 7/32-inch drill used in the second spindle is fed at a higher rate than it would be if the preliminary drilling operation had not been resorted to. By this means it is possible to so regulate the feeds of the two drills that no idle time results. As soon as the drilled piece is removed from the second spindle position, it is located in a similar jig, and reamed by a 1 1/4-inch reamer in the third spindle. While the three tools are operating, the attendant is busy at the other three spindles of the machine, after which it is time to return to the opposite end and start over again. The jigs are not fastened to the machine table, but are located by straps attached to the table; one of these prevents the jig from turning by abutting against a foot projecting from the base of the jig, and the other acts as a locating point at the front of the jig.

Machining Chaser Slots in Die-stock Heads

It is very important to have the chasers accurately fitted in the die-heads, and great care must be exercised in laying out the slots in the cam-plate by means of which the chasers are opened and closed. The practice in machining the malleable iron die-head castings for the accommodation of the chasers, is to first rough-mill them and then to finish the slots by broaching. Broaching has been found to give the desired degree of accuracy. In Fig. 8 is shown the set-up of a Lapointe broaching machine for finishing the slots in the type of die-head illustrated in Fig. 3. The work *C* is located on a special fixture *D*, which is attached to the head of the machine. In the illustration broach *A* is shown located in guide *B*, as it would appear near the end of the broach travel.

Another type of broaching fixture which will accommodate four small die-head castings is illustrated in Fig. 9. In this case, broach *A* rides on its back on bar *B*. The work is

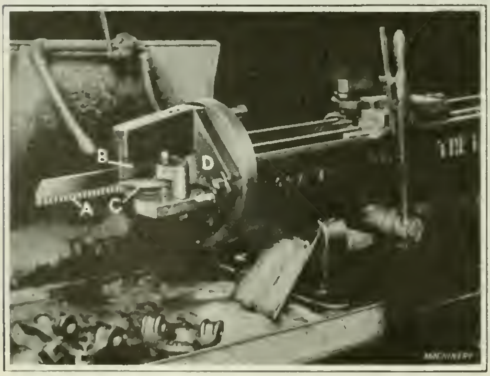

Fig. 8. Broaching Chaser Slots in Die-heads of the Type shown in Fig. 3

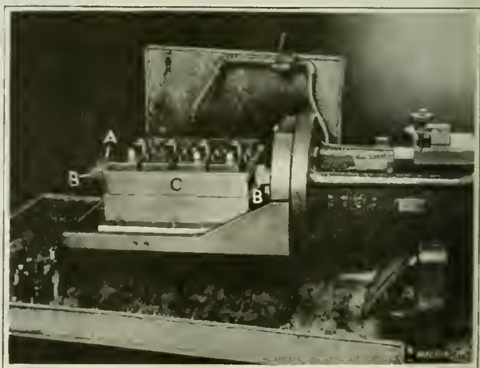

Fig. 9. Broaching Chaser Slots in the Smaller Die-heads, using a Gang Fixture

clamped in an inverted position in fixture C so that the cut is up. These die-heads are also milled previous to broaching, and the broaching fixture is arranged so that when it is clamped in position the milled slots align with the broach. Small die-heads like these are for use on die-stocks employed for threading the very smallest sizes of pipe. An unusual feature of the broaching fixture shown in Fig. 9 is its massive size for such a small piece of work. This heavy construction, however, provides the necessary support for the broach to maintain the required accuracy.

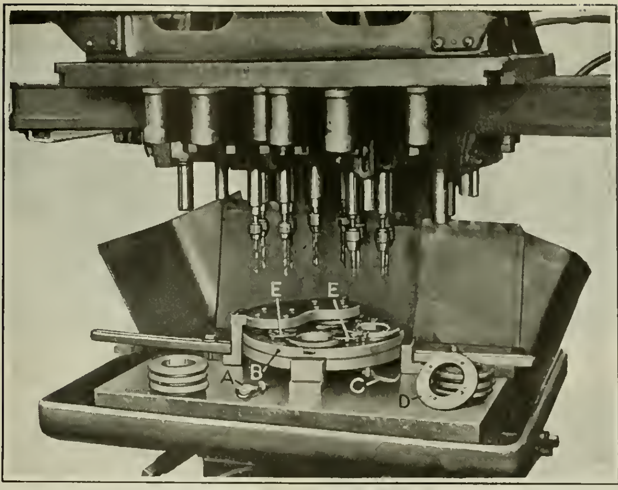

Fig. 10. Multiple-spindle Drilling Machine of the Cluster Type, and Indexing Jig used in drilling Chaser Cam-plates

Before the cam-plate slots, Fig. 5, can be milled, a preliminary drilling and counterboring operation is performed on the "Natco" multiple drilling machine illustrated in Fig. 10. The holes thus produced are for starting the end-mills used in cutting the slots. The indexing type of drill jig used for this work accommodates four chaser cam-plates, and can be indexed from station to station by inserting the removable handle A in hole B of the revolving jig plate after latch C has been depressed. There are three clusters of tools, two of four drills each, and one of four counterbores. These are all working at once while the operator is loading and unloading the fourth station. A number of the unmachined plates are shown lying on the machine table, and one which is partly drilled and counterbored may be seen at D. The work is held on the indexing jig plate by two flat springs E which are attached to the plate by a screw at the center so that they can easily be raised from the work and swung to one side when unloading. There is sufficient tension in these springs to prevent the work from changing position during the drilling operation.

Milling the Cam-plate Slots

In milling the pin slots in these chaser cam-plates a special duplex end-milling machine, designed and constructed by the Borden Co., is employed. This machine is illustrated in Fig. 11. The machine has an ordinary worm and worm-wheel feed mechanism on each end. The faceplates C on which the work is mounted are revolved by master cams A and B to produce the special form of cam slots. An end-mill D of the proper diameter is used in taking the cut. The procedure is as follows:

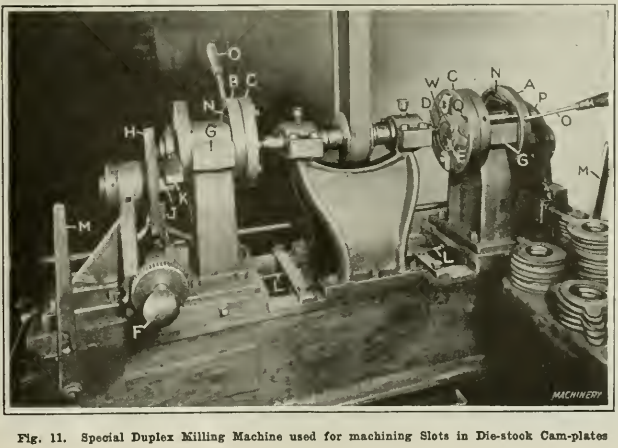

Fig. 11. Special Duplex Milling Machine used for machining Slots in Die-stock Cam-plates

After attaching the cam-plate W to the faceplate of the machine by the aid of a central locating stud E and suitable clamps, the operator advances each carriage against stops L until the end-mill enters one of the previously counterbored starting holes. The carriages are traversed by the hand-levers M to bring them against the stops. The feed is then engaged by raising the worm-handle F, and a combined radial and rotary movement of the faceplate is obtained by the engagement of a cam-roll in slot N of the master cam. This cam-roll is attached to the end of the bearings G, and always remains in engagement with the slot in the master cam.

Obtaining Variable Rotary Feed

A rather ingenious arrangement has been employed in this machine for obtaining a variable rotary speed in feeding the work past the end-mills. This variation in speed is necessary because of the design of the slot, it being evident that at the central section of the slot the direction changes from approximately a concentric path to an abrupt angle, which is almost radial in direction (see cam B, Fig. 5). The variation in rate of feed is accomplished by mounting the feed worm-wheel H eccentric relative to the center of the faceplate of the machine and below it. There is a dog J on the inside of the worm-wheel, by which the faceplate is driven through the medium of lever K, which is fixed to the faceplate shaft. The relative position of the centers of the worm-wheel and of the faceplate is such that when the abrupt change in direction of the path is reached, the driving dog J will travel toward the center of the faceplate on the lever K, and so the angular movement of the driver will transmit to the faceplate a greater rotary movement when driving from this position than when the lever arm from the center of the dog to the center of the faceplate is longer. To express it in another way, the lever arm of the driver is shortened, which results in a greater movement at the circumference of the faceplate. At the end of this abrupt change in path, it is necessary to resume a slower rate of feed, and the relation of the driving dog to the center of the faceplate permits this to be done by again increasing the length of the lever arm of the driver.

At the termination of one slot, the feed knocks off and the operator turns the master cam backward by means of handles O so that the cam-roll is again at the beginning of the slot. The two carriages are slid away from the end-mill sufficiently to enable the faceplate to be indexed through an arc of 90 degrees preparatory to starting the second slot. The index-pin and bushing are shown at P and Q, respectively.

On the types of cam-plates in which the slots follow a more uniform cam curve (as cam A, Fig. 5) machines of the same type are used, but in this case it is not necessary to employ a master cam, the cam-plates simply being mounted eccentrically relative to the center of rotation of the faceplate.

The second article on the manufacture of pipe threading dies, which will be published in June MACHINERY, will contain a detailed description of the operations employed in manufacturing the thread chasers, the heat-treating and inspection practices, and the device used in registering the amount of pull required in threading a pipe.

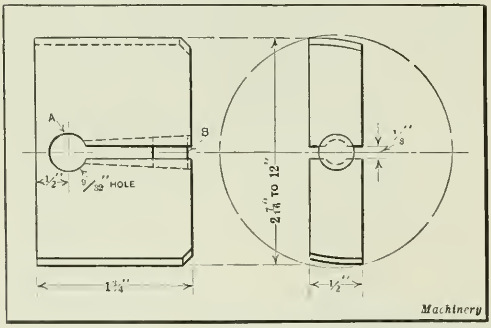
ADJUSTABLE REAMER BLADE

By LOUIS J. KESSLER

The writer read with interest the description of a new style of adjustable reamer blade, which appeared on page 231 of November, 1921, MACHINERY. Another adjustable reamer blade of somewhat different construction, which is used in the plant where the writer is employed, is described in the following. The cutters range in size from 2 7/16 inches up to the large blades used for reaming holes 12 inches in diameter. They are referred to in the shop as "floating double-end cutters" and all sizes are made adjustable within certain limits. Annealed flat high-speed steel stock ½ inch by 1¾ inches is standard for making all sizes.

The adjustable feature will be apparent from an inspection of the illustration. After the cutters have been turned about 0.015 inch over size, a 9/32-inch hole is drilled at A.



Floating Reamer Blade of Adjustable Type

A hole for a No. 5 taper pin is then drilled in the end of the cutter so that it will break into hole A. The ⅛-inch slot shown in the illustration is then cut in the blade.

After being hardened, a short taper pin B is driven into the tapered hole just tight enough to prevent it from falling out. The cutter is then placed on an arbor held between centers on a grinder and ground to size and relieved. The width of the cutter at the back end is made about 0.0015 inch less than the width at the front or cutting end. When worn so that it cuts under size, the cutter can be readily expanded by driving in tapered pin B.

This style of cutter has been in use for several years on boring mills, lathes, and drilling machines for reaming operations on all kinds of materials. The bars in which the cutters are held must always be properly centered or aligned with the holes being reamed. Not more than 0.005 inch on the side of a hole should be left for reaming. The maximum amount of expansion obtainable with this type of cutter is approximately 0.030 inch.

SIMPLIFIED FORMULA FOR STRENGTH OF GEAR TEETH

By DAVID T. MALPARTIDA

The formulas given in this article make it possible to determine directly the diametral or circular pitch for a gear when the horsepower to be transmitted and the velocity in feet per minute at the pitch diameter are known.

On page 595 of MACHINERY'S HANDBOOK this formula is given:

$$W = \frac{SAY}{P} \qquad (1)$$

in which

W = maximum safe tangential load in pounds at pitch diameter;
S = allowable unit stress for material at given velocity;
A = width of face in inches;
Y = outline factor for Lewis formula (as applied to diametral pitch); and
P = diametral pitch.

Let P_1 = circular pitch $= \frac{3.1416}{P}$, or $P = \frac{3.1416}{P_1}$

Inserting this value in Formula (1), we have:

$$W = \frac{P_1SAY}{3.1416}$$

But A (the width of face) is usually a certain number of times the circular pitch; so that we may write $A = kP_1$, where k generally is from 2 to 3 for cast teeth gears. Then

$$W = \frac{P_1SkP_1Y}{3.1416} = \frac{P_1^2SkY}{3.1416}$$

From this it follows that

$$P_1 = \sqrt{\frac{3.1416W}{SkY}}$$

But $W = \frac{33{,}000 \text{ H.P.}}{V}$ (see page 595, MACHINERY'S HANDBOOK) in which V = velocity in feet per minute at pitch diameter. Hence,

$$P_1 = \sqrt{\frac{3.1416 \times 33{,}000 \text{ H.P.}}{SkYV}} \qquad (2)$$

To obtain the diametral pitch P, substitute $\frac{3.1416}{P}$ for P_1 in Formula (2) and solve for P:

$$P = \sqrt{\frac{3.1416SkYV}{33{,}000 \text{ H.P.}}} \qquad (3)$$

For cut teeth gears, k is generally from 3 to 4.

For gears with cast teeth, the writer uses the following values for the static unit stress S_s:

Cast iron, 4000; phosphor-bronze, 6000; 0.30 carbon steel, 7500; 0.50 carbon steel, 12,500; steel (average) 10,000 (all in pounds per square inch).

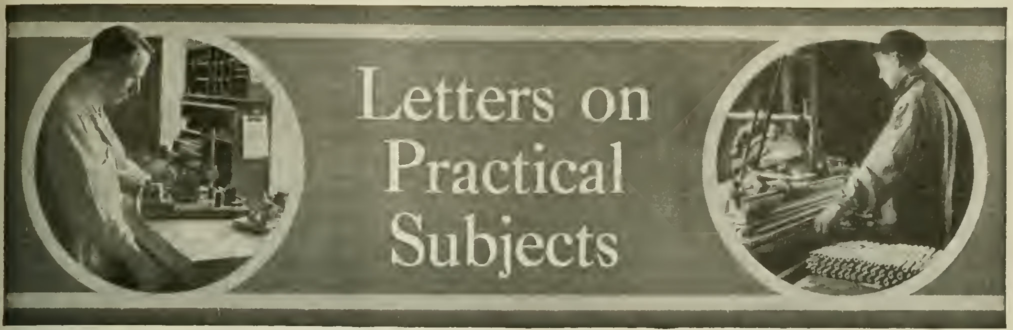
These values apply to steady load conditions; for intermittent service, use from 50 to 75 per cent of these values.

From these values S can be found as follows:

$$S = S_s \times \frac{600}{600 + V}$$

* * *

According to index figures of prices collected by Dwight P. Robinson & Co., engineers and constructors, New York City, if the price index for 1914 is assumed as 100, the index figure for January, 1922, for metals and metal products is 117. The average of all commodities is 148, showing that the metal-working industries have reduced their prices far below the average of the industries in general. Building materials have an index figure of 202, one of the highest on the list.

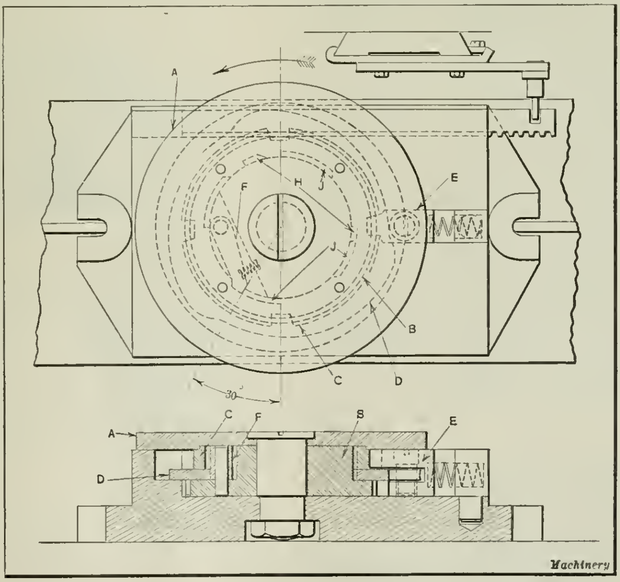


INDEX MILLING FIXTURE

An indexing milling fixture which may be used either on a hand- or a power-fed milling machine is shown in the accompanying illustration. This fixture is of simple design and positive operation. It lends itself to a rather broad application, although it is not recommended for an index movement of less than 45 degrees. The illustration shows the fixture as arranged for a 90-degree index movement. The special use for which an equipment of this kind is recommended is in the milling of a large number of small pieces, where a considerable amount of time may be saved by clamping four holding devices on the fixture plate *A*. By this means high production may be obtained, utilizing the fixture as in station milling, one side being loaded while the holding device at the opposite side is at work.

The construction and operation of the device are as follows: A stationary rack is connected to the column of the machine and is capable of adjustment for position relative to the machine spindle. The backward movement of the machine table causes the gear *B*, which is loose on a central stud, to rotate in the direction indicated by the arrow. The gear is cut out to accommodate a spring pawl *F*, by means of which movement is imparted to the index-plate *C* and thence to the fixture plate *A*. The index-plate is attached to the fixture plate, and in this case contains four notches *J*. The outer periphery of the plunger plate *D* is a three-lobe cam which operates the spring plunger *E*, and permits the indexing movement of the fixture to take place.

In the illustration the fixture is shown just prior to the backward movement of the table after the cut has been taken. Pawl *F* engages one of three notches *H* in the plunger plate, and as the gear is rotated this plate is moved through 30 degrees, withdrawing plunger *E* from the notch in the index-plate at which time the pawl also engages one of the four long notches *J* in the index-plate. Continued rotation of the gear from this point turns the index-plate 90 degrees, when the plate is again locked in place by the plunger. During the forward movement of the table and while the cut is being taken, the index-plate remains locked by the plunger. The 30-degree reverse table travel before the index movement occurs, is for the purpose of preventing pawl *F* from again coming into the indexing position until the table has carried the work backward for enough to clear the cutter.



Indexing Milling Fixture for Use in milling a Large Number of Small Pieces

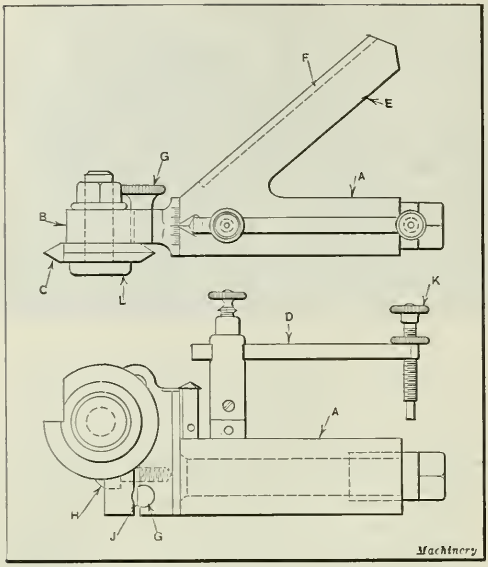
As previously mentioned, the design may be modified to suit different cases, but the main points in the construction are that the index-plate must be fastened to the fixture plate and that the plunger plate must have one less cam rise than there are index movements.

Fitchburg, Mass. E. E. Lakso

THREAD-CUTTING TOOL

In the following is described a thread-cutting tool designed by the writer with the object of combining some of the most desirable features found in different types of thread-cutting tools. Although this tool has now been in use for a number of years the writer has yet to find its equal for ease of manipulation or for accuracy. The tool is composed of the following parts: A block or holder *A* which fits the lathe toolpost; a swivel head *B* which holds the cutter *C* and allows it to be set at any angle within its range; and a swinging gage-bar *D* with an adjustable stop *K* which is used to set the cutter in its proper position after it has been ground.

The part *A* is a piece of machine steel finished accurately to the shape shown. A dovetail slot cut in the side of arm *E* holds a data plate *F* which can be made to suit the class of work for which the tool is generally used. The part *B* is made from tool steel, finished to size and graduated in degrees. This piece is hardened and drawn to a spring temper. The cutter *C* can be counter-



Thread-cutting Tool

sunk on one side to allow a countersunk head bolt to be employed, if desired, so that the tool can be used for cutting threads close to a shoulder. The cutters are hardened and drawn to a light straw color, after which the bolt holes are lapped to size. After the holes are lapped, the cutters are placed on an arbor and ground accurately to the correct form for thread-cutting.

By means of button *G* and adjusting screw *H* the holder can be adapted for use either as a spring or a solid tool. When used as a spring tool, the flat side on button *G* is brought parallel with the slot in part *B*, leaving an opening of about 1/16 inch at *J*, and thus allowing the spring in the upper part of *B* to act. When in use as a solid tool, the flat surface on button *G* is turned at right angles with the slot in part *B* and adjusting screw *H* tightened. Part *B* is graduated in degrees to read in both directions as shown, thus allowing the cutter to be set to correspond with the helix angle of either right- or left-hand threads.

The gage-bar *D* and adjusting screw *K* are of great assistance when the point of the tool breaks, as it is a simple matter to loosen the nut on screw *L*, remove the cutter and grind it, after which it can be set back in the same position without removing the work from the lathe. By swinging bar *D* around and using the lower end of screw *K* as a stop, the cutting point of tool *C* can be located at the proper height. The plate *F* is marked to give the diameter of screw, number of threads per inch, angle of thread, and also total depth of thread. This has proved a convenient method of presenting these data, and as many slides are made up as are required to cover the range of threads likely to be cut. When setting the tool in the lathe, a parallel is first placed between the faceplate and the side of the holder, after which the cutter is adjusted for height.

Chicago, Ill. A. H. Wilson

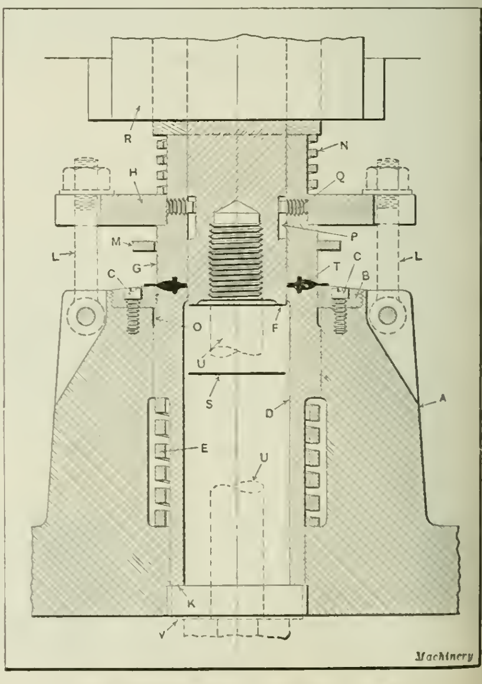
TRIMMING DIE FOR SMALL FORGINGS

The accompanying illustration shows a trimming die for removing the fin or flash from cycle free-wheel ring forgings in one operation. This die has a cast-steel bolster *A* into the top of which is screwed the hardened external trimming ring *B*. Two fillister-head screws *C* are inserted in ring *B* to prevent it from working loose. The punch *D*, which is made of special punch steel, serves as an extractor and also forms the ring for punching out the center part *S* of the forging.

On the up stroke the spring *E* actuates punch *D*, causing the forging *T* to be extracted from ring *B*. The center punch *F* is also made of special punch steel and is hardened and ground. This member forms a center which locates the sliding punch *G*. There is a shoulder on the outside diameter of punch *G*, on which flange *H* rests. It is necessary to provide a stripper *M* for the outer flash. Spring *N* acts on punch *G* through flange *H*.

The operation of the tool is very simple, and it is well adapted for use on a single-acting press. Referring to the illustration, it will be noted that the center of the forging has just been punched and that the fin is falling through the hole in punch *D*. As the ram of the press continues its downward stroke, punch *G* will clip the outer part of the forging. On the return of ram *R*, stripper *M* removes the fin from punch *G*. Punch *D*, actuated by spring *E*, follows the up stroke of the press until the shoulder at *O* strikes the bottom of the trimming ring *B*. Ram *R* continues its upward stroke carrying with it punch *F*.

Punch *G*, through the action of spring *N*, will remain down until punch *F* has moved upward a sufficient distance to bring the bottom of the slot *P* into contact with the screw *Q*. This enables ram *R* to open the dies so that the finished forging can be taken out. It should be noted that punch *G* and extractor *D* are both formed at the ends to fit the forging. This is necessary to prevent any distortion of the forging, which is of very light weight and is required to be kept within close limits of accuracy, only 1/32 inch being allowed for finishing. Center punch *F* is threaded for an extractor bolt *U* (shown in dotted lines) on which is placed a mild steel washer *V*, which rests on the end of punch *D* at point *K* when the bolt is employed to release the dies. It will be noticed in the illustration that two swinging bolts *L*, shown by dotted lines, are fitted into slots cast into bolster *A*. When the dies become worn, they occasionally stick in ring *B*. The extractor bolt is then screwed into the punch *F*



Die for trimming Flash from Small Forgings from beneath the press table. The bolt thus clamps the parts *R*, *F*, *G*, and *D* together as one piece. The dies are then released by turning the flywheel by hand. To release a forging in case it becomes stuck on punch *F*, it is only necessary to swing the bolts *L* into slots cut in flange *H* so that the punch can be readily withdrawn.

Cleveland, Ohio C. F. George

CONNECTING-ROD BORING AND REAMING FIXTURE

The fixture shown in Fig. 1 was designed to perform the finish-boring and final reaming operations on a connecting-rod crankshaft bearing. It insures a bearing of accurate size and one that is parallel and square with the wrist-pin bushing hole. The connecting-rod *A* is held on the wrist-pin end by means of a spring collet *B* actuated by the screw *C*. On the crankpin end it is held by the sliding arbor *D* which locates it, prior to clamping, by the forked clamp *E* actuated by the screw-operated tapered wedge *F*.

The arbor *D* is hollow and has a hole ground at the connecting-rod end to take the end of the reamer-bar *H*. It also has a stop-pin *G* at the other end so that there will be no chance for the workman to force the connecting-rod over the small shoulder on the arbor; this shoulder is necessary because the bushings in which the arbors *D* and *H* slide are made large enough to let the reamer and cutting tools through. The left-hand end of reamer-bar *H* is made to fit into a "Magic" chuck, and the right-hand end is provided with a pilot and a standard shell reamer taper to take the reamer shown in Fig. 2.

The reamer is composed of a shell carrying a single fly tool *K* on the front end, which bores the bearing to within 0.003 inch of the required size. At the back of this reamer are inserted eight duplex reamer blades, one of which is shown at *L*. Each of these blades is 1 inch long and set at a 5-degree angle with the axis to form a left-hand spiral reamer. This reamer produces a fine finish and a very accurate hole.

The body of the fixture is made of cast iron and is well ribbed. It can be set up in a lathe or on a horizontal boring machine. When in operation, the connecting-rod is inserted while the reamer is pulled back. After the rod is in place

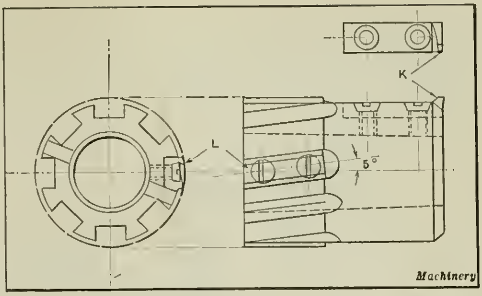


Fig. 2. Combination Boring and Reaming Cutter used in Fixture shown in Fig. 1

the reamer is fed up while being rotated at a very high speed. Compressed air is used to blow the chips away from the cutting edges of the tool.

Pittsburg, Pa. William Owen

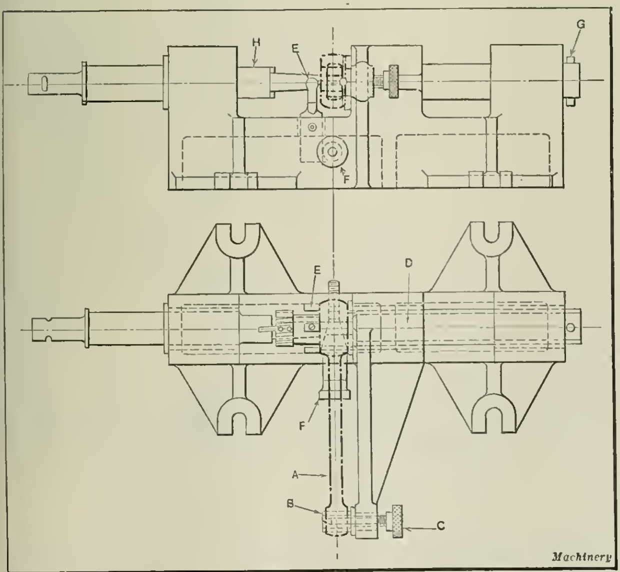

Fig. 1. Boring and Reaming Fixture for Connecting-rod Bearing

LISTS FOR CHECKING DRAWINGS

A list as an aid in checking drawings has been tried out at one time or another in nearly every drafting-room. Checking lists are very good in principle, but in practice it is usually found that the checkers lay them away as soon as the novelty has worn off. One firm has insured daily reference to its checking lists by providing blank spaces to the right of each item on the list. The drawing number is entered at the head of the column and as each item is checked, a mark is made in the proper space.

When the checking is completed, the check list and drawings are turned in to the chief draftsman. The improvement in the quality of checking which was noticeable when checking lists were first introduced in this drafting-room has been maintained, although the lists have been in use for more than eight months. The two check lists adopted (one for lay-out and one for detail drawings) were compiled after a study of several representative ones. The scope of the lists examined varied widely and none of them could be adopted outright. It seems to be necessary for each drafting-room to make its own checking list to suit local conditions.

The lists finally adopted, which proved satisfactory in this particular instance, are given here simply to illustrate the general nature of the checking system. After the lists were prepared, they were carefully traced and blueprint copies furnished to the checkers. At the head of the lists a space was left for the name of the checker and the date. It will be noted that the various items in the check list for lay-out drawings are arranged in groups; for instance, in the first group there are only two items, namely, the drawing number and the original data, while in the third group there are ten items, including the group heading and the subheadings.

The check list for lay-out drawings included the following items in the order given:

1. Drawing number; original data.

2. Design, including (a) rigidity; (b) strength; (c) formulas; and (d) numerical work.

3. Practice, including (A) finish, under which are given the items (a) limits of accuracy necessary, and (b) use of finish pads; (B) methods of fastening, with reference to bolts, studs, cap-screws, etc., and their (a)

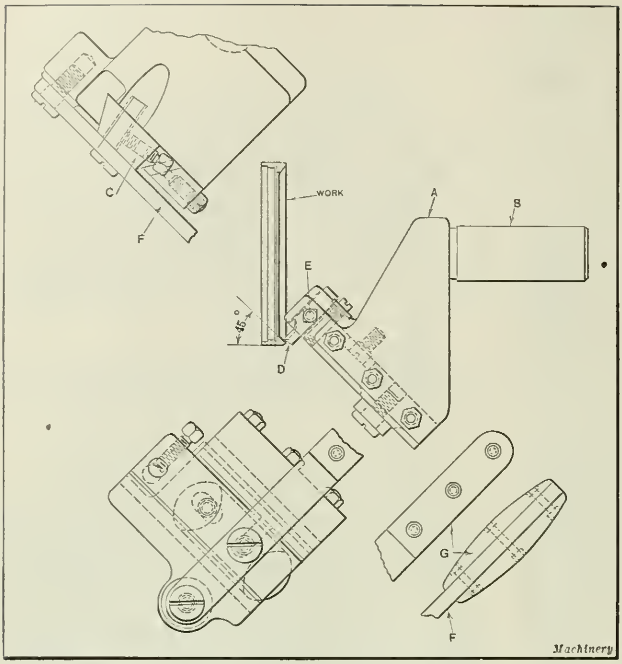

Fig. 1. Auxiliary Cross-slide designed for turning a 45-degree Taper

position; (b) size; (c) number; (d) removable with standard wrenches; and (e) clearance provided for bolt-heads and nuts.

4. Ease of manufacturing parts with reference to: (A) molding, including (a) fillets of sufficient size; (b) draft; and (c) cores; (B) forging, with reference to (a) machining, (b) use of jigs and fixtures, (c) use of standard sizes and standard parts, and (d) use of old parts, patterns, etc.

5. Interference, with reference to: (a) assembly checked with detailed drawings, and (b) operation of machine from checking assembly drawings.

6. Operation with regard to (a) simplicity, (b) ease of adjustment, (c) ease of repairing, and (d) provision for proper lubrication.

7. Check drawings with drafting-room standards.

The items to be checked as given on the check list for detail drawings, were as follows: Drawing number; neatness and clearness; crowding; lettering; center and section lines; projections correct; drawn in relative assembled position; drawn to scale; all necessary dimensions given; dimensions repeated; finish marks; limits; notes; name; number of pieces required; material specification and treatment; drawing, pattern and piece numbers; initials, date and scale; use of a part already made; standard parts and sizes; easily machined and molded; checks with component parts; how fastened in place; easily assembled; interference of moving parts; interference in assembly; lubrication; check with drafting-room standards; index card; drawing checked.

Spinner

AUXILIARY CROSS-SLIDES FOR TURRET LATHES

The special turret tools shown in Figs. 1, 2, and 3 were designed for the purpose of providing a more sensitive feed and stop than is possible with the standard style of box-tool, boring tool, or facing tool, and at the same time affording a means of obtaining greater production through the provision of a lighter and therefore faster means of feeding the cutter. Too often a large heavy turret is employed when taking a comparatively light cut, the work being placed on the large machine because of its size or the nature of other operations that are to be performed.

An example of this class of work is shown in Fig. 1. The large diameter of the work in this case made it necessary to use a machine as large as a No. 2 Brown & Sharpe or a No. 2 Warner & Swasey hand screw machine. The cast-iron holder *A*, with its shank *B* cast integral, is provided with a gibbed dovetail slide *C*. The cutter *D* is made from round tool steel, and is retained in the slide by a set-screw *E*. The slide is operated by the lever *F*, the handle of which is shown at *G*.

The accuracy obtained by the use of this tool in finishing the work to the required 45-degree angle was greater than that resulting from the use of a formed blade held in a regular box-tool holder. The expense for cutters was also considerably reduced by the use of the auxiliary slide. A tool of this design need never become obsolete, owing to the fact that it can be easily equipped for application to a large variety of work.

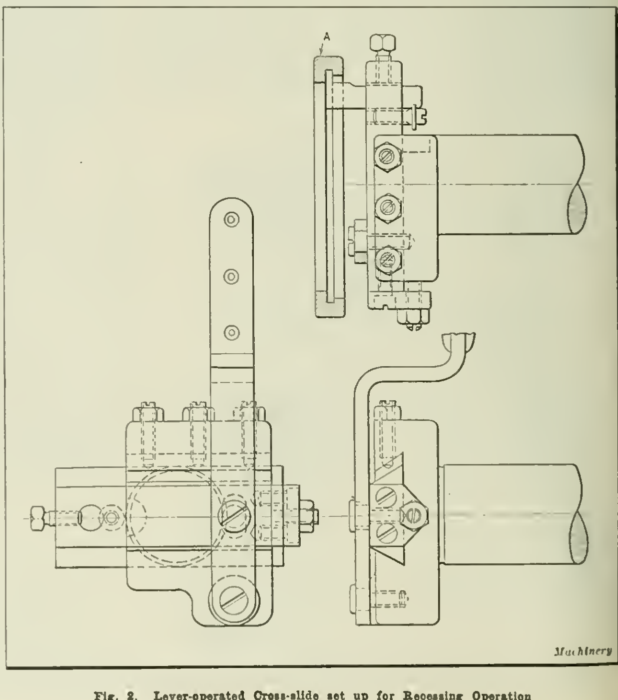

Fig. 2. Lever-operated Cross-slide set up for Recessing Operation

The tool shown in Fig. 2 is similar in design to that shown in Fig. 1. It was originally intended for performing a recessing operation on the part shown at *A*, but it could also be used without change for a variety of boring, facing, or forming operations by providing the necessary style of cutter. This type of tool provides a convenient means of finish-forming when the cross-slide toolposts are used for rough-forming and cutting off. Circular forming cutters for this kind of work should be made with stems to suit the holder. If the holder is intended to be used with a large variety of cutters, it should have a larger hole than otherwise and be provided with a set of bushings to correspond with the cutters.

A somewhat different style of holder is illustrated in Fig. 3, which was designed to accommodate three cutters, as shown. The question of using the regular feed of the hand screw machine or that of the auxiliary slide depends largely upon the class of work to be done, and whether a high production rate or extreme accuracy is more desirable. The use of auxiliary slides of the types described would greatly increase the accuracy obtainable on hand screw machines having worn cross-slides and turret-slides or turret tool-holes that have become battered and out of alignment.

In such cases it is possible to obtain quite accurate results if the work is chucked and has a hole in the center (as is usually the case) by aligning the turret tool with the spindle by means of a pilot on the tool and a bushing in the spindle. The slide on the tool would then take the place of the worn cross-slide for the finishing operation, with results equivalent to those obtained with a new machine. In Fig. 4 is shown an auxiliary tool-slide adapted for use on a bench lathe, bench mill, floor lathe, or hand screw machine. The work shown at *A* was more accurately machined by the use of the special tool-slide in this particular case than it could have been by using the regular cross-slide and a forming tool. This special tool also made it possible to increase production more than 100 per cent.

HENDEY MACHINE COMPANY 1870-1920

An anniversary volume entitled "Hendey 1870-1920" has been published by the Hendey Machine Co., Torrington, Conn., in which is recorded the history of the company from the time of its foundation in 1870 until the end of the first half century of its existence. This book contains an interesting account of the founder, Henry J. Hendey, of this well-known machine tool building enterprise, of whom it says that "confronted by adverse conditions, hampered by lack of money, but with a splendid faith in what the future held, his many fine qualities and sheer strength of character asserted themselves. An unshaken courage, a steadfast determination, decision; these were his outstanding characteristics."

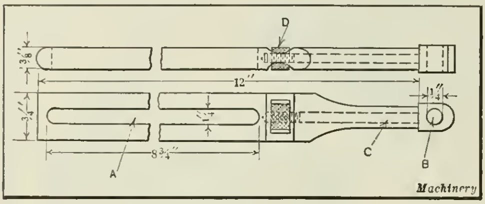
In 1870, Henry J. Hendey, a toolmaker of Torrington, Conn., and his younger brother Arthur Hendey, then a patternmaker in New Haven, associated themselves in the launching of a new enterprise with a very humble beginning. In referring to the starting of the business, the review states that "in the present period of business inactivity, there is a homely lesson in the courage and confidence of the founder of this enterprise, who, due to business depression, was at the time unemployed, but who did not hesitate to face forward, backed only by mentality and muscle and that invariable and constant asset, an unfaltering faith in America."

The motive power of the first shop was a three-horsepower rotary engine made by Henry Hendey at night after leaving his daily task. This engine has been preserved and is still to be seen on a table in the engine room of the present Hendey plant in Torrington. The gradual growth of the business from its small beginning to its present proportions is well illustrated by many interesting photographs showing the earlier shops and the present plant. The book also shows the development of the types of machines associated with the name Hendey, from the simple designs of 1870 to the high-production shapers, milling machines, and lathes of 1922. It is being distributed to the friends and customers of the company.

SHOP AND DRAFTING-ROOM KINKS

UNIVERSAL INDICATOR HOLDER

The device shown herewith was made by the writer for the purpose of holding an indicator in any desired position. The slot *A* permits the holder to be attached to a machine or fixture by means of a ¼-inch bolt or cap-screw. A ¼-inch hole *B* in the threaded member *C* provides a means of holding the indicator itself. Part *C* is a good fit in the shank of the holder, and is clamped in position by means of a knurled nut *D*. From the illustration it will be noted that slot *A* provides a means of adjusting the position of the indicator either outward or inward for a distance of approximately 8 inches, and that part *C* to which the indicator is directly attached can be revolved about its axis and locked in any desired position.

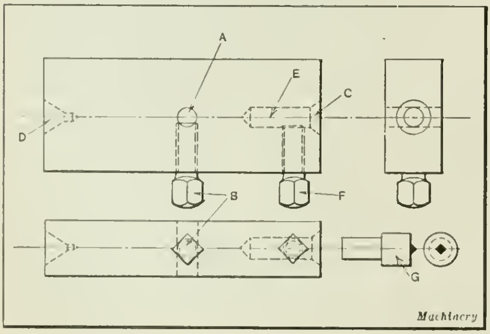


Adjustable Holder for Indicator

Rochester, N. Y. PHILIP A. HALL

HOLDER FOR TRUING DIAMOND

A convenient diamond-holder for tool-room work is shown in the accompanying illustration. It may be made from a piece of ½- by ¾-inch machine steel about 3½ inches long. It is finished all over and can be held on a magnetic chuck for truing surface-grinder wheels. For this work the flat side of the holder is placed on the magnetic chuck with the diamond held in hole *A*, where it is locked in place by set-screw *B*. It is understood, of course, that the diamond itself is mounted in a short round holder *G*. For truing a wheel on an electric toolpost grinder, the block is held by means of the centers *C* and *D*, the diamond being held in the same position as when used on a surface grinder. The machine centers should be screwed up tight to prevent the block from turning; excessive pressure, however, is not necessary if large centers are made in the block at *C* and *D*. The diamond-holder may also be held in a vise with the diamond clamped in hole *E* which is on the same center line as the countersunk center *C*. In this position, the diamond is locked in place by screw *F*.

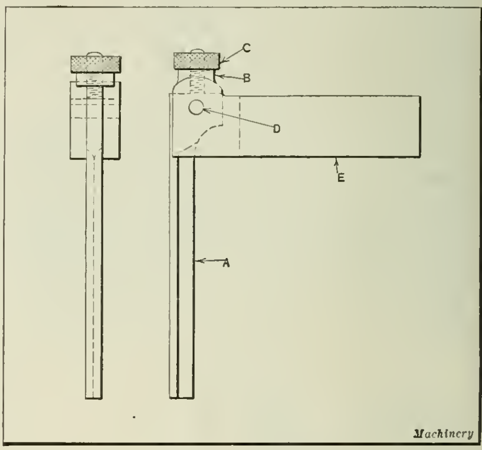


Holder for Grinding-wheel Truing Diamond

Ilion, N. Y. D. R. GALLAGHER

DIEMAKER'S SQUARE

The square shown in the accompanying illustration is of unusual design. It has the distinct advantage of being readily set to any angle within the narrow limits usually called for in diemaking. The body *E* is slotted at the front end to receive the blade *A*, and the latter is threaded at the top for nut *C*. Washer *B* is fitted to the radial part of body *E* and is a sliding fit on the screw. When nut *C* is tightened the blade will retain its exact setting, as washer *B* does not turn with the nut. The blade *A* is machined to a knife-edge on one side and swivels on a pin *D*. It can be assembled with the knife-edge down if desired.



Diemaker's Square

Rosemount, Montreal, Canada HARRY MOORE

WORK OF THE DEPARTMENT OF COMMERCE

The Bureau of Foreign and Domestic Commerce, the Bureau of Census, and the Bureau of Standards are at present the three chief points of contact between the Government and the commerce and industry of the country. These three bureaus receive annually about 300,000 inquiries. In a single day the Bureau of Foreign and Domestic Commerce received 514 inquiries from commercial concerns all over the country having to do with the promotion of foreign trade. The greatest difficulty under which the department labors is that the salary scale of the men and women employed in this important work dates back to 1914, and hence in many cases their compensation is about one-half that obtained for similar work in the general commercial field. The department is essentially in competition with business houses in finding men, and the economic pressure exerted on those employed by the department from the outside is constant and must be recognized. In the Bureau of Standards alone the turnover during the last five or six years has been about 50 per cent.

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

LEATHER WASHERS FOR CLEANING SHAFTING

R. F. B.—How are leather washers applied to lineshafting to keep the shafting clean between the pulleys?

A.—The leather washers which are sometimes used for this purpose simply have holes that are considerably larger than the shaft, so that the washer may easily be turned or twisted to an inclined position relative to the shaft. As the shafting revolves, the washer travels from one pulley to another, and when it comes into contact with the hub of a pulley its angular position is changed, so that it begins to travel in the opposite direction. The backward and forward movement is continued automatically, and as the result the shaft is kept clean and bright.

ROLLER BEARING TANGENCY PROBLEM

L. W. C.—In making tapered roller bearing cones, it sometimes happens that the cone is required to be ground accurately to a given radius r, Fig. 1. AB represents the back face of the finished cone, CD the back face of the cone before grinding, EF the finished bore, and GH the bore before finishing. In cases of this kind it is obviously important that the proper allowance be made for finish-grinding. The destructive effect of a sharp point or edge of steel on the face of the grinding wheel makes it desirable to so proportion the cone that as little stock as possible will need to be removed at the point where the back face joins radius r. The problem of determining radius R occurs when it is planned to make the radius of the unfinished forging and the finished radius tangent to each other in order to eliminate as far as possible the use of the wheel where the destructive effect is greatest. The problem, therefore, consists in determining the radius R, of a circle which is tangent to a given smaller circle, and to two lines at right angles to each other at given unequal distances from tangents to the smaller circle, as indicated in Fig. 2. In the illustration, the dimensions a, b, and r are known. Please show how to find R.

A.—In solving this problem, we may start out with three equations, assuming three unknown quantities R, y, and z, Fig. 2. From these three equations we obtain by substitution the final equation in which R is the only unknown quantity. Note that $x = \sqrt{y^2 + z^2}$.

We then have the three equations:

$$R = x + r = \sqrt{y^2 + z^2} + r \qquad (1)$$
$$R = y + r + a \qquad (2)$$
$$R = z + r + b \qquad (3)$$

Transposing,

$$z = R - r - b$$

Then, from Equation (1),

$$R = \sqrt{y^2 + (R - r - b)^2} + r$$

Transposing terms in Equation (2) we have,

$$y = R - r - a$$

Therefore

$$R = \sqrt{(R - r - a)^2 + (R - r - b)^2} + r$$

It is, of course, possible to solve this equation for R by transposing r to the left-hand side of the equation and then squaring both sides, which will result in a quadratic equation. In a problem of this type, however, the trial method will be equally rapid—that is, a trial value may be substituted for R that is as nearly exact as it is possible to determine by measuring a scale drawing. The substituted value is then slightly adjusted until it satisfies the equation.

CALCULATING DIAMETER OF ROLL FOR ROLLER CLUTCH

W. A. Z.—In the accompanying diagram are shown the conditions encountered in the design of a roller clutch. From the dimensions given, please explain the method of finding the diameter of the roll.

ANSWERED BY LEWIS D. CASTOR

A.—Referring to the diagram, it will be evident that

$$OK = \sqrt{1.25^2 + 0.25^2} = 1.2747$$

$$\text{Sin } OKA = \frac{0.25}{1.2747} = 0.19612$$

Hence

$$OKA = 11 \text{ degrees } 19 \text{ minutes}$$

By construction, angle AKH = 60 degrees; therefore

$$OKH = 60 \text{ deg.} + 11 \text{ deg. } 19 \text{ min.} = 71 \text{ deg. } 19 \text{ min.}$$

and

$$HK = r \times \sec 30 \text{ degrees} = r \times 1.1547$$

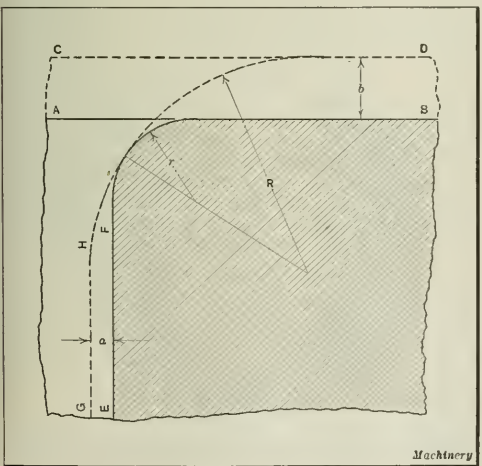

Fig. 1. Section of Roller Bearing Cone illustrating Tangency Problem

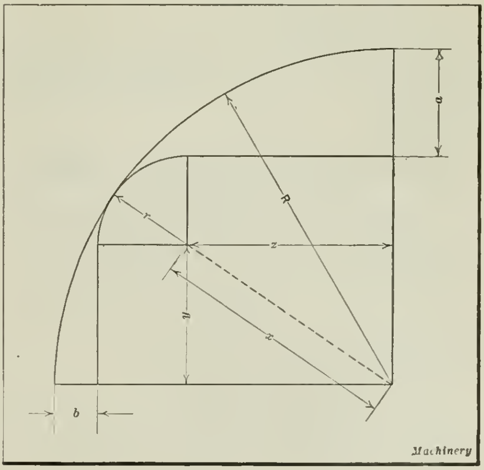

Fig. 2. Diagram used in the Solution of the Tangency Problem

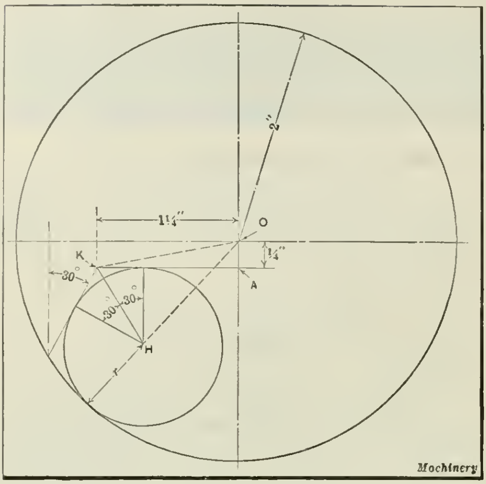

Diagram for finding Diameter of Roll for Roller Clutch

Also

$$OH = 2 - r$$

According to the equation given in MACHINERY'S HANDBOOK, page 152, for solving an obtuse-angled triangle, when two sides and the angle between them are known, we have:

OH or $2 - r = \sqrt{HK^2 + OK^2 - 2\,(HK \times OK \times \cos OKH)}$

Substituting the numerical values of the known quantities,

$$2 - r =$$

$$\sqrt{(1.1547r)^2 + 1.2747^2 - 2\,(1.1547r \times 1.2747 \times 0.32034)}$$

$$2 - r = \sqrt{1.3333r^2 + 1.6248 - 2\,(1.1547r \times 0.40833)}$$

$$= \sqrt{1.3333r^2 - 0.9430r + 1.6248}$$

Squaring the left-hand member, we have,

$$4 - 4r + r^2 = 1.333r^2 - 0.943r + 1.625$$

Transposing and uniting terms

$$0.333r^2 + 3.057r = 2.375$$

or

$$r^2 + 9.18r = 7.1321$$

Solving this quadratic equation according to the formula given in MACHINERY'S HANDBOOK, on page 100,

$$r = -\frac{9.18}{2} \pm \sqrt{\frac{9.18^2}{4} + 7.1321}$$

$$r = -4.59 \pm 5.3104$$

$$r = 0.7204 \text{ inch}$$

Hence the diameter of the roll is equal to $2r$ or 1.4408 inches. It will be noted that in the foregoing solution only such formulas as are to be found in MACHINERY'S HANDBOOK are employed.

REMOVING ONE-HALF THE VOLUME OF A SPHERE

F. D. K.—Please give a general method of determining the diameter of the hole that must be drilled through the center of a 3-inch sphere to remove one-half the contents.

ANSWERED BY W. W. JOHNSON, CLEVELAND, OHIO

From the diagram it will be seen that the material to be removed by drilling consists of two equal spherical segments and a cylinder.

Let R = the radius of the sphere, and
$2h$ = the altitude of the cylinder.

Then

$R - h$ = the altitude of the spherical segment

and

$\sqrt{R^2 - h^2}$ = the radius of the base of the segment and the radius of the cylinder.

The volume of the two spherical segments in terms of R and h is:

$$2[1/2\ \pi(R - h)\ (R^2 - h^2) + 1/6\ \pi(R - h)^3]$$

and the volume of the cylinder $= 2\pi h(R^2 - h^2)$

To remove $\frac{1}{n}$ of the sphere we have 2 times the volume of one segment plus the volume of the cylinder $= \frac{1}{n}$ the volume of the sphere.

Therefore,

$$\pi(R - h)\ (R^2 - h^2) + \frac{1}{3}\pi(R - h)^3 + 2\pi h(R^2 - h^2) = \frac{1}{n}\left(\frac{4}{3}\pi R^2\right)$$

Expanding and combining terms,

$$\frac{4}{3}\pi(R^3 - h^3) = \frac{1}{n}\left(\frac{4}{3}\pi R^2\right)$$

Removing the factor $\frac{4}{3}\pi$,

$$R^2 - h^3 = \frac{1}{n}R^3 \qquad (1)$$

Again, referring to the diagram, $h = R \cos \phi$. Substituting this value for h in Equation (1), and removing the factor R^3,

$$\text{Cos}^3\ \phi = 1 - \frac{1}{n} = \frac{n - 1}{n}$$

and

$$\text{Cos}\ \phi = \sqrt[3]{\frac{n - 1}{n}}$$

To remove one-half the volume of the sphere, let $n = 2$. Then

$$\text{Cos}\ \phi = \frac{1}{\sqrt[3]{2}},$$

and

$$\phi = 37 \text{ degrees } 28 \text{ minutes } 2 \text{ seconds}$$

Let D = diameter of sphere, and
d = diameter of hole.

Then,

$$d = D \sin \phi$$

For a 3-inch sphere this gives $d = 1.825$ inches.

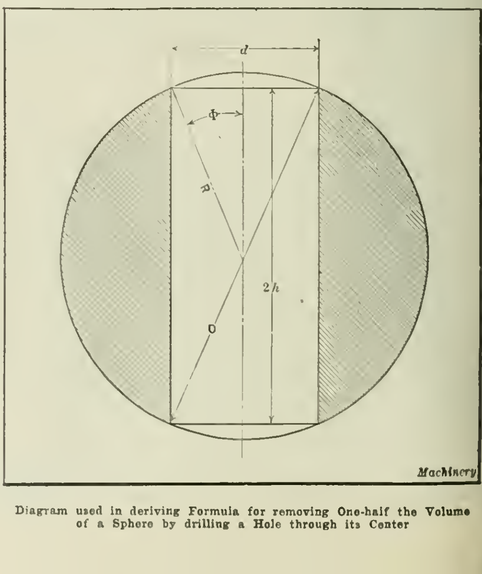

Diagram used in deriving Formula for removing One-half the Volume of a Sphere by drilling a Hole through its Center

The British Metal-working Industries

From MACHINERY'S Special Correspondent

London, April 14

AT the time of writing, the engineering dispute involving a lock-out of 250,000 men dominates all other conditions in the metal-working industries. The dispute hinges on the question of managerial rights, working conditions, and over-time. There is no evidence that a majority of the Amalgamated Engineering Union seriously challenges any fundamental rights of management, and it is expected in many quarters that the real bone of contention will ultimately be found to be a case of wage reduction.

That trade has dropped to a low ebb, due to the effect of the engineering dispute, cannot be denied, but this condition, it is thought, is only momentary. Indications of better conditions are too pronounced to admit of denial.

The Machine Tool Industry

Most of the firms engaged in the machine tool industry are members of the Engineers' Employers Federation, so that all the workers are locked out except apprentices. Prior to the lock-out the machine tool industry showed flickers of improvement, more particularly in connection with foreign business, which indicated an early revival.

A welcome piece of news was the statement made at the recent annual meeting of the Machine Tool Trades Association that 90 per cent of the government stock of surplus machine tools had been disposed of, and that only about 2500 machines remained to be sold. Altogether the Disposal Board has sold over 60,000 machines. Unfortunately government disposal does not represent the end of the matter, because it does not follow that the machines sold are actually in use; in fact, a considerable proportion of the machines are in the hands of dealers and will be certain to make their reappearance on the market as the demand increases.

A number of inquiries for machine tools has been received from abroad, but buyers are insistent on getting the lowest prices possible. As an indication of this, it might be mentioned that in some cases orders have been offered at 25 per cent less than the price quoted. This, of course, does not represent the average buyer's idea, but applies more to cases where machines can be used to advantage but are not urgently needed. Wage reductions in prospect always have two effects—either the buyer decides to wait until he can get the full benefit of reduced manufacturing costs, or if he does place an order, he expects the manufacturer to charge on the basis of the new wage rates.

One of the paramount troubles in the trade is the accumulation of stocks that can be replaced for less than the original cost of manufacture and that will still further depreciate in value as greater reductions are made in wages. Losses appear to be inevitable in the case of machines manufactured under the artificial conditions of a year ago. Activity is displayed in the small tool line, but orders are mostly for small quantities and quick delivery.

The Automobile Industry

In the automobile industry it is particularly unfortunate that the labor dispute should come along just at this time. During the last few weeks many promising inquiries from abroad have been reaching the manufacturers, and with the home season developing satisfactorily, factories have been actively preparing for increased output. Most firms are members of the Engineers' Employers Federation, and they have been forced to get along without toolmakers and fitters, who probably represent about 20 to 25 per cent of the total force. A number of machine operators and assemblers remain at work, but they cannot maintain production much longer alone.

The scarcity of stocks will bring deliveries to a standstill in many shops unless terms are speedily agreed upon. In certain departments there has been a considerable accumulation of finished parts for the completion of orders already started, but if production is interrupted in other allied branches these stocks will not help. Normally, manufacturers have plenty of materials and can go ahead safely in anticipation of the spring season, but there are various considerations which have deterred them from doing so this year. For instance, there is the lack of working capital and the restrictions on credit. Then there is the desire to get the utmost advantage from a falling market for raw materials. Most firms have, in fact, based their prices for this year's models on the assumption that materials would have reached a lower level. The light car makers are the busiest, but some of the commercial truck makers are working overtime.

Railway and Locomotive Engineering

Locomotive builders report conditions improving, especially inquiry from abroad, and will doubtless find an outlet for their product as soon as the present labor troubles are over. The Rumanian state railways, it is understood, contemplate placing a large order in which Glasgow manufacturers are expected to participate. Structural engineers have better prospects, perhaps, than any other branch, chiefly owing to railway developments in the Colonies and abroad. An important contract, involving a sum of £350,000, has been received by William Arrol & Co., Ltd., the well-known Glasgow engineers and bridge-builders. This is for the erection of work-shops for the Mexican State Railways at Enugo, and is the initial part of a big development scheme which includes the erection of a bridge over the river Benue.

The Iron and Steel Field

For the most part iron and steel users are buying only for immediate requirements, and in view of the uncertainty of the labor situation it is but natural that they should restrict their purchases at the present time. Even so, values remain steady. No inclination to delay deliveries of pig iron under existing contracts is noticeable, and some pressing inquiries have been received from Continental countries, including one of 1400 tons from Germany. Italy and Belgium are also in the market.

In the gray iron and malleable foundries, there is much more activity. One firm in Birmingham recently began a night shift and is making extensions to its plant that will double its output. This firm states that although the orders for castings are principally for the automobile industry, a good general trade has developed in the last few weeks.

The small concessions made by railway companies in the transit rates of fuel to steel works and blast furnaces have proved of little value, and the export trade is hampered by comparatively high freight rates.

Shipbuilding

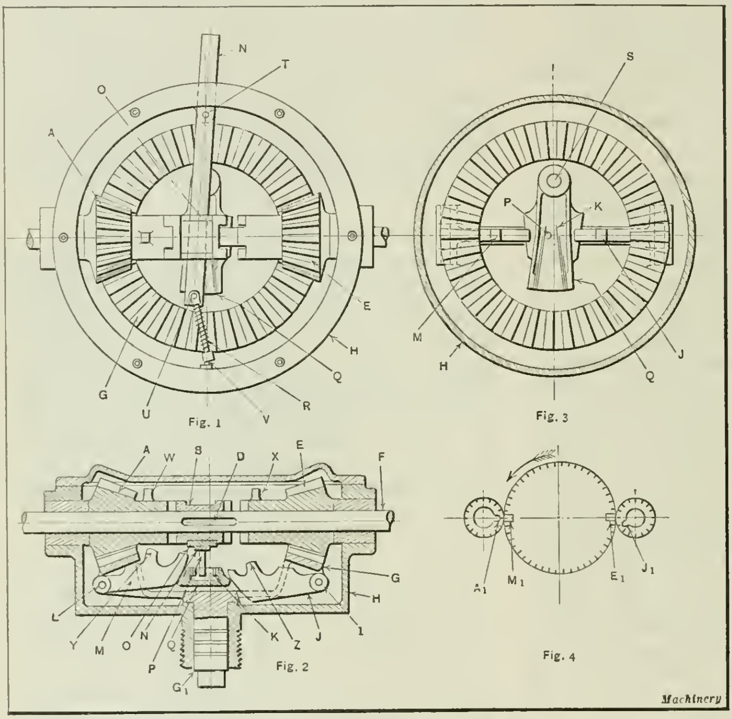
The shipbuilding industry, at the time of writing, is at a standstill owing to the cooperation with the engineers' union, but quite apart from that disturbing feature, it must be some time before orders will mature from this quarter. The machine tools in the shipyard engineering shops which, under normal conditions of night and day shifts last about two years, have not been worked under these conditions since the armistice, and consequently are still in good condition.

RECIPROCATING MOTION MECHANISM

By DAVID ERSSON

The reciprocating motion mechanism which is described in this article is one important unit in the construction of a washing machine. The principal driving members of the mechanism consist of the commonly employed gear and double pinions, the latter being located diametrically opposite each other. The reversing parts are of simple construction and are designed to eliminate wear and friction as far as possible. They have been found to work faultlessly and are positive in their action. In Figs. 1, 2, and 3 the same reference letters are used to denote the same parts.

The cast-iron housing H carries the vertical shaft G_1, which connects the main gear G with the drum on the washing machine. The two pinions A and E run on the horizontal shaft F which is connected with the motor or power source. This shaft is provided with a key-slot and key D upon which the double-ended clutch jaw B slides. The center of this clutch jaw is recessed to receive a semicircular bushing O. This bushing has a square section on its outer side which is in contact with the starting and stopping lever N. The bushing O is provided with flanges on both sides which keep lever N in its proper position.



Figs. 1 to 3. Reversing Mechanism used on Washing Machine. Fig. 4. Diagrammatical Lay-out showing Relative Positions of Reversing Lugs

Another lever Q swivels on a stud S driven into gear G. Movement is imparted from lever N to lever Q by a pin P which is driven into lever N. This pin extends down into a recess in lever Q and works against two shock-absorbing springs K, one spring being located on each side of the recess. Gear G carries, besides stud S and reversing lever Q, the two cams J and M located in slots which extend below the gear and toward the center. These cams are arranged diametrically opposite each other and are pivoted on their respective studs I and L.

The form of the cams is best seen by reference to Fig. 2. On the upper side of the cams are located lugs Y and Z which at intervals come in contact with lugs W and X, the latter being cast on the extensions of pinions A and E. The purpose of the cams is to push lever Q over the center, one cam coming into action when the main gear is revolving to the right and the other when it is revolving to the left. Thus when cam M is in the position shown with lever Q over to the left of the center, lug Y comes in line with lug W on pinion A at a certain moment. When this happens lug W pushes the cam down and this, in turn, forces lever Q over the center to a similar position on the right, carrying with it the other movable parts—pin P, lever N, bushing O. and clutch jaw B. The latter member is now disengaged from pinion A and engaged with pinion E, thus imparting the reciprocating or reversing motion to gear G.

When lever Q moves over to the right it also pushes cam J up into a new position, ready to act similarly to the other cam. To obtain a good working action, there must be a certain ratio between the gear and the mating pinions, and this ratio must be based on the number of revolutions which the washing machine barrel is required to make before reversing. In this case eight revolutions are chosen for half a period, or double that (sixteen revolutions) for one whole period. To obtain this, the ratio must be 8 to 23. The number of teeth in this case is 16 for the pinions and 46 for the gear. Another thing to be taken into consideration is the location of the lugs on the pinions. Fig. 4 shows a diagrammatical lay-out of the relative positions of these lugs in regard to each other and also to the cams. Assume that the barrel of the washing machine has completed one period of sixteen revolutions and is ready for the next period, and that the gear will now revolve in the direction indicated by the arrow for the next eight revolutions. After completing the eight revolutions, the direction of rotation is reversed by means of lug J_1, which comes in contact with cam E_1. To obtain this action, the gear and pinions must be so assembled that lug J_1 lacks just two tooth spaces of making contact with cam E_1, when lug A_1 is in contact with cam M_1, as illustrated.

When the required eight revolutions are completed, lug A_1 again comes in contact with cam M_1 and the motion is reversed again for the next eight revolutions. A coil spring R, Fig. 1, holds lever N in the required position on each side of the center. This spring is seated at point V on the housing, and is guided on the lever by means of a pin U. Lever N is mounted on a pin T located diametrically opposite point V on the housing. The lever is extended outside the casing so that the operator can get a good grip on it for starting and stopping the mechanism.

* * *

The installation of sixty-seven double-frame steam drop-hammers at the Highland Park plant of the Ford Motor Co., Detroit, now in process, is an important step by the Ford organization in its plan to do practically all of its own drop-forging work. The new hammers range in size from 800 to 5000 pounds' capacity and are being placed in operation immediately upon being set up.

STRIPPERS FOR DRAWING DIES

By N. T. THURSTON

The success of a drawing die or push-through die depends largely upon the efficiency of the stripper employed to strip the stock from the punch on the upward stroke of the press ram. Even with a properly designed stripper there is likely to be some spoilage, particularly when drawing light gage metal. This spoilage is increased, of course, when the stripper is not the correct type for the work. Each of the three styles of strippers described in the following has its distinct features, and it is the purpose of this article to make clear the class of work for which each has been found best adapted.

Stripper for Small Work

The die shown in Fig. 1 is equipped with a type of stripper which has proved satisfactory for small work. This stripper, however, will seldom be found suitable for shells over 1 inch in diameter. A shell of 22-gage brass stock, ½ inch in diameter and 2 inches long is representative of the class of work for which this type should be used. The stripper consists of a split ring of tool steel composed of four parts or segments. As shown in the illustration, the segments are grooved to receive a circular wire spring *A* which holds them in place. As the shell is pushed through the die and enters the stripper, the segments are forced back allowing the shell to pass through.

On the return stroke of the punch the segments grip the punch above the shell and thus serve to strip the shell from the punch. This stripper is the least positive of the three described in this article, and its success depends upon using it with shells of small diameter having thin walls. The stripper is held flat and in place by the tool steel forming plate *B*. This plate, in turn, is kept in position by the three clamps fastened to the top of the die, one of which is shown at *C*. By merely removing the clamps, the forming plate and the stripper are left free so that they can be lifted from the die.

Stripper for Thick-walled Shells

The die shown in Fig. 2 is equipped with spring-actuated strippers, and has been found to be best suited for use in dies employed for drawing thick-walled shells varying from 1½ to 5 inches in diameter that are less than 6 inches in length. This die is mounted on a machine steel base while the forming parts are of tool steel, hardened and ground. The strippers *A* are also of tool steel, hardened and ground, and are kept in constant contact with the shell by the compression springs *B* which force them outward into the die opening. These strippers are provided with a shoulder so that they can extend into the die opening only a certain distance, and they are made a good sliding fit in the slots in ring *C*.

As these strippers have only a small bearing surface on the shell, it is necessary to make them rather sharp on the edges which come in contact with the work. As will be noted by referring to the view in the upper right-hand corner of Fig. 2, the end of the stripper which bears on the work is not only rounded, but also beveled at an angle of 2 degrees. For this reason the stripping action is severe, and shells having thin walls are found to tear and wrinkle badly when this type of stripper is used. This type, however, is the most positive of the three types described in this article. It has proved most successful when used on shells having a wall thickness of not less than 20 gage. A shallow 8-gage steel shell, for instance, is well handled by this stripper, whereas a stripper of the type shown in Fig. 1 would be entirely unsuitable. The rate of production on work of the type shown in Fig. 2 can be very high, as a good operator, protected by safety devices, can keep the press running continuously, 5000 pieces in a ten-hour day being the average production.

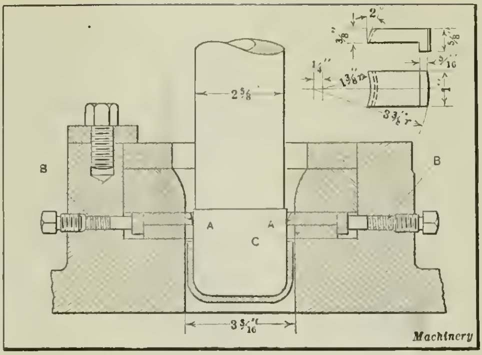


Fig. 1. Drawing Die equipped with Segment Type Stripper

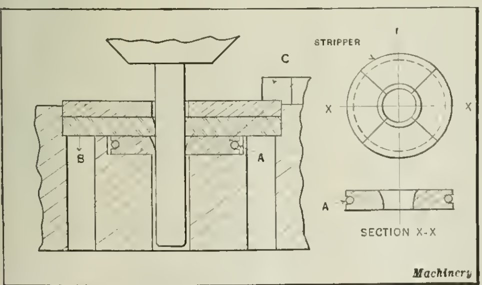

Fig. 2. Die equipped with Two Spring-actuated Strippers

Stripper for Large-diameter Thin-walled Shells

The die shown in Fig. 3 is equipped with a stripper constructed on an entirely different principle from that of the strippers previously described. In the types described, spring pressure is applied at right angles to the part of the shell being pushed through the die. In the type shown in Fig. 3, however, spring *A* applies pressure in a direction parallel to the path of the shell, and the gripping action of the jaws *B* is similar to that of a collet. This die is held in a cast-iron base, the forming ring being tool steel, hardened and ground, as are also the gripping jaws. The plate *C* held to the bottom of the die by four ½-inch screws (not shown) is machine steel and holds the six action-pin springs in place.

As the shell passes through the forming ring, it strikes the jaws of the collet and forces them down and outward. The ¼-inch clearance at *D* between the bottom of the jaws and the top of the machine-steel ring below them permits this downward movement. At the end of the downward stroke the top of the shell is still in contact with the base of the jaws, which, actuated by the constant spring pressure forcing them upward, grip the shell and hold it fast while the punch continues upward and thus strips the shell off so that it drops through the die at the next stroke.

The action-pins *F* are made from 1-inch cold-rolled stock machined to ½ inch at both ends. A clearance of ⅛ inch is provided in the holes in which the pins enter the jaws. Without this clearance the jaws would not be able to expand or contract. The pins extending into the base of the jaws for about ½ inch serve to keep the jaws from moving in a circular direction. The compression springs used on the pins have an inside diameter of ⅝ inch and a length of about 2½ inches. The gripping power of the stripper is adjusted by the machine-steel ring *E* which lies on the top of the jaws. By grinding off the under side of this ring against which the jaws are forced by the springs, a greater upward and inward movement of the jaws is permitted.

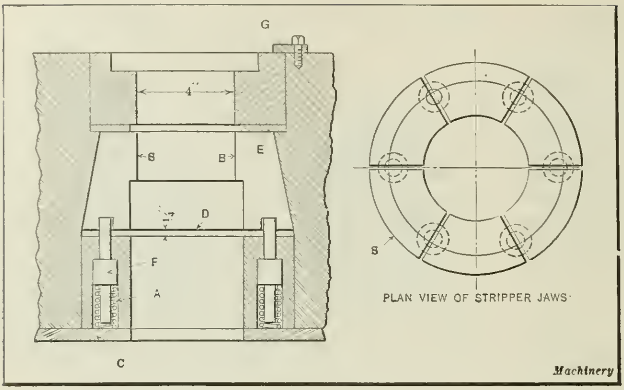

Fig. 3. Push-through Die fitted with Stripper adapted for Long Thin-shelled Work

This of course causes the shell to be more tightly gripped. To provide for an equal pressure on the jaw sections, the spring-actuated pins are placed under the separations in the jaws so that each pin bears on two sections of the stripper at the same time. The forming ring in the top of the die is left loose and can be lifted out of the die at any time by removing the three cleats *G* at the top.

This type of stripper was found to be the best for stripping shells about 4½ inches in diameter and about 12 inches long, which were being pushed through the die on a rack-and-pinion press. Inspection of the shells pressed through the die on which this stripper was employed, showed that less than 2 per cent failed to pass because of defects resulting from the stripping operation, whereas about 15 per cent were spoiled when a stripper of the type shown in Fig. 2 was employed. The stripper shown in Fig. 3 is best suited for stripping shells of rather large diameter having comparatively thin walls. The reason that it is useful on such work is that it has a large bearing surface which comes in contact with the work during the stripping operation.

REPAIRING CRANKSHAFT OF PUMP

By JAMES ELLIS

The writer recently had occasion to assist in repairing a hydraulic pump that had given considerable trouble. The pump was of the four-cylinder type having a crankshaft of the design shown at *A*. The break occurred at the point *B*, as indicated by the broken line. Several crankshafts had previously broken at this point and several sets of gears had also been worn out in an incredibly short time.

The difficulties encountered in replacing a pump crankshaft of this type will be readily understood by those experienced in the design of this kind of pump. The method of overcoming these difficulties in making the repair should therefore be of interest to designers as well as to those handling repair work. The chief difficulty in replacing the gears, pinions, pinion-shaft, or crankshaft of a pump of this type is in obtaining accurate alignment of the pinions *F* with respect to each other, and also with respect to their mating gears *G* which must also be properly aligned on the crankshaft.

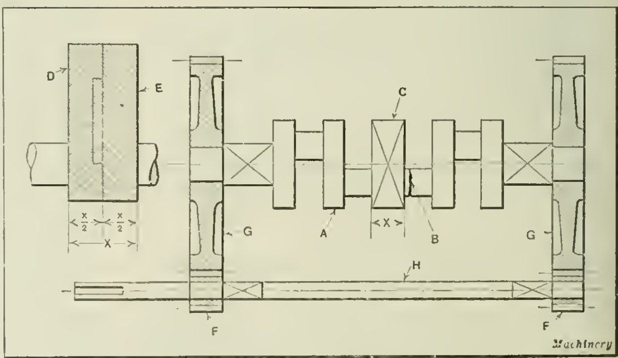
If any of these members are out of alignment, the torque produced in shaft *H* and in the crankshaft will cause unequal loads to be imposed on the gears, which will result in unequal wear on the gear teeth. As the wear increases, the difference in the load carried by each gear also increases until some one of the stressed members is broken.

In making the repair, the halves of two broken crankshafts were used. The bearing *C* of one broken crankshaft was machined as shown at *D* in the enlarged sectional view at the left, while the bearing of the other half was machined as shown at *E* to fit the recess in *D*. This allowed the load to be evenly distributed on the gears as was originally intended; that is, the gear at the right-hand end of the crankshaft and its mating pinion would carry one-half the load, while the gear and pinion at the other end of the shaft would carry the other half of the load. The full width of the original bearing surface at *C* was retained, and the shoulder (shown in the enlarged view at the left) allowed the thrust from the cylinders to be transmitted from one half of the bearing *C* to the other half, and at the same time it did not allow any of the turning force to be transmitted from one end of the crankshaft to the other.

At the time that this repair was made it was regarded as more or less of a makeshift, but after noting the satisfactory manner in which the pump operated, the writer has been led to believe that this construction would not be out of place in a new machine, provided that a large sized bearing is used at the center of the crankshaft. This construction would eliminate much of the tedious work of laying out keyways and the cost of production would be lowered. The pump repaired in the manner described has been in operation twenty-four hours a day for several months. A new shaft previously installed broke before it had been in operation for that length of time. The drive pinions are also resisting wear much better than they did when the one-piece crankshaft was used. The extra cost of making the shaft in two sections would probably be more than compensated for when building new machines, by the time saved in assembling.

* * *

Farmers of New York State, according to the *Review of Industry*, have taken a decided stand in favor of the repeal of the Full Crew Act, and a bill to abrogate the measure is to be submitted to the legislature. It is estimated that the waste resulting from this law has amounted in New York alone to from $2,000,000 to $3,000,000 since the law went into effect in 1913. In Pennsylvania the waste averaged $4,000,000 a year until the people of that state had the law repealed last year. Indiana has stricken a similar law from its statutes. Missouri voted against the measure in the proportion of 2 to 1. In Massachusetts, Oklahoma and Ohio, Full Crew Acts were vetoed by executive action.



Hydraulic Pump Crankshaft which broke at B

CALCULATING THE HORSEPOWER OF SPUR GEARS

By FRED ROSS EBERHARDT, Manager Gear Department
Newark Gear Cutting Machine Co., Newark, N. J.

As electric motors are used more widely for machine and mill drives, there is more frequent occasion to figure the size of gears required, and as motors are rated according to horsepower and speed in revolutions per minute, it is desirable to rate or calculate gears the same way, rather than to figure the breaking strength of the gears at loads in pounds.

The Lewis and Barth formulas are generally accepted as being the most satisfactory for industrial gearing where the pitch-line velocity is under 2000 feet per minute. In their usual forms, however, they are rather cumbersome to use, and it is very easy to make errors. Realizing the inadequacy of the ordinary formulas, a number of charts have been prepared by various engineers. It has been the writer's experience that these charts, as a rule, seem to be simple, but are even more complicated than the arithmetical process required to work out the Lewis formula, or else they are so abbreviated as to be inaccurate.

The following formula, which is based on the Lewis formula, has been arranged to simplify this work, especially for those who frequently have to calculate the power-transmitting capacity of gearing. In this formula

H = horsepower;
S = allowable static unit stress;
W = width of gear face in inches;
Y = outline factor for given number of teeth and pressure angle (see MACHINERY'S HANDBOOK, page 595, for table of factors);
V = velocity in feet per minute at pitch line of gear = 0.262 × pitch diameter in inches × R. P. M.; and
P = diametral pitch.

$$H = \frac{SWYV}{P\,55\,(600 + V)}$$

In using this formula, the values of S for accurately cut gears made of different materials are as follows: cast iron, 8000; semi-steel, 9000; U. S. Government bronze, 10,000; 0.30 per cent carbon steel, 15,000; 0.50 per cent carbon steel, 25,000; rawhide, 5000; bakelite, condensite, formica, textoil, etc., 5000.

Example—Find the horsepower that can be transmitted safely by a cast-iron spur gear which is to have 40 teeth of 4 diametral pitch, a 2-inch face width, and a speed of 80 R. P. M. It is assumed that the gear has accurately cut teeth, and the pressure angle is 14½ degrees. Then,

$$H = \frac{8000 \times 2 \times 0.34 \times 210}{4 \times 55 \times (600 + 210)}$$

$$= \frac{80 \times 2 \times 34 \times 210}{4 \times 55 \times 810} = 6.4 \text{ horsepower}$$

It will be noted that the arithmetical work is reduced somewhat simply by dropping the decimal point from the outline factor 0.34 and at the same time cancelling two ciphers from 8000 representing the static unit stress.

In determining the power-transmitting capacity of spur gears having cut teeth, the following general rules should be considered:

1. The horsepower a gear will transmit depends upon the quality of the material, accuracy of the teeth, rigidity of shafts, bearings, and housings, and the accuracy of the shaft alignment.

2. A gear supported on only one side should be made with a comparatively narrow face, a good rule being to make the face width in inches equal to 10 ÷ diametral pitch.

3. The gears should always be made *strong* enough; that is, they should be capable of transmitting at least 25 per cent more than the rated horsepower. The reason for this is that everything mechanical is subject to overload from one cause or another. If the drive is subject to a known overload, the gears should be made strong enough for the full overload, plus about 25 per cent for safety. Gears for crushers, rolls, and reciprocating pumps must often be made capable of carrying 250 per cent of the normal or rated load.

4. While it is possible to make spur gears with as few as three teeth, it is well known that small numbers of teeth are not satisfactory for high-speed or hard work. As a rule, it is not practical to use a pinion with less than 18 teeth, when the pitch line velocity exceeds 800 feet per minute.

5. When the gears are of rigid construction, mounted on rigid shafts supported on both sides of the gear face, and run in oil, a pitch-line velocity of 2000 feet per minute is permissible in some cases. Usually, however, it is well to keep below 800 feet per minute for metal gears to be used under ordinary conditions. Above 800 feet per minute it is well to use rawhide or bakelite for one of the gears, the other gear being made of metal. If noise is not objectionable, both gears may be made of metal. Strength and quietness can be obtained by making the pinion of laminated construction, using alternate plates of steel and bakelite, riveted together.

* * *

MACHINISTS AND TOOLMAKERS IN THE UNITED STATES

The Bureau of Census of the Department of Commerce has just completed a compilation of the number of machinists and toolmakers in the United States, classified according to states. From this compilation, as given in the accompanying table, it appears that in 1920 there were over 800,000 machinists and 55,000 toolmakers in the country, as compared with 461,300 machinists and 9240 toolmakers in 1910.

The twelve leading states as regards the number of machinists employed, in the order of their importance, are New York, Pennsylvania, Ohio, Illinois, Michigan, Massachusetts, New Jersey, California, Indiana, Wisconsin, Connecticut, and Missouri. The twelve leading states as regards the number of toolmakers employed are Michigan, New York, Ohio, Connecticut, Massachusetts, Illinois, New Jersey, Pennsylvania, Wisconsin, Rhode Island, Indiana and Missouri.

MACHINISTS AND TOOLMAKERS IN THE UNITED STATES ACCORDING TO 1920 CENSUS

State	Machinists	Toolmakers and Die-Sinkers	State	Machinists	Toolmakers and Die-Sinkers	State	Machinists	Toolmakers and Die-Sinkers	State	Machinists	Toolmakers and Die-Sinkers
United States	801,896	55,089	Illinois	63,889	4,098	Montana	2,142	5	Rhode Island	10,899	1,387

Machinery

The Machine-building Industries

THE gradual improvement in the machine tool business referred to in this review last month continues. In standard lines the improvement is very slow, and in some lines it is not perceptible; but there has been a fair demand for special machinery, and the automotive industries have either placed orders for, or are inquiring about, a fair amount of new equipment.

One of the most encouraging signs is the increased activity in the iron and steel field, which always, in due course, brings about a demand for machine tools and other shop equipment. About the middle of April the average operation in this industry was close to 75 per cent, the United States Steel Corporation in the Chicago district operating at 80 per cent of capacity, and the steel works in the Pittsburg district running close to 70 per cent. A very large part of the demand comes from the railroad field, hundreds of thousands of tons of steel being required for railroad cars and locomotives that have been ordered recently. Extensive repair work on the great number of freight cars out of commission also increases the demand for steel, and the building of new cars and locomotives and the repairing of old ones will naturally put into operation existing machine tool equipment and probably create some new demand.

Conditions in Different Branches of the Industry

The volume of business in the tool and contract field is increasing materially; but conditions are not satisfactory, because the prices quoted are too low and competition is not based on an accurate knowledge of costs. A number of the tool shops started during the war have gone out of business; but there are still a great many more shops of this type than present conditions warrant, and it is expected that there will be a further reduction in their number.

In the gear industry conditions are 'spotted.' This business has had its ups and downs during the entire depression. The makers of automobile gears are experiencing a steadier demand, and one of the largest gear manufacturers in this field is running over 50 per cent of the maximum capacity; this represents a business considerably in excess of the prewar output of this company.

In the die-casting field there has been a substantial improvement, especially in the demand for new dies. The diemaking departments of some of the die-casting plants are working overtime; others are occupied at about 100 per cent with regular time and force. The production of die-castings is not quite so active as die-making, but the improvement even in this field is noteworthy. Present activity in some plants is well over 50 per cent of capacity.

The ball-bearing industry shows signs of greater activity. One well-known maker states that while the present demand is only from 35 to 40 per cent of maximum capacity it is 50 per cent greater than the average demand for 1921. This statement is borne out by the conditions in the ball making factories, which have experienced a similar improvement.

The process of finding an outlet for the excess shop capacity in the machine tool and special tool field is making progress. In addition to the activities previously mentioned in past months in this review, some plants are turning to automobile accessories, watchmakers' machinery, truck parts, radio parts, etc., to keep their shops at least partly busy.

A constantly increasing interest in high-production and cost-reducing machinery and devices is being taken by manufacturers in general, particularly in the automobile field. The maker of a line of machine tools especially suitable for plants where high production counts, has for years tried to interest one of the largest and best-known automobile plants in his machines; but it was only recently that he was successful in gaining even an opportunity to demonstrate what his machines can do. The reduced prices on cars make it necessary for the builders to investigate every possible means of reducing manufacturing costs.

In the general machine-building field there has been a substantial demand for road-building and excavating machines, and some plants that ordinarily produce other equipment for which there is but a small demand at present, are keeping partially busy by diverting their organization and equipment to the building of such machinery. A large hydraulic pressed steel concern reports a definite business improvement in all of its plants.

The Automobile Industry

In the automobile industry there seems to be more confidence than there has been for the last eighteen months. It is true that automobile plants are now running at a higher rate than the average for the year, due to the seasonal demand, but the buying of dealers is said to be generally for actual sales rather than for stock.

The number of automobiles registered in the United States during the last twenty years, according to figures compiled by the Automobile Chamber of Commerce, are of considerable interest. In 1900 there were less than 14,000 automobiles registered. In 1905 this number had risen to 78,000, and in 1910 to 468,000. In 1915 there were close to 2,500,000 cars; in 1920, 9,211,000; and in 1921, 9,245,000. The schedule for the April production of Ford cars calls for over 90,000 automobiles. The total production of automobiles during February, according to the Department of Commerce statistics, was 109,005 passenger cars and 12,898 trucks.

The Truck and Tractor Industry

In the motor truck industry there has been an increase in the number of orders received, and an optimistic feeling prevails among truck manufacturers and dealers. The buying is more conservative than it was two years ago, and manufacturers have to make prompt shipments in order to close sales. There has also been a definite change for the better in the automobile parts business, but buying is largely for immediate requirements.

The tractor industry begins to show signs of improvement. One of the largest tractor builders in the Middle West reduced a stock of 5000 tractors to 400 during the fall and winter, and at that point began to operate on a manufacturing schedule of 75 tractors a day to replenish its stock. In the general farm machinery line, there has been but a slight change, but the Federal Reserve banks state that the reports from the agricultural sections are growing more favorable and that a spring demand is in evidence.

The Influence of the Radio Business

The demand for radio apparatus has created a considerable business for shops having suitable equipment for this kind of work. Small sizes of hand and automatic screw machines and power presses are needed chiefly for making the parts for receiving sets. Some of the machine tool builders have obtained business from this source, but much of the work is done by existing plants having the necessary equipment, a large part of which is idle on account of the general depression in the metal-working field. There will doubtless be a considerable volume of business in the radio field for some time to come, and if all the manufacturers of radio apparatus begin to make their own parts, instead of buying them from other concerns, there will be a demand for new machinery from this industry.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW AMERICAN METAL-WORKING MACHINERY

The New Tool descriptions in MACHINERY are restricted to the special field the journal covers—machine tools and accessories and other machine shop equipment. The editorial policy is to describe the machine or accessory so as to give the technical reader a definite idea of the design, construction, and function of the machine, of the mechanical principles involved, and of its application.

Blanchard Vertical-Spindle Surface Grinding Machine

PROBABLY the heaviest and most powerful vertical-spindle surface grinding machine ever built has been developed by the Blanchard Machine Co., 64 State St., Cambridge, Mass. This machine weighs about 30,000 pounds, is 12 feet 6 inches long, 7 feet 6 inches wide, and 10 feet high. In general arrangement it is similar to the No. 16 Blanchard grinding machine. The work is carried on a rotary magnetic chuck, which is moved horizontally from the loading to the grinding position, and then rotates continuously while the grinding wheel is gradually being fed downward. The chuck and table of the machine are traversed by power.

The grinding wheel is held by sulphur in a cast-iron retaining ring attached to the faceplate by six screws, and is wire-banded. The wheel-head weighs three tons and has a sixty-horsepower induction motor built into it, which runs at a speed of 600 revolutions per minute. The rotor is mounted directly on the wheel-spindle, which is carried in two large radial-thrust ball bearings. A spring take-up at the upper end exerts an upward pull on the spindle that exceeds the weight of the rotating parts by about 1000 pounds. This initial load on the lower or main thrust bearing serves to eliminate all play or backlash. The main bearing has a rated thrust-load capacity of over 25,000 pounds. Fig. 3 shows the principal parts of the wheel-head, with a man of average height standing behind them to give an idea of their size. The main ball bearing is in the left foreground of the illustration.

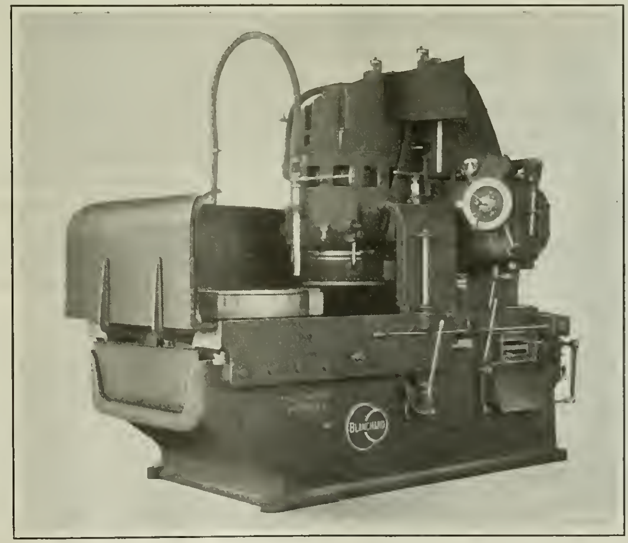

Fig. 1. No. 27-R High-power Vertical-spindle Surface Grinding Machine built by the Blanchard Machine Co.

The wheel-head slides vertically on the column, this movement being controlled by a feed-screw carried in ball bearings in the column. The feed-screw is driven through a gear-box, the mechanism of which is driven by the upper pulley at the right end of the machine. The latter may be clearly seen in Fig. 2. Double friction clutches provide for the rapid raising or lowering of the wheel-head. Both hand and power feeds are obtained by means of the box on the front of the column. The power feed has an automatic stop, and is supplied with a convenient adjustment which gives feeds of from 0.0005 to 0.005 inch per revolution of the chuck. One lever controls the engagement of the power feed and the raising and lowering clutches, the lever being so designed that these cannot be simultaneously engaged. The hand feed is 0.010 inch per crank revolution.

The wheel has a safety guard constructed of 5/16-inch steel plate which is supported on three steel rods, and it has a convenient rack-and-pinion mechanism for vertical adjustment. A dresser attached to the wheel-head provides for truing the wheel face while grinding. Water is supplied to the inside of the wheel through a 2-inch pipe and to the outside nozzle through a 1½-inch pipe. The column is fastened to the base by means of the usual Blanchard three-point support, which makes it easy to maintain proper alignment of the column.

The large pulley, seen in Fig. 2 near the base of the machine, transmits power for rotating the chuck, while the pulley to the right of it drives the water pump and the table-traversing mechanism. The chuck is driven through a four-speed gear-box having sliding gears and a friction clutch for starting and stopping. This clutch is interlocked with the gear-shifting mechanism. Power for all purposes, except driving the grinding wheel, is supplied by a 5-horsepower motor on the back of the column. The rotary magnetic chuck is of the one-piece steel type, and has closely spaced holes suitable for holding either small or large work. The face is made of brass and steel, and is waterproofed.

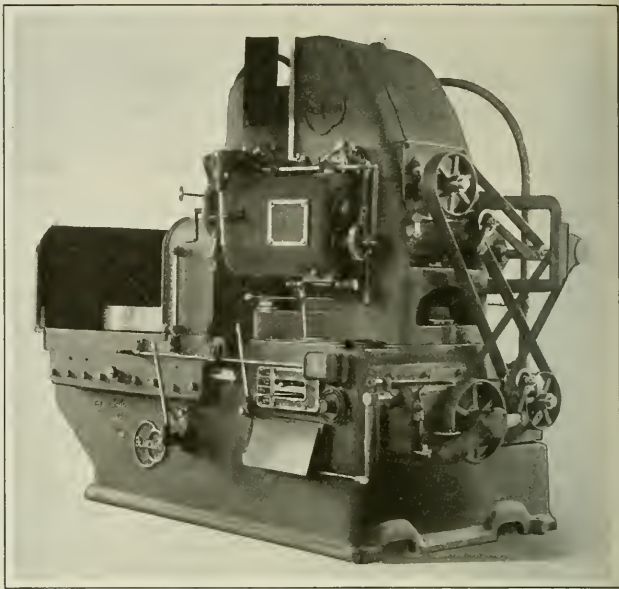

Fig. 2. Right-hand End of Blanchard Grinding Machine, showing Drive to Various Units

The chuck is caried on a table sliding on one flat way and one V-Way on the base. The table spans the base in such a way that all water and chips from the work fall directly into the first part of the water tank in the base. Here most of the solid material settles to the bottom, and the water overflows into the rear part of the tank where any remaining material settles. The water then flows under a skimmer which retains floating dirt and over another dam into the pump tank. The main tank is designed to facilitate cleaning. Both parts are so arranged that the entire bottom can be reached with the hoe provided, and an incline leading to an overhanging drip edge makes it easy to remove dirt into any receptacle. The pump tank holds 425 gallons.

Water guards made of ⅛-inch steel plate entirely surround the work and the grinding wheel. The section on the front of the machine was removed at the time the photographs were taken. The question of lubrication was carefully studied in the designing stage. Both main gear-boxes have pressure-feed lubrication from submerged gear pumps to every bearing. Other important units have a reservoir of oil with means for circulating or splashing to all bearings.

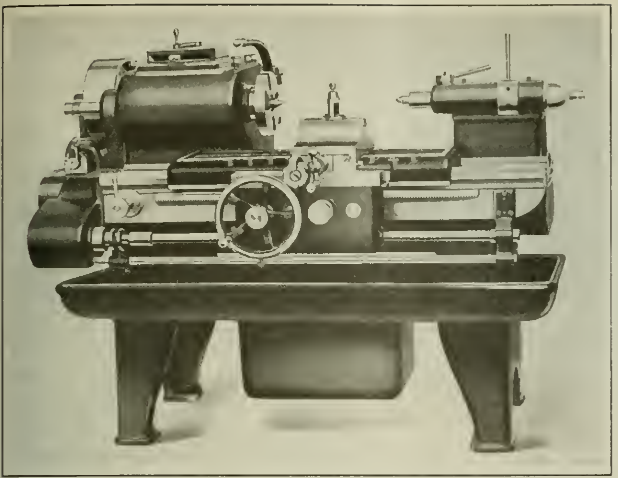
Some of the specifications of this machine are as follows: Range of work with a standard 42-inch chuck, 48 inches in diameter by 20 inches high; with an over-size 48-inch chuck, 48 inches in diameter and 16 inches high; maximum swing inside of water guards, 60 inches; wheel size, 27 inches in diameter by 7 inches thick and 2 or 3 inches width of rim; wheel speed, 580 revolutions per minute or 4100 feet per minute; and chuck speeds 3, 5, 8, and 13 revolutions per minute.

SUNDSTRAND HEAVY-DUTY MANUFACTURING LATHE

A 12-inch manufacturing lathe which is intended for specialized production but which is also suitable for handling a variety of work because of the incorporation of a cross-feed, quick-change feed and reverse to the carriage, is here illustrated. This machine can also be used for thread-cutting by substituting a lead-screw in place of the feed-rod. It has recently been added to the line of equipment built by the Rockford Tool Co., 2400 Eleventh St., Rockford, Ill. The bed is of the patented construction employed in Sundstrand lathes, having separate ways for the carriage, and the headstock and tailstock. This design allows the carriage to travel to the end of the bed in front of the tailstock and eliminates overhang of the tailstock spindle when short work is being supported.

The headstock is of the selective-speed type, and is driven by a single pulley furnished with a friction clutch. The clutch-operating lever is conveniently located, and the same movement that disengages the clutch automatically applies a brake which almost instantly stops the spindle. Nine spindle speeds are obtainable by means of two levers on top of the headstock, which operate sliding gears. The spindle can be locked by a plunger at the front end of the

Fig. 3. Principal Parts of the Wheel-head



Sundstrand Twelve-inch Manufacturing Lathe built by the Rockford Tool Co.

headstock, so that chucks and faceplates may be conveniently removed. The spindle has a hole running through its entire length, and the rear end is extended to permit the attachment of an air cylinder, draw-in attachments, expansion chucking device, etc.

The carriage has an exceptionally long bearing surface on the ways, and is arranged with a slide-block for a taper attachment. Provision is also made for mounting extra cross-slides, special tool-holder blocks, and similar attachments. A multiple stop collar furnishes a positive stop for the cross-slide when turning shafts with shoulders.

The apron is of the double-wall type, and so designed that a lead-screw can be substituted for the feed-rod. Practically all standard threads may be cut after such substitution, by the use of a few additional change-gears. The main feed-shaft or the lead-screw is connected to the feed-box shaft by means of a sliding clutch operated from a trip-rod on which collars can be placed at any point to stop the carriage movement automatically. The taper attachment is conveniently placed below the carriage, where it can easily be reached for adjustment.

A tool placed on the rear ways of the bed between the headstock and tailstock works simultaneously with the carriage, being driven by means of a rack fastened to the carriage. The tailstock is of a quick-acting design. The motor is attached to the rear of the bed, a silent chain transmitting power from the motor to the main driving shaft. An eccentric bushing provides for taking up slack of the chain.

Some of the specifications of this lathe are as follows: Swing over carriage, 12 inches; maximum distance between centers, 18 inches; diameter of hole through spindle, 1 11/32 inches; length of carriage on bed, 34 inches; number of feeds, 29; range of feeds, from 0.005 to 0.043 inch; range of spindle speeds, from 36 to 251 revolutions per minute; and weight of machine, 3130 pounds.

SENECA FALLS LATHES

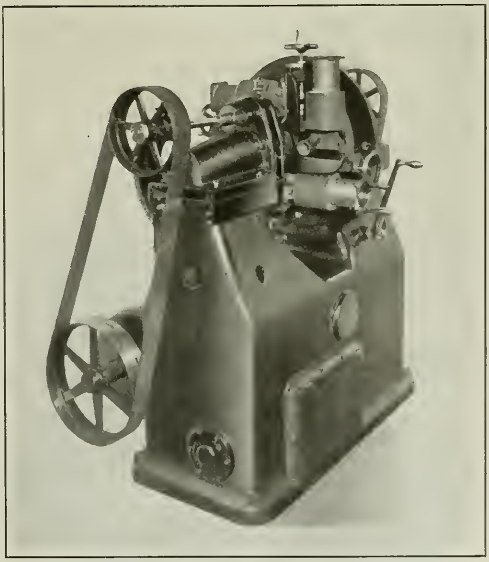
A line of engine lathes designed especially for the radio industry and automobile service stations is being made in various sizes ranging from 9 to 13 inches swing by the Seneca Falls Mfg. Co., 381 Fall St., Seneca Falls, N. Y. These machines are sold under the trade name of "Handy," and are similar in design to the gap-bed lathe described in February, 1920, MACHINERY, with the exception of the bed. The latter corresponds to the bed provided on the lathe described in April, 1919, MACHINERY. These lathes may be arranged for either belt or motor drive.

The same company is placing on the market a plain turning lathe, not provided with thread-cutting equipment. This machine will be of particular interest to the manufacturers of small electrical apparatus. It has a swing of 10⅛ inches, takes work up to 12 inches long between centers, and has feeds of from 0.002 to 0.040 inch per revolution of the spindle. It has a three-step cone pulley.

SEMI-AUTOMATIC TWO-WAY BORING MACHINE

A semi-automatic two-way boring machine designed primarily for boring, bottoming, and reaming the intake and exhaust ports of gas-engine cylinders, but which is also adaptable to similar operations on other work, is a product of the Manufacturers' Consulting Engineers, McCarthy Bldg., Syracuse, N. Y. An indexing fixture at the middle of the machine receives four pieces of work at one time. The work is clamped on the fixture in any of the four positions by tightening up a handwheel. The cutters are mounted in two multiple heads, which are placed on opposite sides of the fixture. Each head is supplied with three cutters. The two heads are fed simultaneously toward the work, and each time this movement is made, an operation is performed on three of the cylinders. At the same time the fourth is unloaded and a new one substituted. There is plenty of time between movements of the cutter-heads for reloading.

The feed of the cutter-heads is started by throwing in the clutch through the operation of a hand-lever at the front of the machine. One piece is completed every twenty seconds. The holes reamed in the work are 1 9/16 inches in diameter and 1 inch long. The motor for driving the machine is placed inside the base and drives a shaft running the length of the machine at the rear, which has a pulley on each end. Power is transmitted from the motor to this shaft through a chain and sprockets, and the pulleys on the ends of the shaft transmit the drive to the cutter-heads.



Motor-driven Semi-automatic Two-way Boring Machine brought out by the Manufacturers' Consulting Engineers

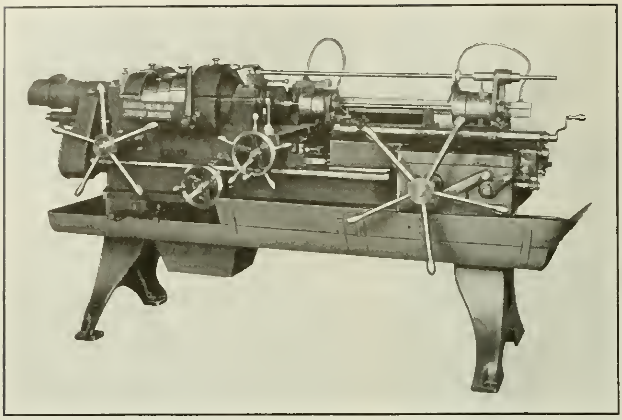


Fig. 1. Staybolt Machine built by the Millholland Machine Co.

The main driving shaft has a worm near the middle which drives a worm-wheel on a shaft having two cams. These cams actuate lever arms connecting with the cutter-heads and cause them to reciprocate to and from the work. A trip on the camshaft throws out the clutch at the completion of each cycle and stops the movement of the cutter-heads. The latter slide on ways similar to those of a shaper, and the work is positively held in alignment with the cutter-heads by the shaft on which the work-fixture is mounted. Each cutter has a multiplicity of cutting edges, which permits the use of a rapid feed per revolution.

LASSITER-MILLHOLLAND STAYBOLT MACHINE

Increased steam pressures in locomotive boilers have necessitated that the thread of staybolts used in their construction be uniform in pitch and that the lead of the threads on each end be continuous relative to each other. With the staybolt machine illustrated, a continuous lead is assured, as the machine slide is fed by a lead-screw in cutting the threads. This machine is built by the Millholland Machine Co., 1102 W. 23rd St., Indianapolis, Ind., and the Dale Machinery Co., Inc., 17 E. 42nd St., New York City, is the exclusive selling agent. The machine is built in two types, a Model A for rigid side staybolts, which have straight threads cut on both ends, and a Model B, for radial, flexible button-head, and crown staybolts, which have a straight thread on one end and a taper thread on the other or head end.

Fig. 2. Threading a Staybolt on the Lassiter-Millholland Model A Machine

Fig. 1 shows a Model B machine of the cone-pulley type; this machine is also furnished in a geared-head motor-driven design. The three-step cone and back-gears of the headstock give a range of nine spindle speeds. Changes in spindle speeds are made through friction clutches without stopping the spindle. The staybolt forgings are gripped by the square end in a special collet having an adjustable stop. The main slide has two "modern" die-heads, the forward one of which is mounted in a permanent position on the slide, while the rear die-head is adjustable longitudinally by means of a fine-pitch screw. This adjustment adapts the die-heads for cutting staybolts of various lengths. An accurate spacing bar facilitates the setting of the two heads to cut a continuous lead when changing the position of the heads to suit a new job. The die-heads open sufficiently to permit a button-head to be passed through them to the chuck. A V-block on the slide prevents a staybolt from dragging in the die-chasers when the heads are open.

The first operation on staybolts of this class is to turn the surfaces to be threaded. For this operation the die-heads are provided with solid cutters. The cutters of the front die-head are tapered, and this die-head is also equipped with a taper attachment which gives its cutters a slight opening movement as it is fed forward. Both die-heads are opened automatically at the proper instant, and are closed by adjustable cams on a bar at the rear of the machine. During this operation the slide is fed forward at a rapid rate by means of a rack and pinion mechanism, actuated by a long lever on the apron which operates a friction clutch.

For the threading operation on the staybolt ends, chasers may be substituted for the cutters in the die-heads, although in shops where large quantities of staybolts are produced, it is generally preferable to use a second machine for the threading operation. The front die-head is equipped with tapered chasers. The two die-heads are held in a constant relation on the slide, and the latter is fed forward by two half-nuts in the apron which engage the lead-screw. Feeding the slide by means of the lead-screw prevents the die-heads from lagging or creeping.

Because of the different lengths of the surfaces machined, the rear die-head, both in turning and threading, advances about 1½ inches along its corresponding surface before the cutters or chasers of the front die-head begin cutting. This makes it unnecessary to support the rear end of the bolt on a center. The cross-slide is intended for use in facing the under side of the button-head, and may or may not be furnished. Change-gears can be furnished for cutting threads of any standard pitch. This machine has a capacity for staybolts from ¾ to 1½ inches in diameter and 14 to 36 inches in length. The maximum turning length is 5 inches. The net weight of this machine is 3500 pounds.

The Model A machine is intended for producing staybolts from bar stock fed automatically through the headstock spindle. The main slide of this machine is equipped with a turret on which are mounted a stock stop, single-cutter roller box-mill, and a "Modern" automatic self-opening die-head as shown in Fig. 2. After the stock has been fed to the stop, the turret is indexed to bring the box-mill in line with the work. The turret-slide is then fed forward, and during the feeding movement, the portion of the bolt between the ends to be threaded is relieved by the box-mill. The feeding movement is accomplished by means of the rack and pinion mechanism mentioned in connection with the Model B machine.

After the turret-slide has been returned to its original position, the turret is again indexed to bring the die-head in line with the work. The die-head having been closed, the two apron half-nuts are engaged with the lead-screw. Then the slide is fed forward to enable the die-head to cut threads on both ends of the staybolt, during which operation the die-head cannot lag or creep. Fig. 2 shows this operation in process.

As the die-head completes the thread on the first end, the machine is speeded up instantly by means of a friction clutch in the headstock so as to feed the die-head quickly over the relieved portion of the staybolt. When the die-head approaches the opposite end of the staybolt, the machine is again slowed down before the chasers begin cutting the thread. The die-head is automatically opened when the thread is completed. The turret binding bolt has a hole which permits the staybolt to project through the turret. The finished staybolt is cut off from the stock by the tool on the cross-slide. This machine regularly has a capacity for staybolts up to 1⅝ inches in diameter, but it can be arranged for handling work up to 2¼ inches in diameter. The maximum over-all length of staybolts that can be machined is 12 inches. The net weight of this machine is 3000 pounds.

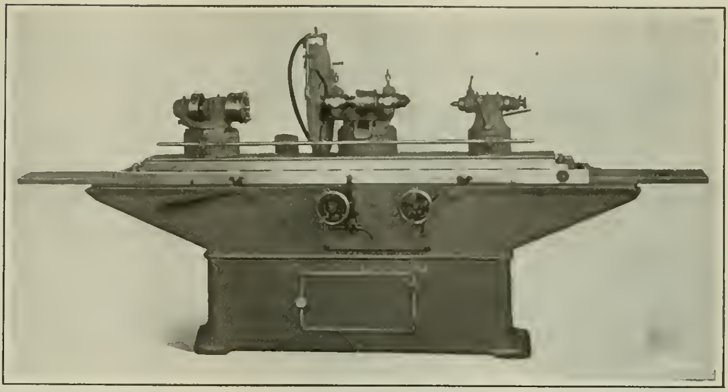

Fig. 1. Grinding Machine brought out by the Brown & Sharpe Mfg. Co. for Automotive Parts, in Addition to Regular Straight and Taper Work

BROWN & SHARPE UNIVERSAL AND CRANKSHAFT GRINDING MACHINE

Automotive crankshafts, pistons, wrist-pins, valve seats and stems, etc., in addition to the regular straight and taper work which a universal grinding machine is capable of handling, may be ground on the No. 4 universal and crankshaft grinding machine here illustrated. This machine has been recently brought out by the Brown & Sharpe Mfg. Co., Providence, R. I., to meet the requirements of motor service shops. Internal and face grinding can also be accomplished on such parts as individual cylinders, clutches, and transmission gears, by means of an internal grinding attachment and chuck. In fact, with the exception of cylinders cast en bloc, all ordinary parts of automobile engines can be ground. Furthermore, the machine can be employed for grinding line reamers, milling cutters, centers, boring-bars, and other tools.

Successful crankshaft grinding depends to a great extent upon the accuracy with which the throw-blocks are constructed. For this reason, the throw-blocks on this machine are made to tool-room accuracy. Their sides are finished relative to the center holes in the sliding blocks. This permits a crankshaft to be readily aligned by placing the blocks on their sides on a surface plate. The blocks are provided with adjustable clamp caps so that crankshafts of various diameters can be accommodated, three center holes for crankshafts of different throws, and an adjustable slide for obtaining a fine adjustment. The sliding block used on the headstock end of a crankshaft has a special extension which, with its recess, provides for grinding flanged crankshafts.

Another noteworthy feature of the machine is the piston arbor, by means of which a piston, in addition to being mounted on dead centers, is ground on its own centers. This method not only insures accuracy, but also enables a used piston to be trued up concentric with the axis on which it was first machined. For valve grinding, the wheel-slide is set at the desired angle, and the corner of the wheel moved across the valve seat. After the wheel-slide has been set, the table remains stationary, the wheel being traversed across the valve seat by the cross-feed.

Aside from the few special features necessary to fit the machine for its particular purpose, the construction is similar to that of the regular No. 4 Brown & Sharpe universal grinding machine. By removing the raising blocks from under the headstock and footstock, changing the size of the grinding wheel and its guard, and making slight additions to the equipment, the machine can be converted into the regular type.

The wheel-spindle is made of tool steel and runs in self-aligning phosphor-bronze boxes provided with means of compensating for wear. The spindle and its boxes can be easily removed to make room for the internal grinding attachment, as shown in Fig. 3. The automatic cross-feed moves the wheel from 0.00025 to 0.004 inch per reversal of the table. It is automatically disengaged when the work has been ground to size. The table travel is also automatic, being controlled by adjustable dogs. The speed and feed of the wheel, the speed of the work, and the table feed, are entirely independent of each other. A single lever is operated to start or stop the rotation of the work and the feed of the table. The table-reversing mechanism permits of grinding work close to shoulders.

The base of the machine rests on the floor at three points. This maintains the alignment of the table, even though the floor may not be absolutely level. Ample overhang at each end of the bed gives a firm support for the table, especially at the end of its traverses. Included in the equipment are back-rests for supporting slender work or splined shafts, as shown in Fig. 2. These rests are universal in all movements.

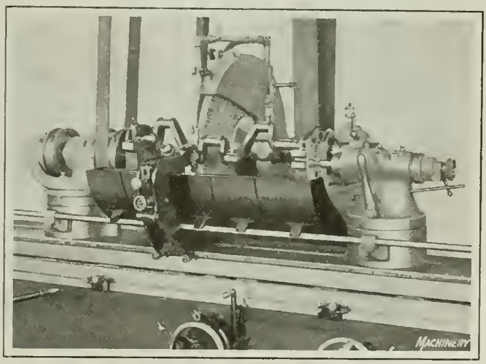

Fig. 2. Grinding a Crankshaft supported during the Operation by a Back-rest

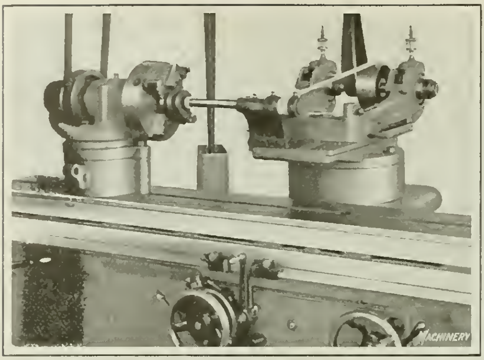

Fig. 3. Internal Grinding made Possible by substituting an Attachment for the Wheel-spindle and its Boxes

and have close adjustments. They automatically compensate for a decrease in diameter as work is ground to size.

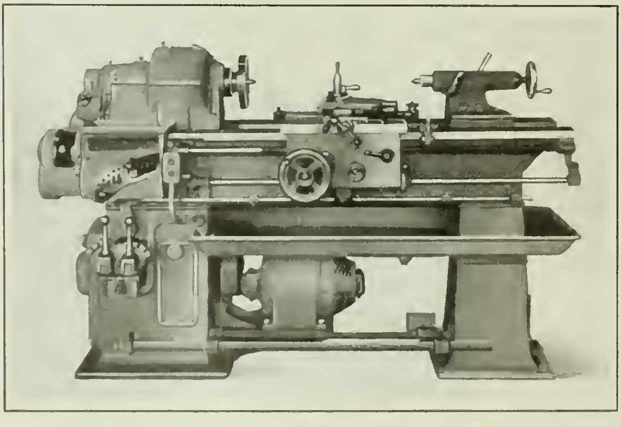
The grinding wheel is 24 inches in diameter, 1 inch thick, and has a hole 5 inches in diameter. It is protected by a heavy guard which confines the spray and particles of abrasive. The footstock carries a holder for the carbon point, by means of which the wheel can be trued without removing work from the centers. Work up to 20¾ inches in diameter and 60 inches in length may be placed on the centers.

HENDEY MOTOR-DRIVEN LATHE

In the 1922 model 14-inch lathe of the Hendey Machine Co., Torrington, Conn., the motor has been placed beneath the oil-pan and the drive is through a speed-box in the left-hand pedestal and thence through a belt to the headstock spindle. By means of this driving arrangement, the lathe retains all the desirable features of the cone type and secures most of the advantages of the geared-head type. Eighteen spindle speeds are obtainable, nine through the speed-box in the pedestal and nine through the customary back-gears in the headstock. Reducing gears are located in the drive between the motor and the speed-box. The latter is oil-tight.

All driving parts of the lathe are enclosed, with the exception of the lead-screw and the faceplate, so as to protect the operator and the machine from injury. The interior of the headstock and speed- and quick-change gear-boxes may be conveniently exposed by the removal of a manhole or cover-plate. The headstock is equipped with a taper spindle and bearings, and is provided with means for taking up end play of the spindle. The single pulley and pinion run on a sleeve readily supplied with oil. An intermediate sliding feed-gear is operated through a conveniently located lever. The back-gear quill may be oiled while in motion. The carriage and compound rest are of improved design, and the tailstock has a graduated sleeve and effective clamping means.

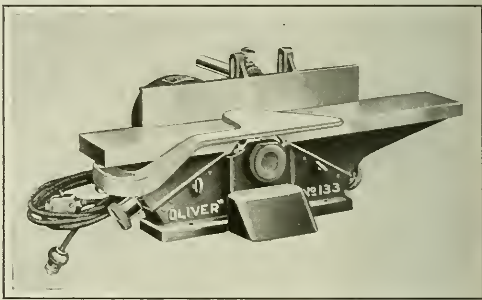
The motor is controlled by push-buttons. An interlocking mechanism between the shifting levers and the starting panel enables the speed of an alternating or direct-current motor to be reduced automatically while gears are being shifted. Supplementary control of the spindle is obtained through a treadle running the full length of the bed. Pressure on this treadle instantly causes the spindle to stop rotating, and permits quick examination or calipering of work. The tension on the driving belt may be altered by means of a single-screw adjustment.



Motor-driven Lathe placed on the Market by the Hendey Machine Co.

OLIVER HAND PLANER AND JOINTER

The work of patternmakers in jointing and fitting small patterns, is facilitated by the portable motor-driven hand planer and jointer shown in the accompanying illustration. This machine is now being placed on the market by the Oliver Machinery Co., Grand Rapids, Mich. It is made in two sizes, 6 inches and 4 inches, which plane to a width of 6¼ and 4¼ inches respectively, and rabbet up to ½ inch.



No. 133 Hand Planer and Jointer added to the line of Patternmaking Equipment built by the Oliver Machinery Co.

The tables are mounted on inclined dovetailed ways on which they are raised or lowered by means of a handwheel and screw. They may be easily locked in any position. The fence can be quickly adjusted across the tables and tilted and locked in any position up to 45 degrees. When not in use, the fence can be swung out of the way of the knife jointing and setting attachment with which the machine may be furnished.

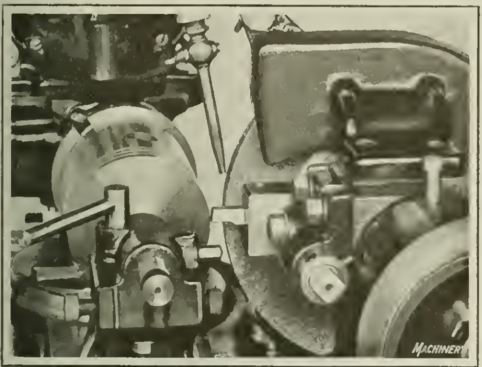
An automatic aluminum guard keeps the unused portion of the knives covered. The cutter-head is of the three-knife circular safety type fitted with three tungsten-chromium knives, ⅛ inch thick and 1 inch wide. The cutting diameter of this head is 3½ inches. The head is direct connected to the motor by means of a universal coupling and runs in self-aligning ball-bearings.

A ¼-horsepower motor is supplied for the 4-inch machine, and a 1/3-horsepower motor for the 6-inch machine. Power for the motor may be taken from a lamp socket, the current supply being controlled through a push-button switch. The machine may be furnished with a rabbeting arm which is mounted on the in-feed table. The knife jointing and setting attachment previously referred to consists of a right-angle way with a sliding block, jointing stone, and aluminum guard. It serves as a guide for setting the knives, and by sliding the jointing stone back and forth while the cutter-head revolves, the knives are sharpened and jointed. This machine may also be provided with a floor stand.

"RE-LI-O" WET GRINDING MACHINE

Machining automobile pistons on a semi-manufacturing basis is one of the operations for which the No. 2 "Re-li-o" grinding machine now being placed on the market by the Van Norman Machine Tool Co., 160 Wilbraham Ave., Springfield Mass., proves especially useful. The machine is like the "Re-li-o" grinding machine described in December, 1921, MACHINERY except that it is equipped for wet grinding and has an improved type of turning-tool holder. Pistons may be finished to size either by grinding only, or by a combined turning and grinding operation. When a considerable amount of metal is to be removed, it may be desirable to run off the larger portion and then grind to size.

A close-up view of the turning-tool holder is shown in the accompanying illustration. This holder can be swung in to and out of the operating position without interfering with the piston set-up or the grinding wheel. In the illustration, the tool is shown in contact with the work. Before bringing the grinding wheel into the operating position, the tool-holder is swung downward. An adjustable collar with a locating stop-pin is mounted on the outer end of the tool-holder shank. This stop-pin swings clear when the tool-holder is released and contacts when the tool is swung up for turning. The illustration also clearly shows the diamond truing tool mounted on the rear side of the tailstock. This machine is also suitable for grinding wrist-pins, valves, armature commutators, etc. In addition, it will be found valuable in the tool-room.

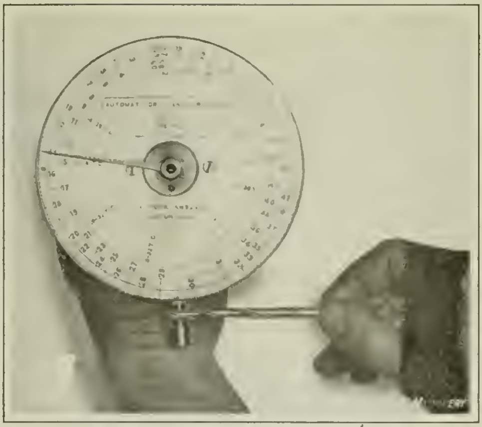


Improved Turning-tool Holder in Use on No. 2 "Re-li-o" Grinding Machine, made by the Van Norman Machine Tool Co.

LAWSON DIAL DRILL AND WIRE GAGE

Drills and wires ranging from No. 1 to 60 gage can be quickly and accurately checked to see whether they are under or over size, or to determine the gage number, by means of the dial gage illustrated. This device is being introduced to the trade by the Victor R. Lawson Co., 35 Hartford St., Boston, Mass. The graduations on the dial show variations to 0.0005 inch. The dial also shows the proper tap drill to be used for drilling holes that will be tapped to a full thread when the corresponding tap is used.

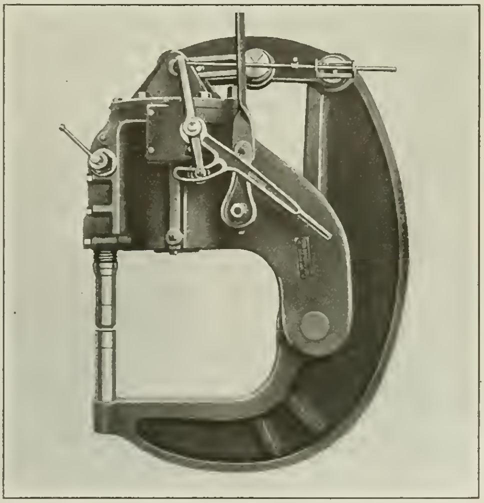
The drill or wire to be gaged is placed between the two jaws at the bottom of the dial. The upper jaw is stationary, and the lower jaw is attached to a rod which extends into a square groove running across the back of the dial. The lower jaw is normally held in contact with the upper one, but to measure a drill it is depressed by pushing downward on the upper end of the rod to which it is attached. In this way the lower jaw may be moved sufficiently to permit a drill to be placed between the two jaws. After a drill has been placed in position, all pressure is released from the sliding rod. The lower jaw then automatically rises into contact with the drill. Movement of the sliding jaw actuates the dial indicator, and so the gage of the drill may be ascertained by observing the position of the indicator. The device is particularly intended for sorting out batches of small drills of mixed sizes. It may be operated by means of a foot-treadle which leaves both hands of the operator free for inserting drills.



Method of using the Drill and Wire Gage made by the Victor R. Lawson Co.

SHEPARD PNEUMATIC RIVETING MACHINE

Light and medium structural riveting, such as is done when constructing roof-trusses, plate beam-box, and crane girders; plate and channel or angle columns, etc., is the service for which the "Pinch-Bug" riveting machine here illustrated was designed. This machine is a product of the Hanna Engineering Works, 1763 Elston Ave., Chicago, Ill. The angular movement of the machine is small, owing to the



Shepard Pneumatic Riveter made by the Hanna Engineering Works

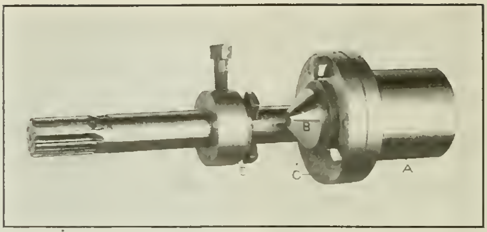


Fig. 1. Non-floating Reamer-holder which is a product of the Marvin & Casler Co.

long radius from the hinge-pin to the die axis. When the machine is suspended with the dies vertical and the cylinder up, the upper die does not move as the rivet is driven. The rivets are put in from the top and driven from below. They may be inserted in advance of the machine, and it is thus possible for the man who inserts the rivets to devote some of his time to other details without interrupting the continuous operation of the machine.

The suspension pin about which the machine is free to oscillate is so located relative to the center of gravity of the equipment that the machine, when suspended, assumes a position in which the upper die screw is vertical. The die screw remains vertical when the unit is opened or closed, because the center of gravity shifts but slightly during operation. A proper working suspension is easily obtained by hoisting the machine to a position in which the upper die will just rest on the work. The machine has a reach of 20 inches, and a gap of either 11½ or 18 inches, depending on whether a short or a long jaw is supplied. It has a capacity of 50 tons on the dies at an air pressure of 100 pounds per square inch and weighs 1490 pounds.

MARVIN & CASLER PRODUCTS

A non-floating reamer-holder, designed on the theory that in order to ream a straight true hole it is necessary to hold the rear end of the reamer in alignment with the center line of the spindle and the hole to be reamed, has been placed on the market by the Marvin & Casler Co., Canastota, N. Y. This holder may be supplied with an adapter sleeve to fit the turrets of turret lathes, the holder in Fig. 1 being supplied with a sleeve *A* to suit the Jones & Lamson turret lathe. Inserted in the sleeve is a cone-shaped machine-steel center plug *B*.

Before lining up the holder with a piece of work, the latter is first bored to a convenient size to receive the center plug, faced a short distance, and the hole slightly chamfered. Then the adapter sleeve is mounted in the turret with the faceplate *C* held to the sleeve by three cap-screws. The holes in the faceplate for these screws are over-size so as to allow the faceplate to float slightly on the sleeve when the screws are not tightened up. After the center plug *B* has been inserted in the sleeve, the turret is advanced to seat the plug in the hole of the work. While in this position the three cap-screws are tightened to hold the faceplate in position, after which the turret is withdrawn from the work and the reamer-holder collar *D* substituted for the center plug. Only one center plug is required for a group of machines. The reamer-holder collar can be furnished in different sizes.

Fig. 2 shows a T-slot nut which is made in different sizes from ½ to 1 inch by the same company. In many cases work being machined is of such a shape that, when old-style T-slot bolts are employed for holding the work to the table, the bolts must be located before the work is set in place. By employing the nut illustrated, however, bolts may be quickly added for more securely clamping work, even after the machining has begun. The nut and stud used with it are made in sizes to suit the small milling machine slots and the large slots of planers and drilling machines. The nut is so designed that its continuous use does not result in wear of the T-slots.

The use of a line of blocks and jacks, made by the Marvin & Casler Co., in supporting work on a machine platen, is illustrated in Fig. 3. The line consists of a jack and a number of blocks and pipe extensions. The jack has a screw member, one end of which is a point while the other end is a flat surface. At *A* is shown a jack at the top of a pipe extension, with the point end of the screw member uppermost, while at *B* the flat end of the screw member supports the work. The jack body is provided with a flange and is also reversible, the flange permitting the use of the body with the pipe extensions. The location of the flange and lengths of the pipe extensions of a set are such that any height between minimum and maximum may be obtained. When using the point end, the jack alone has a minimum height of 1¾ inches, and when using the flat surface of the screw member, 1½ inches. With four pipe extensions the range of height obtainable is from 1¾ to 19 inches.

NEW JERSEY FOUNDRY & MACHINE CO.'S "HANDIMAN"

Users of hand-power hoists of 5 tons or greater capacity will be interested in a patented electric machine which may be suspended in the bight of the operating chain of such hoists, for overhauling the chain, which it accomplishes at the rate of 138 feet per minute, with a pull of 150 pounds. This machine is known as the "Handiman" and is manufactured by the New Jersey Foundry & Machine Co., 90 West St., New York City. It is portable so that it may be used with different hoists about the shop.

The machine has a cast-iron housing in which are con-

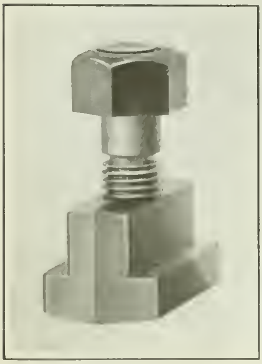

Fig. 2. Casler T-slot Nut

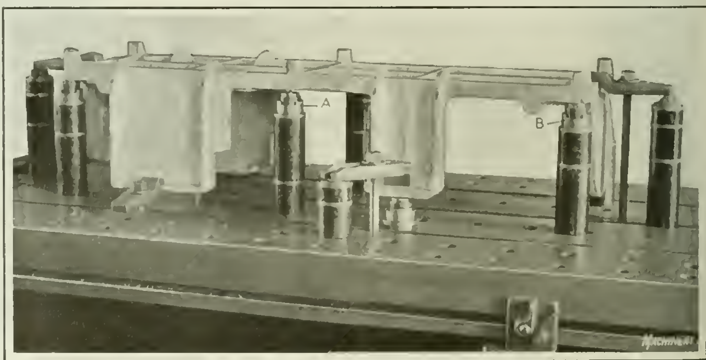

Fig. 3. Supporting Work on a Planer Table by the Use of a Line of Jacks made by the Marvin & Casler Co.

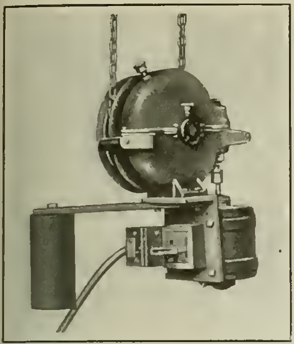


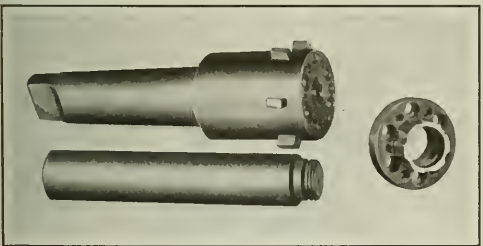
"Handiman" manufactured by the New Jersey Foundry & Machine Co.

tained a worm and worm-gear driven by a ¾-horsepower motor. The worm-wheel shaft extends outside of the housing and carries a grooved sheave having a rubber V-shaped tread which fits any size or pitch of chain and gives a sufficient tractive effort to pull the chain without slippage. The entire unit is so counterbalanced that it hangs in the plane of the chain in which it is mounted.

Current may be supplied from lighting sockets or from a conductor suspended from the hoist, if it is more desirable to bring feeders to that point. A reversing switch provides for running the motor in either direction, for hoisting or lowering. The machine is intended for use in instances where it is desired to obtain faster and easier operation of hoists than is possible by hand, but where the installation of a standard electric hoist would scarcely be warranted.

MADISON ADJUSTABLE BORING HEAD

A boring head intended for both rough- and finish-boring, which can be quickly adjusted by means of a center-pin having a dial graduated to 0.001 inch, is made by the Madison Mfg. Co., Spring and Elton Sts., Muskegon, Mich. One complete revolution of the center-pin increases the diameter across the cutters 0.025 inch. The center-pin is hardened and ground to insure an accurate adjustment. It supports the cutters in a direct line with the thrust of the cut.



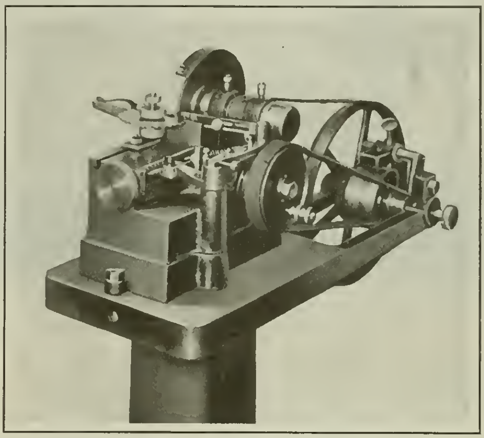
Adjustable Boring Head placed on the Market by the Madison Mfg. Co.

This boring head is designed for use in high-powered machines where rapid production is desired, and as it is provided with six blades, a heavy feed can be employed. High-speed steel blades are generally furnished, but stellite blades may also be supplied. The head is made with any form of shank, and from 2½ to 8 inches in diameter across cutters. The pilot-bar shown is used when boring deep holes.

SCHERR AUTOMATIC SAW SHARPENER

The sharpening of small metal-cutting saws, screw-slotters, etc., 8 inches and less in diameter, may be conveniently accomplished by means of a No. 2 automatic saw sharpener now being introduced to the trade by George Scherr, 126 Liberty St., New York City. Accuracy is assured by an indexing arrangement which, through the intermittent movement of a finger, brings the teeth of the saw successively in alignment with the grinding wheel. This finger is of such design that it functions, even though a tooth may be broken out. The saw is mounted on a slide which is reciprocated to and from the wheel after each indexing. The movement of this slide is set for each job by means of a knurled-head adjusting screw on the slide.

After the saw has been mounted in place and the necessary adjustments have been made, power is transmitted to the feeding and indexing mechanisms through a clutch on the driving shaft. From then on, the operation is automatic until the sharpening of the saw has been completed. The grinding wheel revolves continuously, regardless of whether the clutch is in or out of mesh. The wheel is dressed to suit the shape of the saw teeth. This machine handles saws from 1½ to 8 inches in diameter and up to about 5/32 inch in



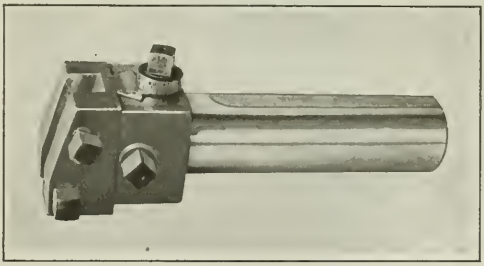
Sharpening Machine for Small Saws, placed on the Market by George Scherr

thickness, with a distance from tooth to tooth, measured along the periphery of the saw, up to ⅜ inch. The weight of the machine on a 30-inch column is about 135 pounds.

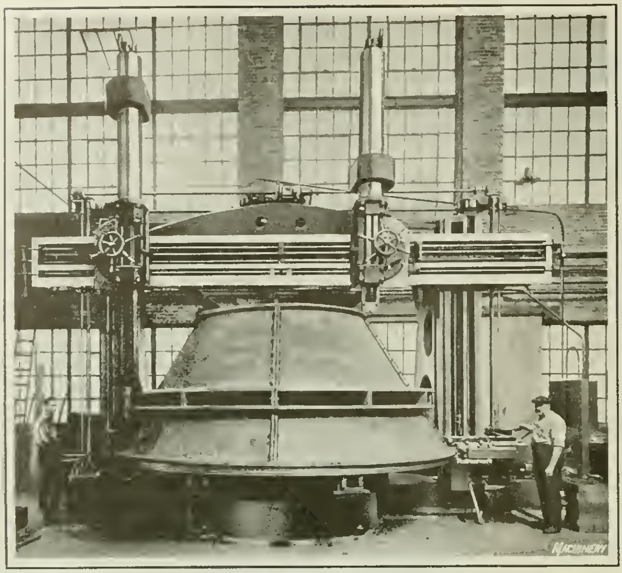
A No. 1 machine of the same general design but of a smaller size is also built, while a No. 3 machine provides for the automatic sharpening of circular and band metal- and wood-cutting saws and milling cutters up to 3/16 inch thick.

WARNER & SWASEY ADJUSTABLE CUTTER-HOLDER

In turning work to accurate size on a turret lathe through the use of a cutter-head, at least two cuts must be taken over the surface being machined. The roughing cut can be held to a limit of about 0.004 inch, when using a common holder, by tapping the cutter lightly with a hammer. Considerable skill, however, is required in taking the finishing cut by the same method, to prevent moving the cutter too far and spoiling the work. An adjustable cutter-holder designed by the Warner & Swasey Co., Cleveland, Ohio, which is here illustrated, eliminates guesswork in adjusting the



Adjustable Cutter-holder made by the Warner & Swasey Co.



Large Boring and Turning Mill built by the Betts Machine Co.

cutter to close limits. The cutter is held at an angle and adjusted by turning the graduated screw which operates the cutter-slide.

The head is made of hardened steel throughout. In using the tool, the locking screw is drawn up tightly and kept in that position. An adjustment can then be made without changing the tension of the screw. An adjustment as small as 0.0005 inch is possible. In addition to the advantage of obtaining the original setting easily, the cutter can be adjusted to cut the work to the desired size when the cutting edges become worn.

BROWN & SHARPE MICROMETER CALIPER

To meet the needs of automobile repair shops for a micrometer caliper having a sufficient range to permit the measurement of both the small-size pistons now supplied on certain automobiles and the large-size pistons used in trucks and tractors, the Brown & Sharpe Mfg. Co., Providence, R. I., has changed the range of the No. 55 micrometer caliper which it manufactures. This caliper will now take measurements from 2 to 6 inches, the range being secured through the use of four anvils. The anvils are held in position by a knurled nut, which enables them to be changed rapidly. The general construction of this tool is similar to other Brown & Sharpe micrometer calipers.

BETTS BORING AND TURNING MILL

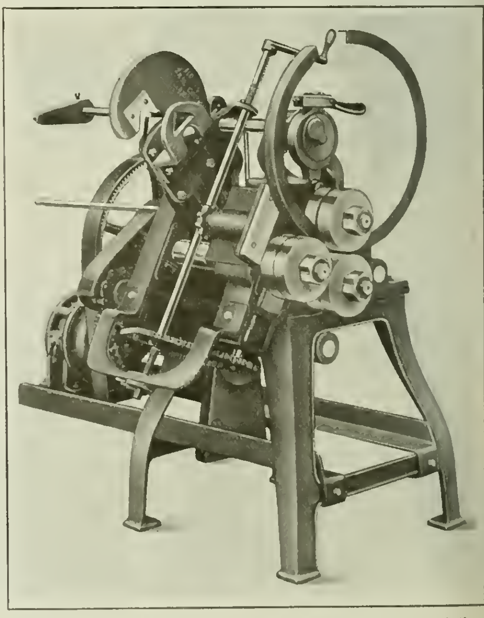
A large boring and turning mill with a capacity for work up to 16 feet 4 inches swing and 8 feet 4 inches height is here illustrated. This machine, which is built by the Betts Machine Co., 400 Blossom Road, Rochester, N. Y., has a number of interesting features. The two tool-heads are equipped with tool-steel spindles of extra long travel, and have a ring-type, self-contained, counterbalancing arrangement. The tool-spindle at the right is provided with a special attachment for turning tapers at any angle from 0 to 90 degrees. The right-hand upright carries a sliding side-head which has both horizontal and vertical power-feeds to the tool-slide. A power rapid traverse is provided for the three heads for each direction in which they may be operated.

This machine is driven by a constant-speed motor through a friction clutch. A brake allows the machine to be stopped instantly without stopping the motor. All speed changes are obtained by means of sliding, hardened steel gears running in a bath of oil. This machine is used principally for turning large castings such as are shown on the table in the illustration.

EXCELSIOR ANGLE-IRON BENDING MACHINE

A machine that will cut to length and bend in a circle angle-iron up to 2 by 2 by ¼ inch has been brought out by the Excelsior Tool & Machine Co., 30th St. and Ridge Ave., East St. Louis, Ill. The machine will also handle bar stock up to 4 by ½ inch and 2-inch T-iron, with the same bending rolls, these being adjustable to meet requirements. Special rolls may also be furnished to suit the bending of pipe channel-iron, or other shapes. The machine has three roll shafts, on each of which are two rolls which may be separated by steel washers of a thickness to suit the angle-iron being bent. Each roll has one straight and one rounded edge. To roll work so that the edge of a leg will be on the outside, the upper rolls should have the square edges together without spacers between them and the lower rolls should have the rounded edges together with spacers between them to allow one leg of the angle-iron to extend between the rolls. Guides are used to insure that the work will be rolled free from twists. With work rolled in this way two pieces may be handled at one time.

To roll work with the edge of one leg toward the inside of the circle, as shown in the illustration, the lower rolls should have the square edges together while the upper rolls should have the rounded edges together with spacers between them. Work of this type must be rolled one piece at a time. The

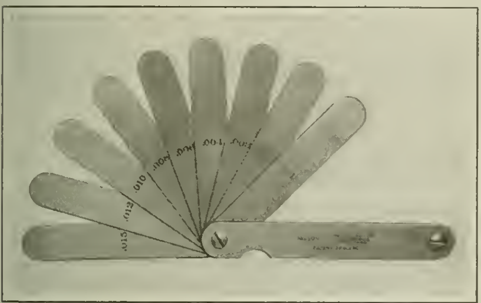


Machine for bending Angle-iron in Circles, which is a Product of the Excelsior Tool & Machine Co.

guides previously referred to are also used for this work. The upper-roll shaft has a 2½-inch movement obtained through eccentrics. This shaft is set with an allowance not exceeding the thickness of the angle-iron leg which extends between the upper and lower rolls. When duplicating work of the same thickness, a set-screw adjustment is used to clamp the eccentric so as to hold the rolls together. The machine is operated through a patented friction clutch and both belt- and motor-driven machines can be started and stopped under pressure. The speed of the rolls is fifteen revolutions or twenty-five lineal feet per minute.

LUFKIN IMPROVED THICKNESS GAGES

The principal feature of a line of improved thickness gages or feelers being placed on the market by the Lufkin Rule Co., Saginaw, Mich., is a patented lock by means of which any leaf may be held firmly in a set position. This feature will appeal particularly to automobile mechanics and repair men. For example, in making adjustments of tappets on engines, the holding of a leaf by means of the lock-nut



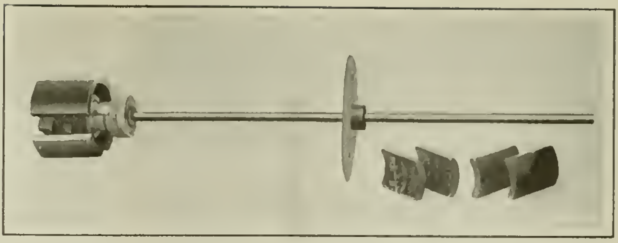
No. 109 Thickness Gage with Patented Lock, which is made by the Lufkin Rule Co.

permits of using the entire length of the leaf. On V-type motors, where work is performed at an angle, the gages are particularly useful.

Each leaf is 3 inches long and ½ inch wide. The No. 06 gage has six leaves ranging in thickness from 0.002 to 0.015 inch; the No. 07, seven leaves ranging from 0.0015 to 0.015 inch; and the No. 09, nine leaves ranging from 0.0015 to 0.015 inch. The thickness of each leaf is clearly marked on one side. On these three gages the thickest leaf and a nameplate serve as a case to protect the other leaves. The No. 109 gage, which is here illustrated, has the same leaves as the No. 09 gage, but is provided with a case into which all the leaves fold.

STIMSON INTERNAL LAPPING TOOL

An internal lapping tool developed particularly for lapping automobile cylinders but which can be furnished in any special size to meet machine shop requirements, has been placed on the market by the Stimson Engineering Co., 598 Sixty-eighth Ave., Milwaukee, Wis. The tool consists of a shaft, at one end of which lapping shoes are mounted. Two sets of shoes are regularly furnished, one of which may be adjusted to from 2¾ to 3½ inches in diameter, and the other to from 3½ to 4¼ inches in diameter. These shoes are held in place by cotter-pins and may be quickly substituted for each other. They are adjustable to the proper diameter by simply turning a tapered nut which is firmly held in position after an adjustment by means of a lock-nut. A disk placed loosely on the shaft rests on top of the casting being



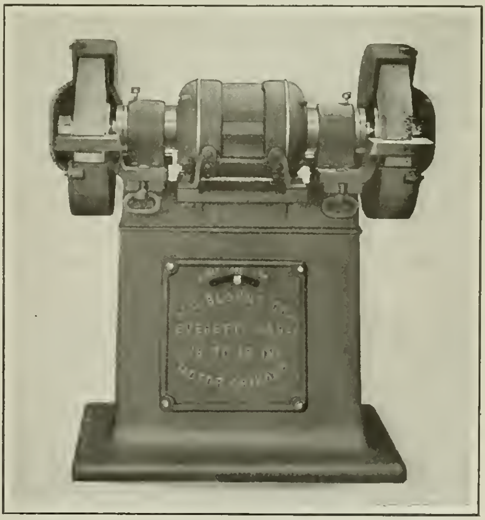
Internal Lapping Tool brought out by the Stimson Engineering Co.

lapped. A collar is employed to regulate the maximum distance between the disk and the lapping shoes, thus controlling the depth to which the tool is fed into the work. This lapping tool may be driven by an electric or air drill or by connection to a machine spindle through the use of a flexible coupling. A patent has been applied for on this device.

BLOUNT HEAVY-DUTY GRINDING MACHINE

A 5-horsepower heavy-duty motor-driven grinding machine equipped with an alternating-current motor and either 18- by 3- by 1½-inch or 16 by 3 by 1½-inch grinding wheels, is a recent addition to the line of machine tool equipment built by the J. G. Blount Co., Everett, Mass. The machine is equipped with S K F ball bearings throughout. The motor end shields are iron castings on which a recess is turned, and they are bolted directly to the motor frame. The shields are further secured in position by supports clamped around their hubs and bolted to each side of the head casting. The shield flanges are screwed into the shields. These flanges are machined all over and recessed on the inside. Either plain or exhaust type adjustable wheel guards may be furnished, as desired.

A Westinghouse safety starting switch is mounted within the column on a separate panel, which is easily removed from the rear of the machine without disconnecting the switch. This switch protects the operator and equipment against accidental starting of the motor. The switch cannot be held closed on an overload. The machine weighs 1200 pounds.



Five-horsepower Heavy-duty Grinding Machine brought out by the J. G. Blount Co.

NEW MACHINERY AND TOOLS NOTES

Tool-holder: Lovejoy Tool Works, 331 W. Ohio St., Chicago, Ill. A tool-holder, known as the "Use-em-up," which is intended to effect savings by making it possible to use up short tool bits. It will hold full-length tool bits, but is particularly useful when the tool bits become short through repeated grinding, tool bits as short as 11/16 inch being rigidly held.

Combination Punching and Shearing Machine: Amplex, Inc., 6 W. 32nd St., New York City. A punching and shearing machine having a solid steel frame. The operator's side of the machine is clear of all such encumbrances as flywheels and driving gears. A slanting centering slide allows for making mitering cuts without lifting the work. The machine is arranged for punching both the webs and flanges of structural shapes, and the throat is designed to accommodate broad-flanged Bethlehem shapes. The punch has a lowering device for locating center marks before punching.

Engine Lathes: Carroll & Jamieson Tool Co., 257 Davis St., Batavia, Ohio. A line of lathes designed primarily for tool-rooms and automobile service stations. The 14- and 16-inch machines are of the quick-change type and can be supplied with either single or double back-gears. A semi-quick-change lathe with a single back-gear can be supplied in the 13-inch size. The quick-change gear mechanism provides for cutting all standard and odd threads from 3 to 64 per inch, either right- or left-hand. On the semi-quick-change lathe, three changes of feed are obtainable by shifting a lever, and additional changes may be secured through the use of change-gears.

Elevating Platform Truck: Clark Tructractor Co., Buchanan, Mich. A gasoline-driven elevated truck having a loading platform 26 inches wide by 54 inches long. This truck will elevate a load of 4000 pounds from a minimum height of 11 inches to a maximum height of 16 inches, in eight seconds. Automatic stops control both the upper and lower limits of travel, and the load can be stopped at any point. The lifting mechanism is operated by hydraulic pressure. Power both for driving the truck and elevating the load is obtained from a 15-horsepower, four-cylinder tractor engine. The driving and elevating controls are at the rear of the engine compartment where the operator rides in a standing position.

Crane Magnet Cable Retriever: Pawling & Harnischfeger Co., 38th and National Aves., Milwaukee, Wis. A feeder cable retriever that differs from the ordinary types of cable take-up drums which have positive geared or chain sprocket drives. This retriever is designed to keep the cable taut at all times, a fixed but moderate tension being maintained on the cable. The cable winds up and pays out without slack or undue strains. The drum is driven only in the hoisting direction, the gearing being proportioned to drive the drum at a greater peripheral speed than that at which the magnet is being hoisted. This arrangement causes the friction drive to slip and produces a tension on the cable which may be adjusted by tightening a thrust spring in the friction drive.

* * *

EXAMINATIONS FOR PATENT AND TRADEMARK EXAMINERS

Examinations to fill vacancies in positions of assistant examiner in the Patent Office will be held by the Civil Service Commission on May 10, 11, and 12 and on June 21, 22, and 23 throughout the United States. The entrance salary for these positions is $1500 a year plus a bonus of $20 a month, and there is provision for promotion to positions paying from $1650 to $3900 a year. Technical training is necessary. Announcement is also made of an open competitive examination for assistant examiner of trademarks, to be held on May 24. The salaries for this work range from $1500 to $2050 a year. Full information and application blanks may be secured from the United States Civil Service Commission, Washington, D. C., or the Civil Service Board in any city.

GERMAN MACHINE TOOL EXPORTS

Figures received from Germany by the Department of Commerce indicate that there was a considerable decrease in the volume of Germany's machine tool exports during 1921, as compared with 1920 and the pre-war year of 1913. Germany's custom-house returns show that the total machine tool exports for the seven months from May to November, 1921, were 39,046 metric tons. Of these exports 7547 metric tons went to Belgium, and 5087 to France. The Netherlands received 4559 metric tons and Italy 3466, while Austria received 2823. Other countries receiving over 1500 metric tons were Czecho-slovakia, Switzerland, and South America. Countries receiving over 1000 metric tons were Great Britain and Spain, while those receiving over 350 but less than 800 metric tons, were Denmark, Alsace-Lorraine, Norway, and Sweden. Other countries not mentioned in the report received a total of 6000 metric tons. In comparing these figures it should be borne in mind that the German classification of machine tools is an extremely broad one, and includes metal-working, woodworking and stone-working machinery, as well as hydraulic presses, riveting machines and power hammers.

A recent Commerce Report shows that Germany's total machine tool exports during the year 1920 were 94,921 metric tons. During 1920 the Netherlands took over 19,000 metric tons of Germany's machine tool exports and France 13,668, while Switzerland ranked next in importance, taking 11,760 metric tons. Belgium and Italy each took approximately 7500 metric tons; Sweden 5433; Austria 4978; Czecho-slovakia 3360; Spain 3268; Denmark 2806; and South America 2949 metric tons.

RELATION OF UNEMPLOYMENT TO BUSINESS DEPRESSIONS

The President's Conference on Unemployment, held under the chairmanship of Secretary Hoover last fall, recommended that a serious attempt be made to analyze the causes of alternate periods of expansion and depression in industry, reflected in the so-called business cycle, and to find remedies for practical use in business. Acting upon this recommendation, Secretary Hoover appointed a committee which is undertaking a survey through the National Bureau of Economic Research, of which Dr. Wesley C. Mitchell is director.

At the first meeting of the director and the committee, preliminary surveys of the sources of information for such a study, by committees representing the Editorial Conference of Business Paper Editors and the Federated American Engineering Societies, were requested. A second meeting of the committee was held on April 13, at the Department of Commerce, at which the various sub-committees made reports before the general committee and a representative group of trade association secretaries and editors of leading engineering and trade journals. The general committee especially requested cooperation in securing definite suggestions as to members of trade associations who had evolved plans of minimizing the waste of the business cycle.

The report of the general committee will be divided into three parts: (1) a diagnosis of unemployment; (2) relation of unemployment to business cycles; and (3) the proposed measures and preventives of cyclical unemployment. The committee especially asks the industries for suggestions so as to make the third part of the report as practical as possible. Preliminary surveys indicate that constructive measures may be found in long-range planning of construction work, in various plans for stabilizing production, and in the use of statistical indexes of business conditions to meet periods of depression.

Anyone who has had experience along these lines is requested to forward this information to E. E. Hunt, secretary of the committee, Bureau of Foreign and Domestic Commerce, Chamber of Commerce, Washington, D. C.

HARDENING HIGH-SPEED STEEL CUTTERS

By JAMES CRAN

On page 481 of February MACHINERY there appears a note under the heading "Hardening High-speed Cutters." It is the writer's opinion that the procedure here outlined represents rather a short-cut method and that better cutters of high-speed steel would be obtained by the process described in the following. Any small standard furnace, whether oil, gas, or electrically heated, provided it is of the muffle or semi-muffle type and capable of being heated to about 2300 degrees F., answers the purpose. For the best results it is advisable to use three furnaces, but two are more generally used, and good work can be done with only two furnaces.

Method of Hardening when Using Two Furnaces

When two furnaces are used, the cutters to be hardened should be heated in one of them to 1600 or 1650 degrees F. and then transferred to the other furnace registering about 2300 degrees F. While 2300 degrees F. is rather a high temperature for high-speed steel, 2250 degrees F. is considered ideal. As soon as a cutter which has been preheated to about 1600 degrees F. is placed in a furnace registering 2300 degrees F., the temperature of the furnace will drop while the temperature of the cutter rises, and the result is that by the time the cutter has reached the desired temperature of 2250 degrees F. the heat of the furnace will have dropped 50 degrees.

On removing the cutter from the furnace, it should be immediately immersed in oil, which may be fish, linseed, cottonseed, rape, or any of the standard quenching oils in general use. The cutter should be kept moving slowly in the quenching bath until it has reached a black heat, which will be indicated by the cessation of smoke bubbles; it may then be allowed to cool down to the point where it can be handled without gloves. While movement of the cutter in the quenching oil is necessary to facilitate carrying off the heat, this should be done carefully, for if the cutter is moved too fast a vacuum will be formed behind it with the result that only one side of the cutter will actually be in contact with the oil.

Method of Hardening when Using Three Furnaces

When conditions will permit of three furnaces being used, more and better hardening can be done. It is best to have one furnace heated to a temperature of about 1300 degrees F. in which the cutters are preheated slowly and thoroughly until they have reached the temperature of the furnace. They should then be transferred to another furnace having a heat of about 1800 degrees F. and then to one of about 2300 degrees F. The rest of the procedure is the same as stated previously.

Final Heat-treatment

To give the maximum service, all high-speed steel cutters should be subjected to a second or tempering heat of about 1050 degrees F. This second heat makes the cutters much harder and tougher than they are when they come from the quenching bath. In quenching cutters of high-speed steel, it is advisable to leave some of the initial heat in them until they can be heated the second time or tempered, as this will tend to prevent cracking. High-speed steel is harder after being subjected to a second heat than it is when it comes from the quenching bath, because of the alloys it contains and their action in quenching.

It is well known that all steels, when they are in solution (which is the right condition for quenching) are austenitic, or have a grain structure the same as any pure metal. While straight carbon steel and some alloy steels are austenitic at the quenching temperature, the austenite changes to martensite in cooling, and in consequence, if the heating and other conditions are right, the steel will be in the hardest possible condition when quenched.

High-speed steel usually contains from 3½ per cent to 4 per cent chromium and about 18 per cent tungsten. Both of these alloys deter its passing into and coming out of solution; thus it is necessary to heat high-speed steel to a higher temperature than straight carbon steel, to get the various alloys of which it is composed saturated with the iron or ferrite, which comprises the major part of the steel. But it is also possible to make high-speed steel pass into solution at a much lower temperature than 2250 degrees F. by allowing it to soak for a time at 2000 degrees F. or even less. When this is done, however, it is likely to have a very much overheated structure, and in consequence will not stand up like a tool that has been brought quickly to the proper heat.

By watching a high-speed steel cutter closely when it is nearing the critical point, it will be noticed that it begins to have a greasy or sweaty appearance and small bubbles appear which work through each other; this is the ideal condition for quenching. If it is left longer in the furnace, the bubbles will change to blisters, which is a sure sign of overheating. In quenching high-speed steel, the chromium and tungsten tend to keep it in the austenitic condition, making a second heat necessary to bring it to martensite.

Effect of Second Heat on High-speed Steel Cutters

A good example of what a second heat on high-speed tools will do can be had by watching a lathe or planer tool which has been put to work directly after being quenched and ground and then noting the difference in the quality of the tool after a second grinding. After the second grinding it will stand up better than it did at first on account of the heat generated in removing the chip, which changes the structure from austenite to martensite on the extreme end or cutting edge.

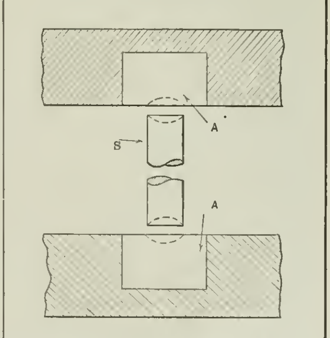
The temperatures here given are intended only as a basis to work from, and it is necessary for the hardener to use judgment according to the size of the pieces to be hardened. Very small tools can be hardened perfectly in a furnace having a temperature as low as 2250 degrees F., because they are not likely to bring the heat of the furnace down very much, but with heavy cutters it may be well to have the temperature of the furnace slightly higher than any of the temperatures here given so as to bring the work to the desired heat without danger of oversoaking it and thereby impairing the structure.

* * *

COLD RIVETS FOR ELECTRICAL APPARATUS

By JOHN E. UNGER

Several types of cold rivets and heading buttons used in making electrical apparatus were described by the writer in an article appearing in March MACHINERY, page 569. In the accompanying illustration is shown another type of button *A* which is being used in a certain plant for upsetting the ends of rivets of the type shown at *B*. It will be seen that the ends of the rivet, as well as the ends of the buttons are concave. In the writer's opinion, this represents poor practice as the heading operation will swell the rivet from end to end without forming a satisfactory head. The upsetting buttons shown were being used in a hydraulic press.



Example of Rivet-heading Buttons of Poor Design

*There were no machine tools or metal-working machinery exported in 1921 to countries not listed.
†The 1920 totals include exports to a few of the smaller countries not listed in the table.

PERSONALS

P. R. Hoopes, formerly associated with the Automatic Machinery & Equipment Co., Philadelphia, Pa., is now connected with Lorenz & Lorenz, Hartford, Conn., as mechanical engineer.

W. C. Ames has been appointed district sales manager of the Sharon Pressed Steel Co. at 20 E. Jackson Blvd., Chicago, Ill., and Ralph E. Phillips has been appointed district sales manager at 66 Broadway, New York City.

W. H. Miller has been appointed supervisor of tools and gages of the inspection and testing department of the Westinghouse Electric & Mfg. Co. at East Pittsburg, Pa., and W. F. Ablauf has been appointed supervisor of mica and mica processes.

Leslie H. Taylor, formerly sales manager of the machine tool division of the Greenfield Tap & Die Corporation, Greenfield, Mass., has become sales manager of the Williams Tool Corporation, Erie, Pa., manufacturer of pipe and bolt threading machinery.

Fred Mathews, formerly vice-president of the Union Metal Products Co., has become general railway sales representative of the A. O. Smith Corporation, Milwaukee, Wis., manufacturer of pressed steel products. Mr. Mathews' offices are at 1306 Consumers Bldg., Chicago, Ill.

W. L. Garcia has become associated with the Fairbanks Co., 416 Broome St., New York City, in the engineering and power transmission department. He has had twenty-five years experience as a transmission engineer. The Fairbanks Co. is sales agent for the Lewellen variable-speed transmission.

R. P. Raymond, formerly chief draftsman for the Columbia Graphophone Co., Bridgeport, Conn., has been appointed superintendent of manufacture for the Columbia Graphophone Co., Ltd., of Toronto, Canada, and will have charge of the manufacture of complete grafonolas, including the cabinets, motors, and records.

H. A. Eaton, Indianapolis and Cincinnati representative of the Precision Grinding Wheel Co., Inc.,. Philadelphia, Pa., has been transferred to the Boston territory and will make his headquarters at the Davis Hardware Co. of Boston. J. O. Smith, previously at Boston, has been transferred to Mr. Eaton's former territory.

H. L. Jones, formerly assistant superintendent of the switchboard and detail department of the Westinghouse Electric and Mfg. Co., East Pittsburg, Pa., has been appointed superintendent of that department. A. J. Bastian, formerly assistant superintendent of the insulating department, has been made superintendent of that department.

W. C. Peterson, formerly metallurgical engineer for the Atlas Crucible Steel Co., has been made manager of the alloy steel division of the Electric Alloy Steel Co., Youngstown, Ohio. Prior to his association with the Atlas Crucible Steel Co., Mr. Peterson was connected for twelve years with the Packard Motor Car Co., having charge of the metallurgical laboratories and heat-treating departments.

George K. Atkinson was elected president and general manager of the Langhaar Ball Bearing Co., Aurora, Ind., at a recent meeting of the board of directors. Mr. Atkinson was formerly connected with the Modern Machine Tool Co. of Cincinnati, and recently was eastern sales manager for the Manufacturers' Equipment Co. of Chicago. L. Langhaar was elected vice-president and will also act as sales manager.

F. G. Davis, for three years representative of the Atlas Crucible Steel Co. in the Detroit district has become district manager of sales in Detroit for the Electric Alloy Steel Co., Youngstown, Ohio. Mr. Davis will occupy a temporary office in Room 1716, Ford Bldg. The company is installing a complete warehouse stock in Detroit, and the district offices will be moved to the new warehouse as soon as arrangements are completed.

Harrison P. Reed, for many years electrical engineer and more recently head of the elevator department of the Cutler-Hammer Mfg. Co., of Milwaukee and New York, has been appointed general manager of the A. Kieckhefer Elevator Co., Milwaukee, Wis. Mr. Reed is a graduate of the Electrical Engineering Department of Cornell University, and is a member of the American Institute of Electrical Engineers and the Engineers' Society of Milwaukee.

Edward Blake, Jr., vice-president of the Greenfield Tap & Die Corporation, Greenfield, Mass., who has been general manager of the company's drill plant at Taunton, has been appointed vice-president in charge of sales and will make his headquarters in Greenfield. Mr. Blake was connected with the Wells Bros. Co. for several years, and eleven years ago became vice-president and general manager of the Lincoln Twist Drill Co. at Taunton, which was sold in July, 1920, to the Greenfield Tap & Die Corporation.

William Ochse, for the last two years sales representative of Manning, Maxwell & Moore, Inc., at Chicago, has become efficiency engineer of the Ohio Machine Tool Co., Kenton, Ohio, manufacturer of shapers and planers. Before joining the sales organization of Manning, Maxwell & Moore, Mr. Ochse was connected for twenty years with Gould & Eberhardt, Newark, N. J., manufacturers of shapers and automatic gear and rack cutting machinery, latterly having charge of their planning and tool design department.

William L. Colt, for nearly five years division manager of Willys-Overland Inc., in the eastern district, with headquarters in New York, has resigned to become president of the Overland Providence Co. Carl P. Spiegelberg, who organized the Overland Providence Co. under the supervision of Mr. Colt, will continue to operate the business as vice-president and general manager. Mr. Colt is well-known in the automobile business. Prior to his association with Willys-Overland, Inc., he was president, for eight years, of the Colt-Stratton Co., distributor of Dodge automobiles in the New York district.

G. F. Sherratt has been appointed manager of the Pittsburg office of the Chain Belt Co., Milwaukee, Wis., which is located in the Union Arcade Bldg. Mr. Sherratt will have charge of all the company's chain and engineering business in the Pittsburg territory, and will render engineering service on power transmitting and material handling problems. The Pittsburg office will handle a complete line of "Rex" chain and material-handling equipment. The Ward Equipment Co., of Pittsburg, will continue to handle the complete line of "Rex" concrete mixers and pavers, and the United Equipment Co. will handle "Rex" traveling water screens.

C. E. Skinner, manager of the research department of the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., has been appointed assistant director of engineering of the company. His duties will cover research standards and other work along these lines, and he will be located in the main offices of the company. Mr. Skinner is known throughout the electric world for his extensive research work, especially on insulation, and his efforts in that direction have had a marked effect on the development of electrical machine design. S. M. Kintner, who is well known for his research and engineering work in the development of radio apparatus, will succeed Mr. Skinner as manager of the research department.

Ralph Barstow, general sales manager of the Greenfield Tap & Die Corporation, Greenfield, Mass., has resigned to go into business for himself as merchandising counselor, in association with Marquis Regan, Inc., at 21 E. 40th St., New York City. The business is not that of advertising, but has to do with sales direction and plans for selling merchandise. Mr. Barstow went to Greenfield in July, 1919, after nine months' service as director of the department of selling and advertising in the American Expeditionary Forces University at Beaune, France. For two years he has been an instructor in sales methods for the State University Extension, which previously adopted a course in sales and advertising of which he is the author.

OBITUARIES

Edward P. Maguire, general manager of the Lapointe Machine Tool Co., Hudson, Mass., died March 28 in St. Vincent's Hospital in Hudson. Mr. Maguire was born in Sharon, Mass., in 1889. He came to Hudson about fifteen years ago and entered the employ of the Lapointe Machine Tool Co. as bookkeeper. When the company was reorganized in 1914 he was made general manager of the plant, and held that position until the time of his death. He is survived by his wife and two children. Mr. Maguire was regarded with esteem and respect by all those who knew him.

Peter Lowe, assistant secretary of the Kempsmith Mfg. Co., Milwaukee, Wis., died in Garrett, Ind., on April 13, aged forty-five years. He was born in Adrian, Mich., in 1877, and started his career as a city reporter for a daily newspaper. Later he was employed as chief bookkeeper and teller in a savings bank, and after six years connection with the bank he started to learn the machinist trade with the ultimate object of becoming a machine tool salesman. As a mechanic he was employed by the Port Huron Engine & Thresher Co., the Gisholt Machine Co., and the Nordyke & Marmon Co. While he was working he took a correspondence course in mechanics, and later took up industrial accounting. He entered the employ of the Kempsmith Mfg. Co. in 1906, taking charge of the cost department. During the time that he was in charge of this department he devised many new methods of recording machine shop costs and making time studies. He also had charge of the finished stock, thus gaining a knowledge of the customers' requirements. In 1911 Mr. Lowe entered the sales department, and was a stockholder and assistant secretary at the time of his death. He had retired from active association with the sales department some time previous to his death on account of ill health.

COMING EVENTS

May 8-10—Annual convention of the National Supply and Machinery Dealers' Association in Atlantic City, N. J.; headquarters, Marlborough-Blenheim Hotel. Secretary, Thomas A. Fernley, 505 Arch St., Philadelphia, Pa.

May 8-10—Twenty-seventh annual convention of the National Association of Manufacturers in New York City; headquarters, Waldorf-Astoria Hotel. General offices of the association, 50 Church St., New York City.

May 8-11—Spring meeting of the American Society of Mechanical Engineers in Atlanta, Ga., Assistant Secretary (Meetings), C. E. Davies, 29 W. 39th St., New York City.

May 9—Meeting of the Society of Industrial Engineers in Chicago, Ill. Business Manager, George C. Dent, 327 S. La Salle St., Chicago.

May 10-12—Ninth National Foreign Trade Convention in Philadelphia, Pa. Secretary, O. K. Davis, 1 Hanover Square, New York City.

May 15-20—Seventh annual convention and exhibition of the National Association of Purchasing Agents in Rochester, N. Y. For further information, address S. M. Crosland, care of the Todd Protectograph Co., 1050 University Ave., Rochester, N. Y.

May 18-20—Annual conference of the National Association of Office Managers in Washington, D. C. Secretary, F. L. Rowland, Gilbert & Barker Mfg. Co., Springfield, Mass. Guests are invited to attend.

June 5-9—Annual convention and exhibit of the American Foundrymen's Association and allied societies in Rochester, N. Y. Secretary C. E. Hoyt, Marquette Bldg., 140 S. Dearborn St., Chicago, Ill.

June 14-21—Annual meeting of the Mechanical Division of the American Railway Association in Atlantic City, N. J. Secretary V. R. Hawthorne, 431 S. Dearborn St., Chicago, Ill.

June 15-24—International exhibition of foundry equipment and materials in Birmingham, England, in connection with the annual convention of the Institution of British Foundrymen.

June 20-24—Summer meeting of the Society of Automotive Engineers at White Sulphur Springs, W. Va. Chairman of Meetings Committee, C. F. Scott, 29 W. 39th St., New York City.

June 26-July 1—Twenty-fifth annual meeting of the American Society for Testing Materials in Atlantic City, N. J.; headquarters, Chalfonte-Haddon Hall Hotel. Secretary, C. L. Warwick, 1315 Spruce St., Philadelphia, Pa.

August 28-September 2—Annual Safety Congress of the National Safety Council in Detroit, Mich. Secretary, S. J. Williams, 168 N. Michigan Ave., Chicago, Ill.

December 7-13—National Exposition of Power and Mechanical Engineering at the Grand Central Palace, New York City. Charles F. Roth, manager, Grand Central Palace, 46th St. and Lexington Ave., New York.

The sectional meetings of the American Society of Mechanical Engineers for the month of May are as follows: May 2—Cleveland Section at the Cleveland Engineering Society Rooms in Hotel Winton, Cleveland, Ohio; May 3—Buffalo Section at Buffalo, N. Y.; May 4-5—Mid-continent section, in joint meeting with other national engineering sections and chapters, at Tulsa, Okla. May 5-6—Virginia section at Charlottesville, Va.

NEW BOOKS AND PAMPHLETS

Engineers' License Laws. 136 pages, 6 by 9 inches. Compiled by the American Association of Engineers, 63 E. Adams St., Chicago, Ill. Price, 50 cents.

This is a compilation of exact copies of the license laws for professional engineers in various states, and it contains sixteen laws now in force in the United States. It has been prepared and published as a service to the profession, for the use of engineers who desire to practice engineering in more than one state, and also for the assistance of those engaged in the preparation of a law in states where engineers are not registered.

The Public Refuses to Pay. By F. Lauriston Bullard. 89 pages, 5 by 8 inches. Published by the Marshall Jones Co., 212 Summer St., Boston, Mass. Price, 50 cents.

This book contains a reprint of editorials appearing in the Boston Herald on the railroad and building situation. It points out how the public pays the cost of excessive building construction, and how the regulations made by the unions have hampered efficient work in railway shops and affected the public welfare. The book is not issued as propaganda in behalf of any cause, the purpose being merely to render a public service by showing how the public suffers from regulations that restrict production and decrease efficiency.

Handbook on Controllers for Electric Motors. 29 pages, 4 by 6¾ inches. Published by the Electric Power Club, 1017 Olive St., St. Louis, Mo. Price, 25 cents.

This pamphlet contains a simple description of controllers for electric motors, and definitions for the various terms applied in that connection. Words which do not appear in the regular dictionaries are explained in simple language, and the meaning of terms with which all users of electrical apparatus should be familiar is given. In addition, information relative to the use of electric controllers is included. Copies may be obtained from the leading manufacturers of electric power and control apparatus or from the secretary of the Electric Power Club, S. N. Clarkson.

Pulling Together. By John T. Broderick. 141 pages, 5 by 7½ inches. Published by Robson & Adee, Schenectady, N. Y. Price, $1, net.

This book deals with the live subject of human relations in industry. It is dedicated to "employers and employes alike, who help each other and the public to see a soul in industry." The introduction, written by the noted scientist, Dr. Charles P. Steinmetz, gives a brief analysis of present industrial conditions, and points out that thinking people in all walks of life are forced to realize more and more that something must be done to bring about better industrial relations. "The great problem before the industrial world today," says Dr. Steinmetz, "is the problem of conciliation and cooperation." This book tells, in a readable way, how a large corporation tried out the plan of employe representation, with highly satisfactory results.

Cooperative Competition. 56 pages, 8½ by 11 inches. Published by the New York Evening Post, 20 Vesey St., New York City. Price, 25 cents.

The subject treated in this pamphlet is of particular interest at this time in view of the wide discussion of trade associations in the technical and general press, and the recent conference of trade association representatives and editors of the technical press with Secretary Hoover. The pamphlet contains twenty-five articles which have appeared daily in the New York Evening Post, outlining the ideas of business men, lawyers, economists, and government officials concerning the proper and legitimate field of the trade association. The introductory article is by Herbert Hoover. The articles point out the field of usefulness of trade associations, and the pitfalls they must avoid. The purpose of the Post, in publishing these articles, is to support the legitimate activities of trade associations, and to bring before the public more prominently the benefits to be derived by such organizations.

The Design and Construction of Oil Engines. By A. H. Goldingham. 480 pages, 5 by 7½ inches. Published by Spon & Chamberlain, 120 Liberty St., New York City. Price, $4.

The remarkable progress in the oil engine industry during recent years has made necessary a new revised and enlarged edition of this book on the construction of oil engines. The new edition has been brought up to date by the addition of 140 pages of new matter and 72 illustrations. Because of the quantity of material added, the book has been divided into two parts, the first of which deals with modern high-compression two-cycle and four-cycle engines, and the second with historical and earlier types of low-compression oil engines. The descriptions of the older engines have been retained, as this information is of great value where such engines are still in service and is also useful for purposes of comparison. The book contains full directions for testing, installing, operating, and repairing oil engines, and describes different American and European types. It is illustrated with many diagrams, which serve to simplify and clarify the descriptive parts of the text.

Crain's Market Data Book and Directory of Class, Trade, and Technical Publications. 456 pages, 6 by 9 inches. Published by G. D. Crain, Jr., 537 S. Dearborn St., Chicago, Ill. Price, $5.

The 1922 edition of this directory has been completely revised, and new industrial and merchandising data, as well as new lists of publications have been included. All of the most recent government census figures are included in the marketing surveys, and figures on the cost of doing business and turnover are given for all retail merchandising fields. In addition to the list of American publications, a complete list of foreign trade and technical papers is given, which should be especially serviceable to those interested in advertising work abroad. The arrangement is the same as in the previous edition. The basic idea of the book is to present statistical and marketing data regarding each industry, trade, or profession and to give a list of publications serving each field, for the benefit of the advertiser or merchandiser. The publication data includes the principal items which advertisers desire to know about mediums, namely, field covered, publication date, closing date, size of type page, maximum and minimum page rates, circulation, etc. Both the markets and the publications are indexed.

Success through Vocational Guidance. By James McKinney and A. M. Simons. 270 pages, 5½ by 8¼ inches. Published by the American Technical Society, Chicago, Ill. Price, $2.

Occupational analysis has received considerable attention in the industrial world in the last few years, and a book on this subject will doubtless be of interest at the present time. The book under discussion is intended to assist people who are starting out on a business career or those who are dissatisfied with their occupations to choose a life work for which they are fitted and which they will find congenial. It outlines, in a general way, the qualifications necessary and the education and training required for different branches of work, and gives an idea of the opportunities offered (or the remuneration received). The lines of work covered include professions, engineering, commerce, accounting, advertising, manufacturing, banking, transportation, building trades, hotel and restaurant keeping, mining, forestry, civil service, social service, and agriculture.

NEW CATALOGUES AND CIRCULARS

A. M. Byers Co., Pittsburg, Pa. Pamphlet entitled "Concerning Pipe. By a Piper," containing information on Byers' wrought-iron pipe.

Columbia Mfg. Co., Belleville, Ill. Supplement A to Grinder Book No. 26, giving list prices of the electric buffers and grinders made by this concern.

New Departure Mfg. Co., Bristol, Conn. Loose-leaf circulars 145 and 146 FE, illustrating installations of New Departure ball bearings in motor-driven wood saws and wood shaper spindles.

Northern Engineering Works, 210 Chene St., Detroit, Mich. Crane and hoist booklet No. 24 G, illustrating installations of Northern electric travelling cranes, gantries, and electric hoists.

Templeton, Kenly & Co., Ltd., 1020 S. Central Ave., Chicago, Ill. Catalogue of "Simplex" jacks, giving data covering the capacity, dimensions, and prices of the different types and sizes.

Climax Motor Devices Co., Chagrin Falls, Ohio. Circular descriptive of the "Climax" cord disk coupling, which is made in four sizes of 5½, 6½, 7½ and 9 inches diameter, for transmitting any desired power load.

Mercury Mfg. Co., 4118 S. Halsted St., Chicago, Ill. Circular showing illustrations of a "trackless train" installation made by this company in Japan. The installation consists of four Mercury Type L-4 tractors and several Mercury Type A-132 warehouse trailers.

Twentieth Century Brass Works, Belleville, Ill. Circular giving specifications for the line of ice-cooled bubbling fountains made by this concern, which are applicable for use in factories, shops, offices, schools, stores, theaters, and other buildings.

Engineering School of Drawing, 457 Main St., Springfield, Mass. Circular outlining the features of the engineering service offered by this school, which includes the making of tracings, detailing, designing, and the developing of inventions.

Sprague Electric Works of General Electric Co., 527 W. 34th St., New York City. Bulletin 67900, descriptive of Sprague narrow-unit panelboards of the safety type, which have been designed to meet the demand for a safety type panel at a moderate price.

Cleveland Punch & Shear Works Co., Cleveland, Ohio. Instruction sheet containing information on the proper care of punches and dies, which is intended to be posted where operators using this class of tools may readily refer to it.

Turbine Air Tool Co., 710 Huron Road, Cleveland, Ohio. Pamphlet entitled "Face the Issue," illustrating and describing a number of production tools, including portable turbine drills and grinders. The weight, capacity, and speed are given for the different sizes.

Chase Metal Works, Waterbury, Conn. Circular entitled "Why Brass Pipe?—Doesn't it Cost More?" containing tables showing weight per lineal foot of seamless brass and copper tubing in plumbers' sizes and iron pipe sizes. The base prices are given for the different sizes.

Chapin-Skelton Corporation, 406 Ash St., Syracuse, N. Y. Catalogue containing tables of dimensions and prices, as well as general descriptive material, covering the line of tools made by this concern, which includes reamers, boring-bars, lathe arbors, counterbores, production tools and special machines.

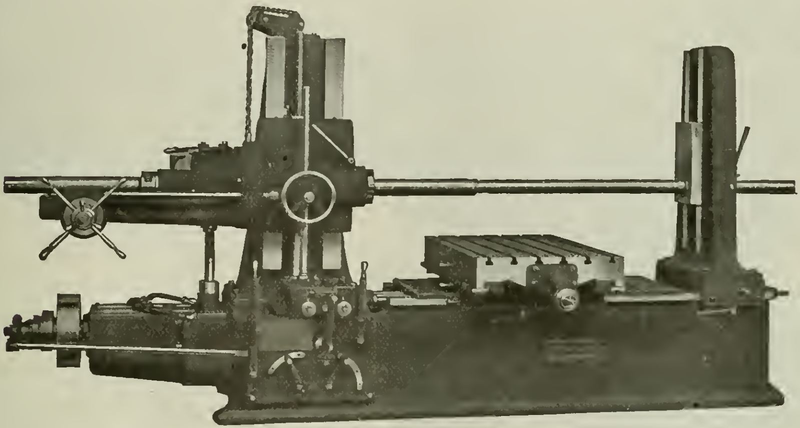
Reynolds Engineering Co., 101 Third Ave., Moline, Ill. Circular illustrating the use of the "Ever-Ready" connecting-rod aligning gage. The advantages of this gage are pointed out, and operating instructions are given. The Blood-Davies Co., 122 S. Michigan Ave., Chicago, Ill., is selling agent for this gage.

Necessity Wrench Shop, 415 Barclay Block, Denver, Col. Pamphlet descriptive of a drop-forged steel wrench, known as the "Necessity" wrench, which is designed for use in places where a double-end tap wrench cannot be employed. Price lists are given for the two different sizes in which this wrench is made.

Monitor Controller Co., Baltimore, Md. Bulletin 102, containing "Thermaload" starter instructions. Directions are given for the installation and care of these starters, and methods of locating and remedying trouble are described. A table of ampere rating of thermal elements to be used with induction motors is included.

It is sometimes astonishing to discover the obvious. One of our customers was astonished to discover that the job he had always been obliged to send to one of his neighbors who had an open side planer, could easily be done on his new

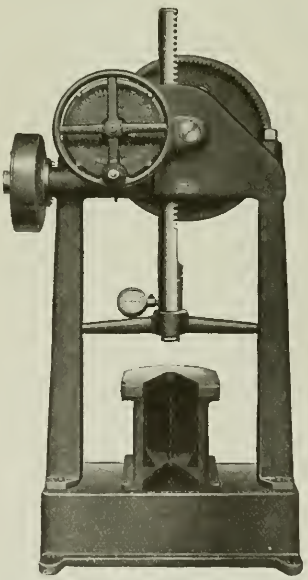
"Precision" BORING, DRILLING & Milling Machine



There is no more "power" in a Press (or other machine) than is put into it. If the power is put in by hand, it is only one man power. In the

LUCAS Power Forcing Press

the power is put in by belt or motor, but it has all the sensitiveness and delicacy of control of the best hand press, with the necessary power for heavy work.



LUCAS MACHINE TOOL CO. NOW AND ALWAYS OF **CLEVELAND, OHIO, U.S.A.**

FOREIGN AGENTS: Alfred Herbert, Ltd., Coventry. Societe Anonyme Belge, Alfred Herbert, Brussels. Aux Forges de Vulcain, Paris. Allied Machinery Company, Turin, Barcelona, Zurich. Benson Brothers, Sydney, Melbourne. V. Lowener, Copenhagen, Christiania, Stockholm. R. S. Stokvis & Zonen, Rotterdam. Andrews & George Company, Tokyo, Japan.

Golden Co., 405 Lexington Ave., New York City, has issued two bulletins in French, containing a description of RBF ball and roller bearings, and data on the application of these bearings to electrical machinery, hoisting machinery, cranes, etc. The calculation of loads is given, as well as numerous illustrations of bearing applications.

Fairbanks Co., 416 Broome St., New York City. Bulletins illustrating and describing the Lewellen variable-speed transmission, which is made in two types—the self-oiling design and the ball-bearing design. This transmission is made in sizes of from 1 to 150 horsepower, and the sizes carried in stock range from 1 to 25 horsepower, inclusive.

W. S. Rockwell Co., 50 Church St., New York City. Bulletin 241, on forging and heating furnaces, pointing out fundamental principles affecting the quality and cost of forgings, and other formed parts. Illustrations of typical equipment are shown, and descriptions are given of the heating and handling methods employed to meet a wide variety of manufacturing conditions.

Lovejoy Tool Works, 331 W. Ohio St., Chicago, Ill. Catalogue 10, illustrating and giving specifications for the line of tools and machinery made by this company for railways, boiler makers, and steel workers. These tools include ratchet drills, drilling posts, screw punches, ratchet wrenches, "Use-Em-Up" drill sockets, roller expanders, flue cutters, pneumatic hammers, ball-bearing jacks, etc.

Kurtz Equipment Co., 57 Houston St., New York City. Circular 294 of "Hallowell" steel lift truck platforms, which are made with steel runners that flare outward at both ends, so that the truck can slide in between skids without damaging them. Booklet R, outlining the features of construction of "Bond" anti-friction swivel truck casters, which operate in ball bearings to insure easy operation under heavy loads.

Ideal Electric & Mfg. Co., Mansfield, Ohio. Bulletins 102 and 103, containing specifications and illustrations of Ideal direct-current motors and generators, and Ideal squirrel-cage and slip-ring induction motors. The bulletins give ratings and speeds for the different sizes and types of motors included in the standard line, as well as other detailed information relative to the construction and application. Copies will be sent to those interested, upon request.

South Bend Lathe Works, 460 E. Madison St., South Bend, Ind. Circular showing South Bend lathes in use on a variety of operations, including grinding, drilling, turning, boring, threading, and milling. The illustrations give a clear idea of the wide range of work for which these machines are adapted. The circular also illustrates some of the different sizes of South Bend quick-change gear lathes, bench lathes, silent chain motor-driven lathes, and gap lathes.

Uehling Instrument Co., Paterson, N. J. Bulletin 112, containing information relative to Uehling carbon dioxide equipment, which is intended to guide the engineer and fireman in reducing fuel waste. The pamphlet points out the advantages of this equipment, outlines the principles of operation and describes the different units. Particular attention is called to the "Pyro-porus" filter which is a recently developed product designed to keep the gas sampling lines clean.

Kingsbury Machine Works, 4320 Tackawanna St., Frankford, Philadelphia, Pa. Catalogue C, treating of Kingsbury thrust bearings. The book contains data on dimensions, principle of operation, lubrication and cooling, unit pressures, friction losses and wear, results of tests, power loss determinations, and standardization of power losses. The different types of thrust bearings produced by this company are illustrated and described and instructions are given for installing and operating them.

Page Steel & Wire Co., Bridgeport, Conn. Catalogue 560, containing information on Page-Armco welding rods and electrodes for oxy-acetylene and electric welding. A list of the fields in which these products are especially applicable is given, and examples of welding operations are shown. Considerable welding data of general interest are included, as for example, diameter of rods used on various thicknesses of metals to be welded, American Welding Society specifications for electrodes, table of deposited metal for a given thickness of plate, electrical units, etc.

F. J. Littell Machine Co., 4125 Ravenswood Ave., Chicago, Ill. Catalogue covering this company's line of automatic feeds for all makes and sizes of punch presses, including automatic roll feeds, dial feeds, and special feeds. Attention is called to the advantages of automatic feeds, namely increased production and safety. The pamphlet also illustrates a line of special machinery made by this concern, which includes automatic straightening and cutting-off machines, wheel-truing tables, winding heads, and crank-shaft and camshaft straightener and tester. Copies will be sent to those interested, upon request.

Jacobs Mfg. Co., Hartford, Conn., has published a reference work known as the "Spindle Book," which is intended for free distribution, particularly among dealers in machine tools and supplies. The book contains spindle specifications of various types of machine tools using either taper-shank drills, taps, or drill chucks. The types of machines included comprise centering machines, drill grinders, flexible shafts, portable electric drills and portable pneumatic drills, tap grinders, tapping machines, drilling machines, bench lathes, and other lathes. The names and addresses of the manufacturers of the various machines and the spindle specifications are given in each case, and an alphabetical list of the manufacturers is given in the back of the book. A chart of arbor holes of Jacobs drill chucks is also included.

Niles-Bement-Pond Co., 111 Broadway, New York City, is issuing a series of pamphlets called the "Progress Reporter," recent numbers of which are especially devoted to railroad requirements. Pamphlet No. 29 deals with roundhouse repair facilities, and contains lists of machine tools required in roundhouse repair shops and terminal dispatching shops. A large number of illustrations of Niles-Bement-Pond machines adapted for this class of service are included. Progress Reporter No. 30 is devoted to modern railroad foundries, and smith and hammer shops. Tables containing lists of machines required in smith and hammer shops and in foundries are given, as well as diagrams showing lay-outs of machine and foundry equipment. This book also contains illustrations of Niles-Bement-Pond foundry and hammer shop equipment.

TRADE NOTES

Whiting Corporation, Harvey, Ill., has moved its Chicago sales office from 1245 Marquette Bldg. to 945 Monadnock Bldg.

Langhaar Ball Bearing Co., Aurora, Ind., is beginning the construction of a new factory, 40 by 150 feet, in Aurora.

Hess-Schenck Co., Cleveland, Ohio, dealer in new and used machinery is now occupying the first floor and basement of its remodeled building at 801 St. Clair Ave.

Monarch Machine Tool Co., 209 Oak St., Sidney, Ohio, is considering installing a sprinkler system in its factory and would like to get in touch with firms making such equipment.

Ready Tool Co., 650 Railroad Ave., Bridgeport, Conn., has discontinued its association with the Mayhew Steel Products, Inc., by mutual agreement, and hereafter will handle all sales of the company direct from Bridgeport.

Electric Furnace Co. has moved its general and sales offices from Alliance to Salem, Ohio. By this change all departments of the company will be consolidated at its works at Wilson St. and Pennsylvania Railroad in Salem.

Simmons Machine Co., Inc., Albany, N. Y., manufacturer and dealer in machinery and tools, has opened a machine tool warehouse at 182 Lafayette St., New York City. All the machines displayed in this warehouse will be tools that have been rebuilt in the Albany plant.

Knauel Tool Works have moved from 1544 24½ St. to 210 Fifth Ave., Rock Island, Ill., where they will continue to manufacture calipers and to develop special machinery and tools for inventors. The new quarters will afford the company about four times the previous shop space.

Tool Equipment Sales Co. is a new sales organization formed by Jesse B. Alton and C. B. Cole in Chicago, Ill., at 18 S. Clinton St. The concern will carry complete stocks for the Alvord Reamer & Tool Co., of Millersburg, Pa., and the Standard Saw & Tool Mfg. Co., Inc., of Boston, Mass.

Gits Bros. Mfg. Co., 1940 S. Kilbourn Ave., Chicago, Ill., manufacturer of the Gits oil-cups for machine tools and all kinds of machinery, has just completed an addition to its factory, of 50 by 75 feet, and reports business in its line to be good. This company is bringing out a one-piece oil-cup.

Meldrum-Gabrielson Corporation, Syracuse, N. Y., has constructed a large new factory at West Fayette and Niagara Sts. The factory is completely equipped with machinery for the manufacture of milling machines, adjustable-limit snap gages, and wood and metal patterns. The firm also has facilities for handling contract work.

Ludlum Steel Co. Watervliet, N. Y., announces that the suit brought by the American Stainless Steel Co. of Pittsburg, Pa., alleging infringement by the Ludlum Steel Co. of the Brearley and Haynes stainless steel patents has been dismissed by the United States District Court at New York on the ground that no infringement was shown.

Sandvik Steel, Inc., has consolidated its general steel and steel belt conveyor departments, both of these departments now being located in the Woolworth Bldg., Suite 2001, 230 Broadway, New York City. The officers of the company are as follows: President and general manager, W. D. Thomas; vice-president, Anders Johnson; secretary, Garrick M. Spencer; and sales manager, Harry Carlson.

William K. Stamets, dealer in machine tools, has moved the Cleveland office of the concern to 971-976 Kirby Building. Agency arrangements have recently been concluded with a group of Hartford manufacturers, including Billings & Spencer Co., Hanson-Whitney Machine Co., Hartford Tap & Gauge Co., Taylor & Fenn Co., and the Whitney Mfg. Co. George D. Miller is manager of the Cleveland office.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., was recently awarded a contract for the electrical equipment of a hot strip mill which is to be installed in the plant of the West Leechburg Steel Co., of Leechburg, Pa. The contract includes direct and alternating-current motors, motor-generator sets and control equipment.

Abrasive Co. of Canada, Ltd., Hamilton, Ont., Canada, manufacturer of artificial abrasives, at its annual meeting of stockholders in Philadelphia, Pa., in March re-elected the directors and the following officers: Frederick S. Dickson, chairman of the board of directors; Louis T. Byers, president; J. Harvey Byers, vice-president and general manager; Lawrence J. Morris, vice-president; and Samuel P. Byers, secretary and treasurer.

Driver-Harris Co., Harrison, N. J., has moved the Chicago branch of the company to larger quarters at 562-574 W. Randolph St. For some time the Chicago facilities have been inadequate, and it is believed that with the larger quarters the office will be able to give better all-around service to the various industries using "Nichrome" products.

Ogden R. Adams, Rochester, N. Y. will hold the third annual machinery demonstration given by the concern, at the Adams plant on Central Ave. and St. Paul St., June 2 and 3. This year two days will be given to the demonstration, which will be on a larger and more diversified scale than heretofore. Manufacturers and their technical experts from various parts of the country will be present to demonstrate their products. Other unusual and interesting features will be presented to make the two days helpful and entertaining to all who attend.

Rockford Milling Machine Co., Rockford, Ill., announces that the Mid-West Machinery Exchange, of Kansas City, Mo., will handle the complete line of Sundstrand lathes manufactured by the Rockford Tool Co., in the Kansas City territory. The English Tool & Supply Co., of Kansas City, will handle the cone-drive milling machines manufactured by the Rockford Milling Machine Co., and the Peden Iron & Steel Co., of Houston, Texas, will handle Rockford milling machines in the state of Texas. The Greensboro Supply Co., of Greensboro, N. C., has been appointed exclusive agent for Rockford milling machines in North and South Carolina.

Mexican Chamber of Commerce of the United States has been incorporated under the laws of the state of New York, with headquarters in the Woolworth Bldg., New York City. The object of the Chamber will be to promote business and economic relations between Mexico and the United States; to spread general information of reciprocal interest, and to foster friendly feeling. The directorate is composed equally of citizens of both countries who will furnish members with accurate information and assistance in the development of actual business. Offices of the Chamber have also been established in Mexico at 45 Bolivar St., Mexico City.

Rivett Lathe & Grinder Co., Boston, Mass., announces that although the extraordinary business conditions have made it necessary for a receiver to be appointed for the company in order to protect the creditors, safeguard the assets and maintain uninterrupted operation of the plant, the receivership will be of a temporary nature. A financial reorganization plan is being worked out to provide sufficient working capital. Although the company, like many other machine tool builders, lacks working capital, it is not insolvent, as the assets are nearly three times the liabilities, according to actual appraisal. The plant will continue in operation on an increased schedule during the receivership, and the company is in a position to accept and ship orders and to contract for new business.

Air Reduction Sales Co., 342 Madison Ave., New York City, has given out further details concerning the activities of this company and the Davis-Bournonville Co., the amalgamation of which was mentioned in the Trade Notes column of April MACHINERY. The Air Reduction Sales Co. owns and operates nineteen oxygen plants in industrial centers of the country, as well as a large number of plants manufacturing acetylene and other gases, and welding and cutting equipment; in addition, extensive laboratories are maintained for carrying on research work in connection with its various activities. The Davis-Bournonville Co. was organized in 1907 by Augustine Davis, Eugene Bournonville, and C. B. Wortham. At this time Mr. Davis and Mr. Bournonville acquired the rights in the United States and Canada for the Gauthier-Ely oxy-acetylene torch. From that time on, the efforts of the company were directed toward the development and improvement of the original positive-pressure torch. Later its line was extended to include oxy-acetylene cutting torches and acetylene generators, and finally a line of machines for welding and cutting was added. It is the intention of the Air Reduction Sales Co. to continue the manufacture of the Davis-Bournonville products under the supervision of the men who developed these apparatuses. The equipment will be marketed under the trade name of Airco-Davis-Bournonville.

Reclaiming a Railroad Scrap Pile

How the Canadian Pacific Railroad Turns its Scrap Pile into a Source of Revenue

By EDWARD K. HAMMOND

IN the operation of an extensive railroad system a vast quantity of scrap material inevitably accumulates. The small quantities which accumulate at various points along the system may not appear to have any great value; but if this waste material is systematically collected and salvaged to the best advantage, the total saving is likely to prove higher than even the best informed men would think possible.

The way in which the Canadian Pacific Railway Co. gathers up scrap in that zone of its system served by the Angus Shops, and sends it to be reclaimed at these shops in Montreal will give an idea of the value of material which can be recovered from a railroad scrap pile. The magnitude of this work will be realized when it is known that at the time the writer visited the plant, there were approximately 7000 tons of scrap piled on the storage space adjacent to the reclaiming dock. This material is shipped to Montreal in freight cars, into which it is dumped without any attempt to sort it at the source.

Upon arrival, the contents of these cars are dumped on the storage grounds, and day laborers are set to work picking over the piles and sorting the material. A preliminary sub-division will result in the piling together of car couplings, brake beam heads, journal boxes, and various other parts which it may be possible to reclaim. Likewise, scrap rubber, broken glass, and other material of the same general nature, are sorted out and later prepared for sale as junk. As an example, armored steam hose is slit in order that the wire may be removed; then rubber and canvas is sold in that form. Scrap glass is packed into barrels for shipment, and in order to make paper more convenient to handle, it is compressed into bales of convenient size for handling. Fig. 1 shows a partial view of the storage space in which usable material is stored, after the contents of the junk cars have been sorted. The slitting of armored rubber steam hose is shown in Fig. 2.

Salvaging Bolts and Nuts Reclaiming Steel Castings

A wide diversity of work is done in the reclaiming department. Many parts can be reclaimed or repaired, so that they can be used again. For instance, if bolts are in fairly good condition, it may be possible to simply rethread the end to adapt them for additional use, but if the bolt is badly bent or the thread is too far gone to lend itself to recutting, the end is sheared off and an entirely new thread is cut, thus making a bolt of shorter length. Similarly, old nuts are sorted for size and retapped to put them in condition for continued use. A special machine is provided for removing broken bolts from nuts. The work of reclaiming nuts is illustrated in Fig. 3.

Many of the malleable and steel castings that are returned to the scrap dock can be made fit for additional service. These castings are frequently cracked, and in such cases the defect is repaired by welding. In other cases the trouble may be due to bending, which is a defect quite often found in the shanks of car couplings. For correcting trouble of this kind, the shop of the reclaiming dock is equipped with several types of hydraulic and pneumatic presses which enable bent pieces to be straightened out in a comparatively short time. One

---

Economy of operation is the great need of the railroad shop, as well as of all branches of industry, at the present time. Every source of waste must be eliminated—every leak must be stopped—if the great railway systems are to be brought back to a paying basis. One of the leaks in railroad operation is the scrap pile. Vast quantities of scrap metal and other waste material accumulate on an extensive railway system, and the transforming of this scrap into useful articles is one of the problems of efficient management. The reclaiming of the scrap pile requires a carefully thought out plan. How this is accomplished on a large Canadian railway system is told in this article.

Fig. 1. Partial View of Storage Space in which Usable Materials are kept in Bins carrying their Part Numbers

of these presses is shown in Fig. 4, engaged in straightening the shank of a car coupling.

How Sheet Steel is Utilized

There are various forms in which sheet steel comes to the reclaiming dock; old shovels of various types are received, sheets of steel that have been scrapped after doing service in various ways, old wheelbarrow trays, etc. When the sheets are large, the oxy-acetylene torch is used to cut them up into sections of a size that may be conveniently handled. In the case of shovels the only thing necessary is to cut off the handle and remove the reinforced section that connects the handle socket to the bottom of the shovel. When this work has been completed, the steel goes to a power press equipped with a compound blanking die which is used for stamping out washers from the scrap sheet metal. This machine is shown in operation in Fig. 5.

Many of the shovels that come to the reclaiming dock have broken handles, while the bottoms are still good enough to be capable of giving a considerable amount of additional service. Conversely, the bottom may be worn out while the handle is in good condition. In addition to using the worn out shovel bottoms for washers, good shovel bottoms and good handles are collected together and refitted.

Methods Used in Reclaiming Steel Rod

In the material sent to the reclaiming dock, there are often considerable quantities of steel rod which is salvaged by either of two methods. In the case of rods of standard size, the procedure is simply to run them through a set of straightening rolls that put the rods into condition for subsequent use. Odd-sized rods have to be treated according to a different method, and the same practice is followed for the utilization of certain other classes of steel. In such cases, the material is heated and rolled out through a "three-high" type of rolling mill into rods of smaller diameter, the scrap material so treated being handled in exactly the same way as billets for hot-rolled steel rods.

Reclaiming Wiping Waste and Recovering the Oil

All railroads have occasion to use large quantities of wiping waste, and instead of following the usual practice of

Fig. 2. Slitting Armored Rubber Steam Hose preparatory to removing the Wire

Fig. 3. Multiple-spindle Nut-tapping Machine used for rethreading Old Nuts

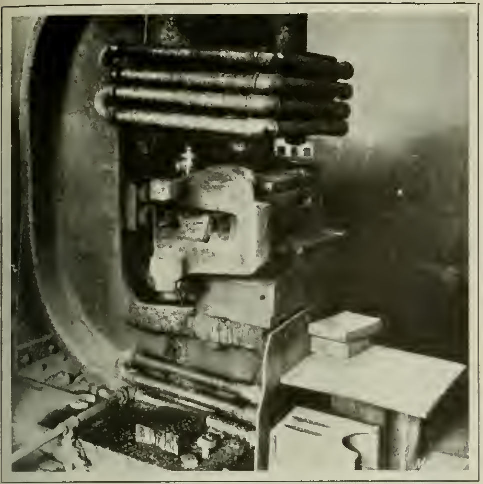


Fig. 4. Special Hydraulic Press used for straightening the Shank of a Bent Car Coupling

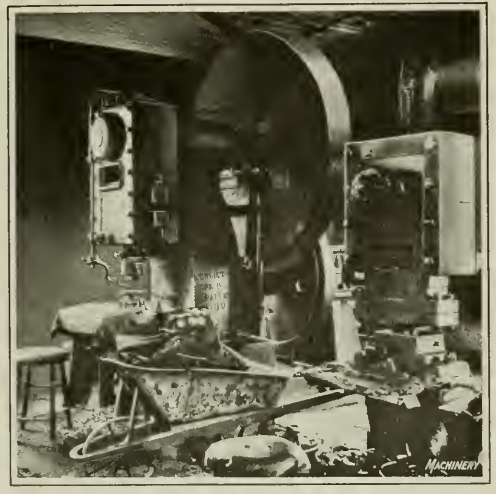

Fig. 5. Power Presses equipped with Compound Dies for piercing and blanking Washers

throwing this material away when it becomes too badly soiled for service, the C. P. R. shops in the zone served by the Angus shops collect it and send it back to these shops, where it is treated by a process that not only cleans the waste, but also recovers a considerable amount of oil. As the greasy waste first comes to the shop, it is placed in a centrifugal separator having a perforated bowl, in which the waste is held while the oil is thrown out through the perforations and caught in a suitable container. Next, the waste is cleaned in a washing machine of the same type as that used by laundries for washing clothes; and finally, the water is removed by subjecting the waste to a second treatment in a centrifugal separator.

Utilization of Scrap Pipe

Scrap pipe is utilized in a number of different ways, the two most important uses being in the construction of frames for farm crossing-gates, and in the making of pipe fitting nipples. In the case of the crossing-gates, it is simply a matter of cutting up the pipe into suitable lengths and threading the ends, so that by the use of couplings, elbows, and tees, a frame is constructed that will be covered with either wire mesh or strands of barbed wire. In using scrap pipe for making nipples, the procedure is quite simple: the material is worked through a pipe cutting and threading machine which cuts off pieces of the required length and threads the ends.

Resetting Spiral Springs

Large quantities of steel springs of various sizes come to the reclaiming dock. After a considerable amount of service, a compression spring often is flattened or a tension spring is drawn out too far to make it capable of fulfilling the required conditions. In the process of reclamation, the first step is to heat each spring and pull it out or subject it to a process of compression, according to the type of spring, after which it is retempered in order to give the steel the required physical properties.

Fig. 6. Accumulation of Scrap Sheet Metal outside the Tinsmith's Shop

How the Tinsmith's Shop is Supplied with Sheet Metal

One of the most extensive branches of the work of reclaiming scrap material at the Angus shops is carried on at the tinsmith's shop. In general no attempt is made to sort out the various classes of material prior to their shipment to the scrap dock. However, an exception is made in the case of the tinsmith's department, to which all sheet metal scrap from the different division shops of the C. P. R. system is shipped direct. A large supply of scrap metal is obtained from old brine tanks from refrigerator cars. The metal from both these sources is galvanized iron, and it is adapted for a variety of purposes. An accumulation of such material outside the tinsmith's shop is shown in Fig. 6.

Where lighter sheet metal is required, a considerable source of supply is obtained from old paint pails, all of which are shipped to Angus after their contents have been used. These pails are dipped into a tank of hot Wyandotte solution, which removes the paint and leaves the sheet metal clean and practically as good as new, without attacking the solder or otherwise affecting the surface of the metal. Some of these pails are cut up and used in sheets, while others are utilized by putting on a special cover and spout and making them into oil-cans of one-half gallon or one gallon capacity. Oil-cans of this type are shown at *R* and *T* in Fig. 7. This illustration also shows a variety of other products made in the Angus tinsmith's shop from scrap sheet metal, including water pans and pails, buckets, oil-cans, etc., the uses of most of which are self-evident. At *I* is shown a steam shield and at *K* a smoke-jack shield; *J* shows a car-heater top, *M* a smoke-jack, *N* a globe ventilator, *O* an engine-cab lamp shade, *P* a fireman's case kit, *Q* a tapered connection for a smoke-jack, *S* an engineer's tool-box, *U* a boiler inspection card-case, and *X* a car ventilator. The articles shown, however, by no means represent the entire range of products obtained as a by-product of the sheet-metal scrap pile.

Recovery of Solder from Joints in the Old Work

An important economy in the utilization of this scrap sheet metal is effected by the reclamation of all the solder used in sealing the joints. Obviously, all sheets of scrap metal that are utilized to advantage must be so cut that the seams carrying solder are removed. The scrap produced

Fig. 7. A Variety of Articles produced from Scrap Sheet Metal

Fig. 8. Furnaces used for the Recovery of Solder from Sheet Metal

in this manner is sent to an oil-heated furnace where the metal is heated sufficiently so that the solder melts and drips through the grate bars into a pan. From this pan the solder is transferred to a refining furnace, where it is remelted in a pot from which the dross is skimmed off, leaving the pure solder in a condition to be cast into bars for subsequent use. In Fig. 8 is shown a view of the equipment used for this purpose.

The value of material recovered at the reclaiming dock has run as high as $71,000 a month. With such savings as this possible, railway executives would do well to ascertain the possibility of applying a similar system for the recovery of all valuable material from the scrap that is produced in the operation of their own shops and in the maintenance of their lines and rolling stock.

* * *

SPANISH AUTOMOBILE INDUSTRY

The Hispano-Suiza Co., which is by far the largest of the three principal automobile manufacturing companies of Spain, has a total annual production capacity of about 2000 cars according to a recent Commerce Report. This company is located in Barcelona, but also operates a factory at Guadalajara for making trucks and various kinds of motor vehicles for the Spanish army. The Elizalde and the Espana automobile companies which are next in importance are also located at Barcelona.

According to Department of Commerce Reports, Spanish factories, as a rule, build only the engine and body of motor vehicles, importing the chassis and using foreign makes of carburetors, ignition, lighting, and oiling systems, etc. It is also stated that in the Spanish automobile field the United States unquestionably holds first place. The number of American-made automobiles in Spain today exceeds the total of all the other cars put together, including those made in Spain. Trucks of German and French manufacture, however, showed a decided gain in the Spanish market during the past year. Official statistics indicate that of the motor trucks imported into Spain during the first nine months of 1920, about 40 per cent came from France, 30 per cent from Germany, while only about 4 per cent came from the United States.

Changes in Patterns that Facilitate Molding

By M. E. DUGGAN

CHANGES in the design of a pattern can sometimes be made which will result in simplifying the method of molding, decreasing the cost of the work, or increasing production. An example of a change of this kind which materially increased the production of castings is shown in Fig. 1. The pattern is for a pouring basin, and the illustration shows the changes that were made to facilitate the production of castings. The patternmaker should realize that it is not always necessary to follow the design exactly;

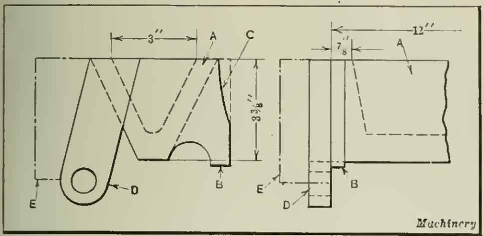

Fig. 1. Pouring Basin Pattern, showing how Improvements in Design simplify Molding

if simple changes can be made which will be of assistance in the molding work and will not affect the product, these changes should be made. If a pattern is to be molded in green sand, it may cause the molder considerable trouble in making the mold and in extracting the pattern, or if the mold is to be made with the assistance of dry sand cores, the extra cost of making these cores and the work of setting them in the mold may make it necessary to employ a different method.

In the present instance, sixteen sizes of pouring basins of various lengths were to be made from gray iron. The basin proper *A* is V-shaped and has a 3/16-inch radius at the bottom on the inside. This point in design would not have materially affected the method of molding if only a few castings were required, but when a number were to be produced the difficulties caused by this small radius made the pattern entirely impractical and the molding method slow and unsatisfactory. The time required to secure the thin edge of hanging sand in the cope and the possibility that it would drop or be washed away by the molten metal were factors that made it desirable to change the pattern.

First a change was made in the method of molding and then the design of the pattern was changed. In the first change the pattern was used as a core-box for making a dry sand core, which was suspended from the cope face of the mold. This method produced a good casting, but it resulted in a loss to the foundry owner. The second change consisted simply of increasing the size of the radius at the bottom of the basin to 7/16 inch so that it could be molded in green sand as was originally done. The sand was supported in the cope and secured by small pieces of wood. By this simple change the casting could be produced economically and satisfactorily.

These basins had a leg *B* cast at each end, having a graceful curve as indicated at *C* where the leg joined the body of the casting. This design necessitated making the legs loose and pinning them to the pattern, to avoid a deep parting and heavy "cope lift." This design was rejected by the foundry, and the pattern was returned to have the loose pieces secured to the pattern and built out in a straight line as indicated by the dotted outline so that the parting could come in a straight line and the pattern be readily drawn.

A hinge piece such as shown at *D* is also cast at each end of the basin which, in the original design, was intended to be molded in green sand. The slight change made to simplify the molding of this hinge was the use of a dry sand core placed at each end of the mold as indicated at *E*. A standard core-box was made for the hinge core, which was rammed up with the pattern in the mold. After the mold had been finished, it was a simple matter to remove the dry sand cores and draw the pattern without danger of injuring the mold. The cores were then returned to their place in the mold and the cope closed. The alterations here noted were later incorporated in the design of the pattern without affecting the usefulness of the casting.

Improvement in Molding Method

The casting shown in Fig. 2 was intended to be produced by a certain molding procedure, but it was found that by making slight changes in the method of molding, it was possible to produce it more economically. The pattern was originally made in two pieces, allowing 10 inches to extend into the cope and 16 inches into the drag. The intention was to mold the 1¾-inch slot in green sand, since the slots were cut from the pattern, but the molder realized that if this procedure were followed there would be a heavy body of sand hanging in the cope which would require the provision of sand-bars in the cope flask, extending down nearly to the parting line. It would probably have been necessary also to employ gaggers in order to help secure this deep body of sand and prevent it from dropping when the cope was closed.

The changes made by the molder were as follows: He fastened the two parts of the pattern together and made provision for molding the entire pattern in the drag. The pattern was made use of as a core-box to make a core which would extend down to the ribs *A*, and the core was placed

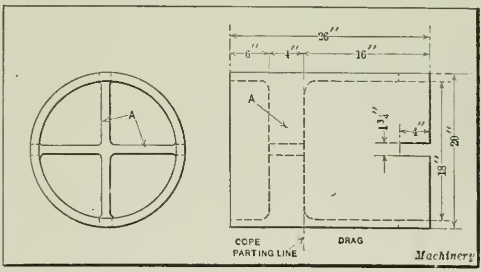

Fig. 2. Casting which was produced more economically through a Change in Molding Methods

in the pattern and made part of the cope by suspending it in the flask, using wire fastened to wooden bars placed crosswise on the top of the flask. This permitted the dry sand core to be lifted with the cope. In ramming up the drag, the four slots already made in the pattern were utilized for locating dry sand cores by means of which these slots were molded. The pattern was drawn out of the drag and the mold finished in the usual way before returning the cope with its hanging dry sand core to its place on the drag. It should be noted that the casting is molded on end, instead of horizontally, as shown in the illustration.

Simplification in Design of Patterns

It is frequently advisable when making castings for replacement, as in repairs, to simplify the design of the pattern in order that the repair part may be molded more quickly. Original designs usually have certain graceful outlines which are not necessary as far as service is concerned, so that when a casting or two is wanted for repairs, certain changes may be made (if a new pattern is required) which will enable the foundry to make the casting without any unnecessary work. A case of this kind is shown in the illustration Fig. 3.

The casting to be replaced was a journal bearing, 15 inches in diameter, provided with anchorages for the babbitt lining. An inspection of the partial section view at the left in the illustration will show that the finished strip at the top of the casting, the pads around the bolt holes and certain other features of design require the use of dry sand cores and other molding work which does not lend itself to rapid production. The view at the right shows the changes in design that were made and how they simplified the production of the casting. In this particular case the patternmaker was empowered to use any means that he felt advisable to produce the casting in the quickest possible time. This privilege

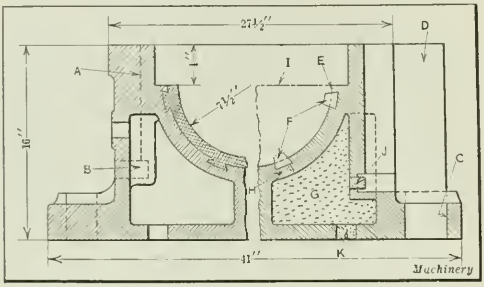

Fig. 3. Casting before and after changing the Design of the Pattern

is not always granted the patternmaker without first consulting the engineering department; but in a repair shop, where the regular manufacturing routine is not so rigidly adhered to, when the patternmaker has that liberty, changes will often be made which will simplify both the design and the molding.

Referring to the changed pattern, it will be seen that the finish strip and pads have been removed and the side of the bearing made straight; also that the bolt slot *A* has been extended and the cored opening *B* for the bolt head located on a level with the pads which surround the bolt hole in the base of the casting. This permits the use of one core for molding the bolt slots, the bolt head slots (of which there are two on each side), and the slotted clamping bolt hole *C*. This core was located in the mold by means of the core-print *D*. Provision was made for molding the babbitt circle *E* in dry sand by loosely attaching core-prints, as at *F*, to the pattern and using the pattern in this condition as a core-box for making the dry sand core *I*. Anchor cores, as shown, were then set into the slots produced in the bearing core at *F*, and pasted in place for producing the anchorage slots for the babbitt.

Provision for locating and supporting the water-chamber core *G* in the mold and for liberating gases was made in the following manner: Stud cores *H* were set on the anchor cores, and other stud cores *J* were located in a hole formed in that section of the main core by which the bolt head slot was produced. This provided the necessary locating and supporting means for the water-chamber core and permitted the use of stud cores at *K* for clamping the water-chamber core down against its supporting cores. These stud cores also provided an outlet for any trapped gases.

PLASTER MOLDS FOR SMALL CASTINGS

By FRANK LUX

Plaster-of-paris molds have been in use for many years, but despite that fact, few people interested in the production of castings realize their value. They are especially useful as a means of producing small castings for experimental work, and in some cases they can also be used to advantage in the production of castings required in the construction of commercial products. A casting made in a plaster-of-paris mold is smoother than one made in a sand mold. This is quite an advantage when the appearance of the casting is important. For instance, if the levers, arms, brackets, etc., used in working models are cast in fine sand molds it is usually necessary to file the castings all over in order to obtain the desired finish, whereas if plaster-of-paris molds are used, a satisfactory surface is produced without filing.

Mixing Plaster for the Molds

Plaster-of-paris alone will not withstand the heat of molten metals, and experience has shown that the addition of asbestos is necessary to insure the success of so-called "plaster-of-paris" molds. Pure plaster would crack when heated, and the castings produced would not be uniform. The percentage of asbestos may be varied according to the material to be cast, although equal amounts of plaster-of-paris and asbestos generally produce very satisfactory results.

The mixing of the plaster is very simple, yet there are several points that require careful consideration. A pan or pail of suitable size is partly filled with water (the amount depending on the quantity of plaster required) and powdered plaster sifted into the water. When the sifted plaster thus piled up reaches the surface of the water, an equal amount of asbestos is added. Care should be taken not to stir the water and plaster-of-paris before adding the asbestos. After the addition of the asbestos the ingredients are stirred thoroughly. The asbestos is used in pulverized form.

Making the Molds

In making the mold, the pattern is placed on a piece of glass or smooth board and enclosed by a frame. If a frame is not obtainable, boards or strips can be used. At *A*, Fig. 1, is shown a frame of standard design. This frame rests on the glass *B*, although a slate-top table can be used if desired. The pattern *C* is located at the center of the frame, and the plaster is poured in until it has covered the pattern and fills the cavity in the frame.

In the lower view of the illustration, is shown a method of using four strips *D*, *E*, *F*, and *G* in place of frame *A*. The strips should be of sufficient height to allow the plaster to cover the pattern entirely, and they should be arranged to suit the size of casting to be made. A small amount of plaster should be poured on the pattern, and a soft brush used to brush the surface of the pattern over with the plaster before filling up the frame. This insures covering the entire surface and prevents the formation of air pockets.

Wooden and metal patterns should be covered with a coat of oil before pouring the plaster. This facilitates the removal of the pattern from the mold after the plaster has set. A mold of this kind will set in from twenty to thirty minutes. The frame is then removed and the top scraped to a flat surface. The plaster forming the drag, with the pattern still in position, is then turned over to permit casting the cope. The entire matching surface of the drag is covered with a solution of soapy water, which prevents the plaster forming the cope from adhering to that of the drag. Thus the two parts of the mold can be easily separated when the plaster has set.

Dowel-pins may be set into the drag before pouring the cope to insure alignment of the two members after the removal of the pattern. It is possible, however, merely to countersink the top surface of the drag, as shown at *A* in Fig. 2. Three or four countersunk depressions, such as shown at *A*, are sufficient to insure proper alignment. When the cope is poured, the depressions in the drag form corresponding projections in the cope, thus providing a means of accurately matching these two members.

In making a mold for the knob shown at *B*, a somewhat different method is used. The knob is placed in a clearance hole *D* of a plaster slab *C*. Putty or wax *E* is then filled in around the knob, bringing the center up to the parting line. This allows half of the pattern to project above the surface. The plaster is then poured in the usual manner, after side frames or strips such as indicated at *F* have been suitably placed. In making the cope for this work, the plaster forming the drag is turned over after it has been separated from the plaster slab. The pattern or mold, in this case, is allowed to remain in the drag. The projecting part of the pattern is next coated with oil, and the parting surface of the plaster slab is coated with soapy water, as previously described. Dowels or countersunk holes are then provided to insure alignment, after which the plaster is poured to complete the cope.

When the mold has set, it is turned up on edge and the two parts are separated by inserting a knife blade in the parting line. Separation is not difficult if the knife blade is inserted in the parting line on all four sides of the mold. The general method of gating molds of this kind is to gouge out sufficient plaster to form the gate while the plaster is comparatively soft and moist. Standard gating methods should be used, since the metal flows the same in a mold of this kind as it does in the ordinary type. Gates can be built in the mold or patterns if desired.

Baking Plaster Molds

A plaster mold is somewhat moist for a considerable time after it has been made, and the best results are obtained by baking the mold in an oven, before using, for from twelve to twenty hours, according to the size, at a temperature of 650 degrees F. If no oven is available, the mold should stand for forty-eight hours in a dry place, after which it should

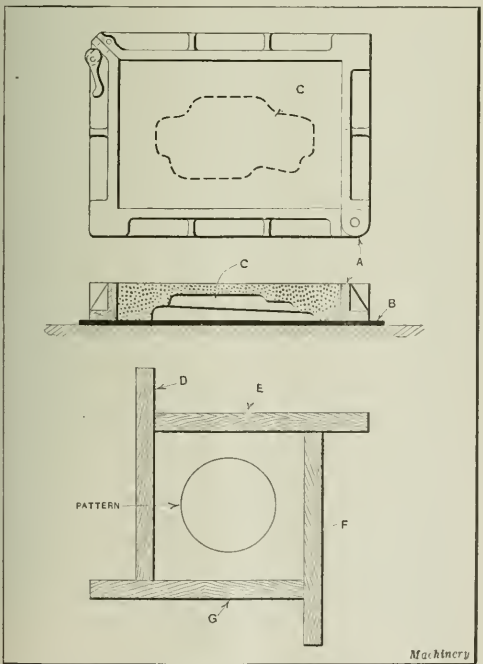

Fig. 1. Frames used in making Plaster-of-paris Molds

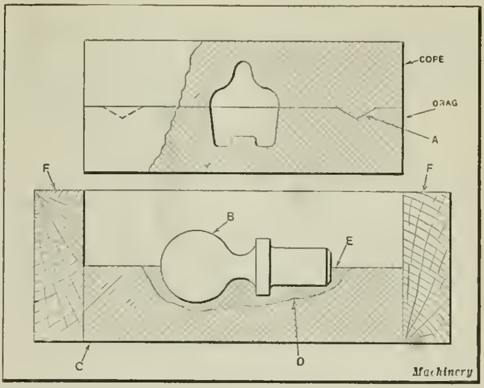

Fig. 2. Examples of Plaster Molding

be thoroughly dried and ready for use. After the mold has been baked or been thoroughly dried, it is clamped together with ordinary wooden clamps and placed on the floor or table so that the gate is at the top. The molten metal is then poured into the mold in the usual way.

Heating Furnaces

When the number of metal castings required is not sufficient to warrant the use of a large metal furnace, it is convenient to use an electrical furnace of the crucible type. The metal is brought to the proper heat, and then poured into the mold, where it is allowed to cool sufficiently to become set. The mold is then broken up and the casting removed and placed in a pickling solution. Some of the metals that can be molded satisfactorily in plaster molds are aluminum, and various grades of brass and cast iron. Stellite has also been cast successfully in plaster molds, and in some instances the results obtained have been better than with carbon or sand molds.

The following examples will serve to show some of the advantages of plaster molds: Assume that a connecting-rod, 5 inches long, of ordinary design is required to be cast in bronze. A wooden pattern could be used or the connecting-rod could be molded in wax, such as may be purchased in an art store. The wax mold can be worked out in a comparatively short time and is immediately ready for use. The surface is covered with oil, and the drag and cope are made as previously described.

Another example is the reproduction of a tablet bearing a face, figure, or some inscription. In this case the tablet is laid on a piece of glass and covered with oil, after which the plaster is poured. After setting, the plaster mold is turned over and the upper surface covered with a solution of soapy water. The dowels are next inserted, and the plaster backing is made. The two members forming the mold are then separated, gates cut, the pattern removed, and the mold dried or baked. By this method the original plate or pattern is reproduced in sharp detail.

Shrinkage Allowance

The allowance for shrinkage of castings made in plaster molds is the same as with other types of molds, and varies only according to the metal to be cast. Plaster generally keeps its size, although some plaster swells slightly. This swelling is governed by the proportions of the ingredients used. A foundry for producing castings from plaster molds does not require much equipment. Metal patterns can be used in making plaster molds, and production methods can be worked out with little difficulty.

There are many little kinks in the use of plaster molds that can be learned only through experience, but this article outlines general methods that will give successful results.

Cutting Internal Spur Gears

Milling Internal Gear Teeth with Formed Cutters—Generating the Teeth on Gear Shaper—Use of Form-copying Gear Planer

By FRANKLIN D. JONES

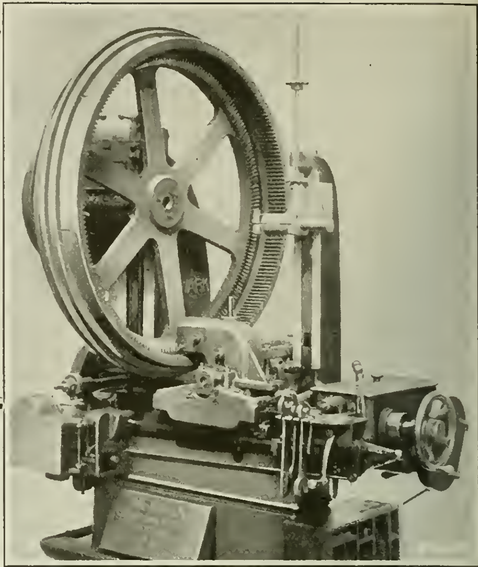

Fig. 1. Cutting an Internal Gear on a Machine equipped with an Internal Attachment

INTERNAL spur gears are cut by methods similar in principle to those employed for external spur gears, although the equipment used may vary somewhat owing to the fact that internal gears have teeth on the inside of a rim and frequently have a web at one side which limits the amount of clearance space at the ends of the teeth. Internal spur gears are usually cut by one of the following methods: (1) By using a formed cutter and milling the teeth; (2) by a molding-generating process, as when using a Fellows gear shaper; (3) by planing, using a machine of the templet or form-copying type (especially applicable to gears of large pitch); and (4) by using a formed tool which reproduces its shape and is given a planing action either on a slotting or a planing type of machine.

The machines used ordinarily for cutting internal gears are designs intended primarily for external gears. These machines are arranged for internal gear-cutting by using some form of attachment which provides means of holding the cutter in the position required for forming gear teeth around an inner surface. Attachments for cutting teeth by the milling process also transmit motion to the cutter.

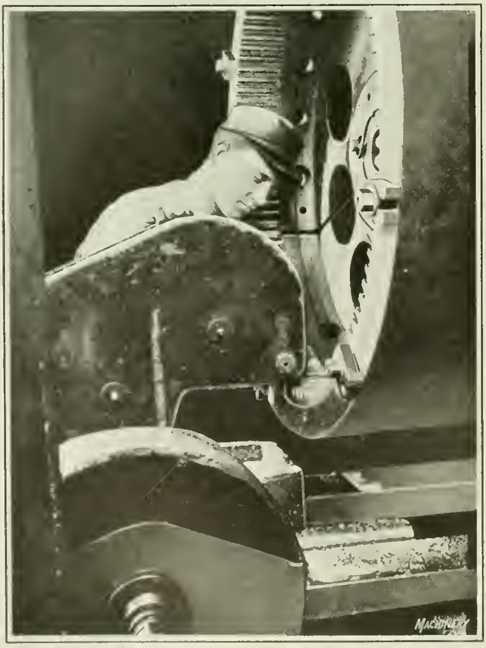

Fig. 2. Detail View of an Internal Gear-cutting Attachment at Work

Automatic gear-cutting machines of the formed-cutter type and designed primarily for spur gearing, are often used for cutting internal spur gears. The machine is adapted to this work by equipping it with a special attachment. Fig. 1 shows one of the Newark machines equipped with an internal attachment, cutting a large cast-iron internal ring gear. This attachment is mounted upon the regular cutter-slide of the machine, and the cutter is held at the end of a rigid arm which projects far enough to enable the cutter to operate on the teeth of an internal gear. The cutter is driven through a train of gearing from the regular cutter-spindle, the locations of the gear-shafts being clearly indicated in the illustration. The ring gear shown in this particular illustration is held in position by means of a cast-iron spider to which the gear is bolted, and the spider, in turn, is mounted on the regular work-spindle. These ring gears have 220 teeth of 5 diametral pitch, 2¾-inch face width, and a pitch diameter of 44 inches. Each tooth space was finished from the solid at one cut, using a feed of 5 inches per minute, and a cutter speed of 68 revolutions per minute. A high-speed steel cutter was used, and as twelve ring gears were required, a special cutter was made and ground to form after hardening.

In Fig. 2 is shown another example of internal gear-cutting. This is a close-up view of a machine made by the Cincinnati Gear Cutting Machine Co., equipped with an internal attachment for cutting steel internal gears having 96 teeth of 2 diametral pitch and a pitch diameter of 48 inches. These gears are also of the ring form, and are held in a special fixture mounted on the machine spindle.

When internal gears having webs are to be cut by means of rotary cutters, it is necessary to provide a clearance at the inner ends of the teeth which is somewhat greater than the radius of the cutter. As this amount of clearance may be objectionable, and as it may be very desirable to have the gear and web formed of one solid casting, the use of formed cutters and the internal gear-cutting attachment may not always be desirable or practicable.

Formed Cutters to Use for Internal Gears

When internal gears are cut by means of formed cutters, a special cutter is usually desirable, because the tooth spaces

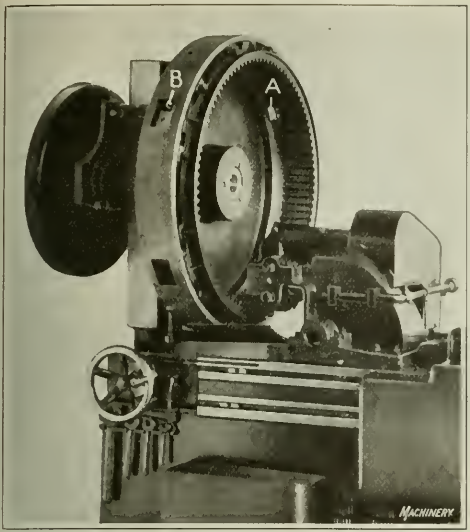

Fig. 3. Special Design of Internal Gear-cutting Attachment

of an internal gear are not the same shape as the tooth spaces of external gearing having the same pitch and number of teeth. This is due to the fact that an internal gear is a spur gear "turned inside out." According to one rule, the standard No. 1 cutter for external gearing may be used for internal gears of 4 diametral pitch and finer, when there are sixty teeth or more. This No. 1 cutter, as applied to external gearing, is intended for all gears having from 135 teeth to a rack. The finer the pitch and the larger the number of teeth, the better the results obtained with a No. 1 cutter.

According to the Brown & Sharpe Mfg. Co., if internal gears of high grade are required in quantity, it is preferable to have a special cutter made. The standard No. 1 cutter is considered satisfactory for jobbing work, and usually when the number of gears to be cut does not warrant obtaining a special cutter, although the use of the No. 1 cutter is not practicable when the number of teeth in the pinion is large in proportion to the number of teeth in the internal gear. If the difference between the number of teeth in the gear and in the pinion is less than 6, it is necessary to depart from the regular 14½-degree shape and use either a reduced depth or a greater pressure angle, or more often both. Ordinarily, the difference should not be less than 15 for the 14½-degree pressure angle. This number may be smaller for a larger pressure angle. According to the Newark Gear Cutting Machine Co., if a special formed cutter is not made to conform to the internal gear to be cut, it is considered preferable to use a straight-sided 29-degree worm milling cutter rather than a regular spur-gear cutter.

Special Attachment for Cutting Internal Gears

The special internal gear-cutting attachment shown in Figs. 3 and 4, applied to a Brown & Sharpe machine, was made for the purpose of cutting internal gears for tractors. This attachment, unlike the standard design, is driven from the cutter driving shaft by a silent chain and sprocket transmission, and it is not connected with the regular cutter-spindle. Fig. 4 shows the attachment with the guards removed. The special chuck or holding fixture receives two blanks at one time. These are held in place by hook-bolts. Recesses *A* and drain-holes *B* allow the cutting compound to escape from the fixture.

Double cutters are used, one for roughing and the other for finishing. The comparatively slow feed for the first cut is automatically increased for succeeding cuts. These cast-steel internal gears have 99 teeth of 3-4 pitch (stub teeth), and the total face width is 4¼ inches. The cutting speed is 74 revolutions per minute, with cutters 4¾ inches in diameter, and the feed is 1¾ inches per minute. The two gears are cut in 6¼ hours.

Cutting Internal Gears on a Gear Shaper

Internal spur gears are cut on a Fellows gear shaper by the same general process as that employed for cutting external spur gears. The same type of cutter is used, and the machine is geared so that cutter and work are rotated in unison like a pinion in mesh with an internal gear. An example of internal gear-cutting on a Fellows machine is illustrated in Fig. 5. Special cutters are not required for internal gearing, and frequently the cutter used for the mating gear or pinion is also used for cutting the internal gear.

The push or downward stroke is ordinarily used for cutting internal gears, instead of the pull or upward cutting stroke commonly employed for external gears. By using the push stroke, it is possible to cut internal gears having a web located very close to the ends of the teeth. In fact, if the groove is wide enough to prevent the chips from packing between the cutter and the work, that is the only requirement. In the case of internal spur gears, the minimum width of the recess or clearance space varies from 3/16 to 9/32 inch for gears ranging from 24 to 4 diametral pitch.

When setting up the machine, an intermediate gear is inserted in the train of change-gears, so that the cutter and work will rotate in the same direction when the machine is at work, instead of in opposite directions as is required when cutting a spur gear. In other words, the machine is geared to give the same relative motion between cutter and work as is obtained when a pinion is running in mesh with a gear, rotation of the pinion and gear being in the same direction for internal gearing and in opposite directions for external gearing.

The four standard sizes of gear shaper cutters having pitch diameters of 1, 2, 3, and 4 inches, respectively, meet all ordinary requirements in cutting internal gears. The size of cutter to use is governed by the number of teeth in the internal gear and the pitch. In the design of internal gear-

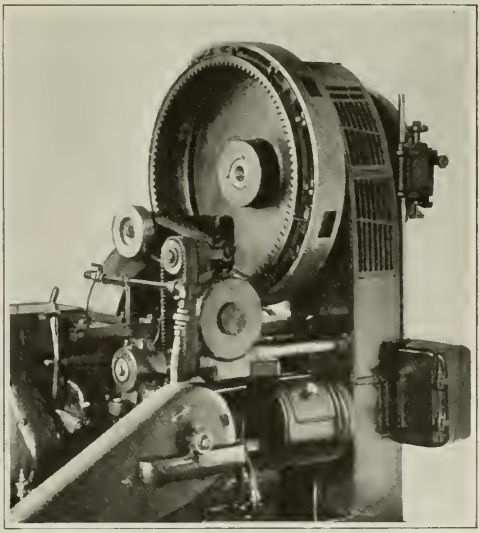

Fig. 4. Guards removed to show Chain Drive of Internal Attachment illustrated in Fig. 3

ing, if the pinion is made too large in proportion to the size of its mating gear, the teeth will not mesh properly because of interference. This also applies when selecting a cutter, since the latter represents a pinion and generates the tooth curves as the cutter and work rotate in unison at the proper ratio. If the difference between the number of teeth in the gear and the number of teeth in the cutter is too small, the cutter will trim off the tops of the teeth due to improper meshing, the result being teeth of incorrect shape.

Internal gears are ordinarily held in special fixtures, the design of which depends on the shape of the gear and the number to be cut. For instance, a simple type of faceplate fixture may be employed when only a few gears are to be cut; whereas, for quantity production it would be economical to construct a special fixture, such, for example, as would enable the gear blanks to be accurately located with greater rapidity than when using a fixture designed for general work.

A typical design of internal fixture is shown in Fig. 6. It consists of a pan-shaped body having a machined seat *A* in which the gear blanks are held by clamping straps *B*. These straps have elongated bolt-holes, and are supported by springs so that they can be pushed back readily for inserting or removing work. The particular fixture shown is used for holding two ring-shaped gears *C*. The fixture is accurately centered in relation to the work-spindle by plug *D*, and it is supported on the cutting side by a roller at *E*.

Internal gears for speed-reducing mechanisms, etc., are often made with helical teeth in order to obtain a more perfect rolling action, and such gears may be cut on the helical type of gear shaper which will be referred to in a succeeding article.

Machine of Slotter Type for Cutting Internal Gears

A machine adapted for cutting internal spur gears, which is designed along the lines of a slotter, is shown in Fig. 7. This machine, which is of an automatic type, is used at the Bilgram Machine Works. When the machine is at work, the table is given an indexing movement, corresponding to the circular pitch of the gear, each time the tool clears the work on the upper stroke. The inward feeding movement occurs after each revolution of the gear blank. The indexing movement is derived through the change-gears *A*; just after this motion occurs, a cam-operated pawl or anchor engages a notched disk and holds the work-table securely during the downward or cutting stroke.

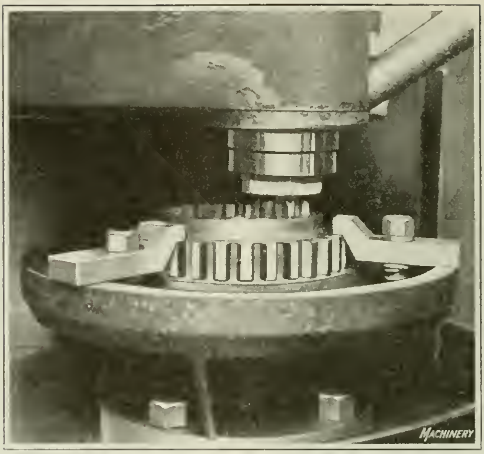

Fig. 5. Cutting an Internal Gear on a Gear Shaper

The feeding movement is obtained through a very ingenious pawl and ratchet mechanism. The ratchet wheel *B* has teeth formed along a spiral which makes several turns around the wheel as the illustration shows. Between the rows of teeth there is a narrow slot engaged by a projection extending below the hub of pawl *C*. This pawl is free to slide along rod *D*, and the projecting part causes the pawl to follow the spiral row of teeth as the ratchet wheel is rotated. As previously mentioned, this feeding mechanism operates after each complete revolution of the work-table, and it is so adjusted that when the tool has been fed to the proper depth the pawl slides out of engagement with the teeth on a blank space so that it cannot rotate the ratchet wheel further. The cutters used on this machine are of the formed type, the tooth curves being a direct reproduction of the cutter itself. The part shown on the machine is made of steel and contains sixty-seven teeth of 8 diametral pitch.

Cutting Large Internal Gears on a Templet-type Planer

The most practical method of cutting large internal gears is on a planer of the form-copying type. An example of internal gear planing on a Gleason machine is illustrated in Fig. 8. This is a regular spur gear planer equipped with a special tool-holder for locating the tool in the position required for cutting internal teeth. The holder is of a heavy, rigid design, which prevents excessive deflection of the tool.

The templets used to control the path followed by the tool conform to the shape required for internal teeth, and

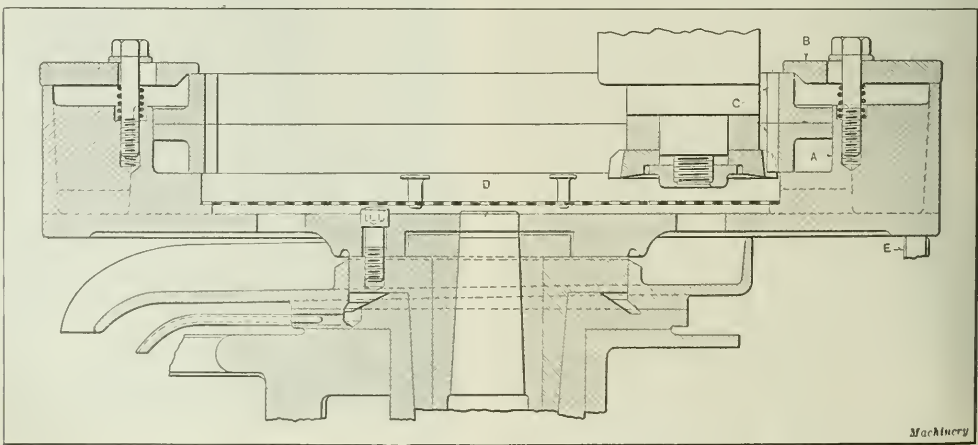

Fig. 6. Fixture for holding Internal Gears while cutting on a Gear Shaper

differ in shape from those used for external gears of the same size. Very satisfactory internal gearing may be cut on planers of this type, which are especially adapted for large work. The chief features governing the operation of gear planers of the templet type were described previously in connection with their application to large spur gears. The procedure of cutting internal gears is practically the same as for external spur gearing, after the machine has been equipped with the special tool-holder referred to.

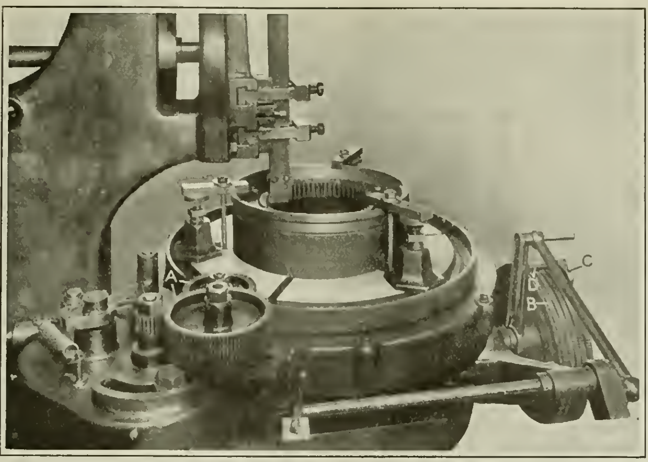

Fig. 7. Internal Gear-cutting Operation on Automatic Machine of Slotter Type

Dimensions for Cutting Internal Spur Gears

As the position of the teeth of an internal gear are reversed as compared with an external gear, the addendum of an internal gear is inside the pitch circle and the dedendum outside; consequently, in machining blanks for internal gears the inside diameter is made equal to the pitch diameter *minus* twice the addendum. If the pitch diameter is not known, the inside diameter may be found by first dividing the number of teeth by the diametral pitch (thus obtaining the pitch diameter) and then subtracting twice the addendum. The addendum of an internal gear, the thickness of the tooth on the pitch circle, and the whole depth of the tooth may be obtained by the same rules or formulas as are used for external spur gears.

Internal gearing is frequently utilized in connection with various forms of speed-reducing mechanisms, since this type of gearing is often conducive to compactness in design. In fact, one advantage of internal gearing is that the center-to-center distance between gear and pinion is much shorter than between two external gears of the same ratio. If the diametral pitch and numbers of teeth in the gear and pinion are known, the center-to-center distance for internal gearing may be determined by subtracting the number of teeth in the pinion from the number of teeth in the gear, and dividing the remainder by twice the diametral pitch. Ordinarily, considerable reduction in speed is obtained through internal gearing, but occasionally gears of low ratio are required and then it may be advisable to use gear teeth of the cycloidal form. When using the involute form, the internal gear should have at least fifteen more teeth than its mating pinion in order to avoid excessive interference.

* * *

The Belgian automobile industry has been unable to supply the home demand since the Armistice, according to a Commerce Report, its total output being not more than 5000 cars a year. American cars are said to be more satisfactory as regards price and quality than the home products.

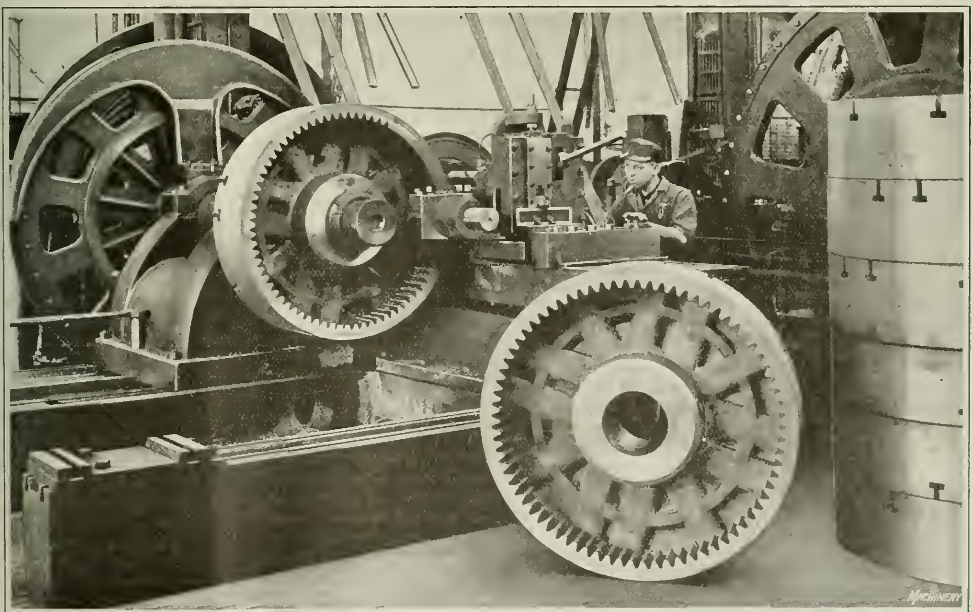

Fig. 8. Example of Internal Gear-cutting on Planer of Form-copying or Templet Type

The German Machine Tool Industry

Berlin, May 3

GERMAN industry in general, and the machinery and machine tool industry in particular presents to the casual observer a picture of activity and apparent prosperity. Were it not for the scarcity of raw materials and fuel, there would apparently be no cloud on the industrial horizon. In reality, however, conditions are not quite so satisfactory as they appear. The great industrial activity is due to the continuation of the selling-out process of Germany, which is accompanied by increases in prices to domestic consumers to such an extent that the great mass of the people in the country must deny themselves all those necessities that are on the price level of the world's markets. It is, therefore, not without fear and uncertainty that the captains of industry look into the future.

A foreboding of what might happen was presented by the strike of the railway employes early in the year. This strike was due to the extremely high prices of food, much of which has to be imported from abroad—and therefore must be sold at the world's market prices—as Germany cannot support its entire population with the agricultural products of its own soil. When imported products have to be bought with the depreciated German mark, prices compared with earning power rise to an almost unbelieveable level. While the skilled workman in Germany earns 10 marks an hour or 80 marks a day, a good suit of clothes costs as much as 6000 marks—in other words, it takes the entire earning power of a workman for seventy-five days to obtain a suit of clothes that at present exchange would be worth $20.

The railway strike lasted about six days, but no strike has ever so seriously threatened the economic existence of the country. Nearly everything came to a standstill, and in the six days the loss to the railroads was 1,800,000,000 marks, the value of destroyed materials 552,000,000 marks, and the estimated direct loss to the country 2,400,000,000 marks.

Results of the Leipzig Fair

More than 15,000 foreign buyers were attracted to the Leipzig Fair this spring, and on one day there were more than 140,000 visitors. The number of orders placed at the fair may be said to have been overwhelming. This applied to the machine tool industry as well, many orders being placed; but this must be considered as a selling-out fair for Germany, because if German money continues to depreciate, the manufacturers will be unable to replenish their stocks of such raw materials as have to be imported from abroad, and will not be in a position to continue production after present supplies are exhausted. Buyers conversant with the conditions in Germany know this, and if the difference between the German and the foreign price is not very large, they are reluctant to place orders in Germany, because they are uncertain as regards deliveries. There are examples on record of foreign makers underbidding German manufacturers by 30 per cent, especially in cases where the German manufacturer is forced to use imported raw materials.

Sliding Scale of Prices

In view of the uncertainty as to prices, orders for future deliveries are not taken at a fixed price, but in accordance with a sliding scale. Several methods are employed to determine this sliding scale. The Association of German Machine Tool Builders has formulated a rule intended to protect the interests both of the manufacturer and of the buyer. In accordance with this rule, current prices are quoted, but these prices are increased, if found necessary, by a certain percentage which is stipulated monthly by the association, the percentage of increase being added from month to month to the original price quoted.

Another rule that is followed on orders for certain classes of equipment is that the prices shall increase by 0.4 per cent for each per cent increase in the prices of raw materials during the first half of the period intervening between the placing of the order and the delivery; and by 0.4 per cent for each per cent of increase in average wages of skilled workmen during the second half of the time intervening between the placing of the order and the delivery.

Prices of Machine Tools in Germany

Expressed in marks, German machine tool prices are from forty to fifty times the prices previous to the war. At that time prices varied from 0.25 to 0.75 mark per pound, according to the size and type of the machine. At pre-war exchange, this meant a variation of from 6 to 18 cents a pound. At the present time the average price per pound of smaller machine tools is 25 marks per pound (from 8 to 9 cents per pound); on larger machine tools the price is approximately half of this, or about 5 cents per pound. A number of examples of present prices are given below:

24-inch lathe, 10-foot bed, weighing 13,200 pounds, 130,000 marks (present exchange, $435).

18-inch engine lathe, 3½ feet extreme distance between centers, weighing 3200 pounds, 48,000 marks (present exchange, $160).

16-inch relieving lathe, 3½ feet between centers, weighing 4200 pounds, 100,000 marks (present exchange, $335).

Vertical milling machine with rotary table, weighing 6500 pounds, 150,000 marks (present exchange, $500).

Centering machine for pieces up to 6 inches in diameter, weighing 700 pounds, 20,000 marks (present exchange, $67).

High-speed drilling machine with capacity for drills up to one inch in diameter, automatic feed, weighing 660 pounds, 15,500 marks (present exchange, $52).

Drilling machine, with capacity for drills up to 1⅝ inches in diameter, weighing 1200 pounds, 20,000 marks (present exchange, $67).

Small vertical boring and turning mill (20-inch capacity) weighing 3300 pounds, 100,000 marks (present exchange, $335).

Horizontal milling machine with single-pulley drive, weighing 10,000 pounds, 200,000 marks (present exchange, $670).

Planer, 40 inches between housings, extreme height of work, 32 inches, weight, 12,000 pounds, 180,000 marks (present exchange, $600).

Planer, 60 inches between housings, extreme height of work, 52 inches, length of table, 13½ feet, weight, 35,000 pounds, 430,000 marks (present exchange, $1435).

Tool grinding machine with 20-inch wheel, weight 1000 pounds, 19,000 marks (present exchange, $64).

Shaper, 26 inches travel of ram, weight 4500 pounds, 105,000 marks (present exchange, $350).

Punch press for holes up to 1¾ inches in diameter and 13/16 inch thickness of plate, weighing 34,500 pounds, 360,000 marks (present exchange, $1200).

Cold saw, 40-inch diameter of saw, weighing 13,600 pounds, 180,000 marks (present exchange, $600).

Plate-bending machine for plates ½ inch thick and up to 6½ feet wide, weighing 9000 pounds, 150,000 marks (present exchange, $500).

General Conditions in the Machine Tool Industry

As already mentioned, business is at a high peak. The shops are overcrowded with orders, and the demand continues to be very brisk. Ludwig Loewe & Co. of Berlin, for example, now employ 3200 men in their shops, and the office employes number 620. It is stated, however, that this firm, like all other machine tool plants, finds it difficult to obtain the necessary raw material and coal.

The wages in the industries are approximately 10 marks per hour (4 cents per hour, present exchange) for skilled workers over twenty-four years of age. The wages for unskilled workers are only 5 per cent less than the wages of skilled men. Women engaged in shop work are paid about 6 marks per hour (2 cents per hour, present exchange). When working on piece-work, all workers earn at least 15 per cent over the hourly wage. For certain skilled work, the wages may be 10 per cent above those mentioned. The working day is eight hours for six days, or a forty-eight hour week. Six to nine days vacation is allowed annually with pay. Men in the engineering departments, capable of independent designing work, are paid from 3500 to 4400 marks a month (present exchange, from $12 to $15), while assistants, draftsmen, etc., earn from 1300 to 1900 marks a month (present exchange, $4.35 to $6.35).

General Industrial Conditions

General industrial conditions are paradoxical. The depreciated value of the mark has created an apparently large export trade with plenty of employment, yet the great masses of the people suffer want and the middle class is brought to the verge of actual poverty. Combinations in the industries are the order of the day, both in the machine tool building industry and in the general machine building field. The aim of these combinations is to lessen competition and reduce production and selling costs. These combinations include not only firms engaged in a similar line of manufacture, but also businesses that are using the raw materials of some other industry. As an example may be cited a combination including one of the largest locomotive builders in Germany, one of the steel mills, and one of the coal mining companies, so that the control of the production from the raw material to the finished product is in the same hands.

In 1921 Germany was still holding second place as a producer of iron and steel—the United States being the leader in this respect, France coming third, and Great Britain, fourth. In 1921 Germany bought 40 per cent of the copper exported from the United States, as compared with 33 per cent previous to the war. Iron ore being scarce in Germany, contracts have been placed for ore in Canada. During the past year exports have increased, but unless raw materials can be obtained from abroad at reasonable prices, Germany cannot continue indefinitely to export, as it is necessary that she first import many of the raw materials which are not found in sufficient quantity, or at all, in Germany. As an example of present methods of trading, it may be mentioned that the Krupp firm of Essen has obtained from Argentina an order for rails, part of which will be paid for by shipments of wool.

The Soviet Government has placed orders for 1000 locomotives in Germany, 85 of which have already been delivered. An order for 1000 locomotives has also been placed by the Soviet Government in Sweden, and the requirements are that all the parts of the locomotives built in Germany and in Sweden must be interchangeable with each other.

Negotiations have been completed between the Siemens-Schuckert Works and large Japanese copper interests, and an agreement has been made to erect a large factory in Tokio for the building of electrical machinery. Twenty of the leading engineers of the Siemens Works, as well as other technical employes and foremen, are just leaving for Tokio. The machinery for the starting of the works will also be supplied by the Siemens-Schuckert Works.

Orders for rails have also been placed in Germany by Brazil, the German bid being 3 per cent lower than that of Belgian makers. An order for a large iron bridge in Argentina has also been obtained by a German concern.

SAVINGS IN THE FOUNDRY

The practice of molding the cylinder casting for a pitcher pump as followed in the foundry of the Goulds Mfg. Co., Seneca Falls, N. Y., shows how money can be saved by giving attention to foundry details. The casting, which is illustrated in Fig. 1, was formerly molded with a green sand core that was rammed up in a core-box and then immediately put in position in the mold. Much difficulty was experienced by this procedure, and it was necessary to have considerable extra work done by an experienced core-maker. A core-box split through the spout was employed, and this core was rammed by hand first from one end and then from the other. When removed from the core-box and placed in position in the mold, it was necessary to be exceptionally careful in handling, and much loss of effort resulted through the disintegration of the core and the overhanging sand in the spouts falling off.

These castings are still molded with a green sand core, but other means of ramming the core are employed. A Mumford jolting machine is used on which a cast-iron box is attached, as illustrated in Figs. 2 and 3. In Fig. 2 the box

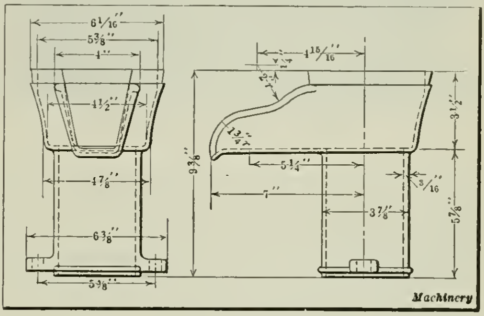

Fig. 1. Pitcher Pump Cylinder Casting

is shown closed and clamped, and the sand is jolted around a central arbor *A* which has ribs for supporting the sand and a square socket at the bottom to locate it in the cast-iron core-box. After the sand has been air-jolted, the top is swept off and the box opened as shown in Fig. 3. There is a pin in the upper end of the central arbor for lifting the core conveniently from the box. After the core has been removed from the box, it is dried in the air, the socket at the lower end of the arbor fitting over a pin to support the core while drying. In jolting this core, the arbors are wet with a clay wash so that the sand will hold, and the sand itself is, of course, dampened. Provision is made for jolting large quantities of these cores at a time and for standing them on pins where they can dry thoroughly and evenly.

Before this arrangement was adopted, blow-holes were produced in the casting by the sand not being evenly or thoroughly dry at the time that the molten iron came into contact with the core. The core-box is rigidly supported at the bottom and at the spout end, and the front cover is located by dowel-pins and can be quickly removed. These facilities make it possible for a boy to make 350 cores a day. This represents a considerable saving as compared with the former practice, which required an experienced molder and core-maker. The use of the jolting machine not only effected a saving in time of more than 50 per cent, but also produced more satisfactory cores than could be made with a hand-rammed core-box, and eliminated the expense of an experienced core-maker.

Economies in Molding Air Chambers

The Goulds piston pump is equipped with an air chamber of the style illustrated by full lines in Fig. 4. The dry sand core for producing the interior of this air chamber at one time was made in a core-box which left a hole in the curved

Fig. 2. Jolting Machine with Cast-iron Core-box in which the Core is jolted

Fig. 3. Jolting Machine shown in Fig. 2, with Front Cover of Core-box removed

end at *A* so that the casting had to be machined at this end and the hole closed with a 3/4-inch gas pipe plug. It was realized that something should be done to reduce this expensive procedure and eliminate, if possible, the necessity for plugging a hole in the casting. This was accomplished by the use of a balanced core, shaped at each end as indicated by the broken line, with a balancing connection of sand at the center so that two cores held together by this body of sand could be placed in the mold and supported without the use of chaplets or any other means. In addition, two sound castings were obtained from each mold so that the subsequent machining operations were entirely dispensed with and double the number of castings were produced in the same time.

* * *

CUTTING THERMIT WELDING COSTS

Investigations recently conducted by the research department of the Metal & Thermit Corporation indicate that the amount of thermit used in making welds is generally needlessly large, and that a saving can be effected by reducing the size of collars or reinforcements, width of gaps, and dimensions of gates and risers. It is claimed that the saving in thermit thus obtained reduces the cost of welding large members or sections at least 10 per cent, and in the case of small sections the saving is much greater.

As an example it was found that a 2- by 4-inch section for which 40 pounds of "railroad thermit" was formerly recommended, could be welded with only 10 pounds of thermit under the new specifications. On the average locomotive frame section a saving of over 10 per cent is generally effected. The use of pneumatic rammers, smaller mold boxes and various labor-saving devices introduced in the past year are also cost-reducing factors.

RESERVE SUPPLIES OF GASOLINE

The greatest reserve of gasoline in the history of the industry is now in storage in the United States, according to a statistical summary issued by the Bureau of Mines, which shows stocks totaling 818,500,000 gallons on hand March 1. The figures indicate an increase of 112,800,000 gallons over the reserve of February 1. The previous high figure set in May, 1921, is exceeded by 18,000,000 gallons. The amount of gasoline in storage March 1 is 138,000,000 gallons more than on the same date a year ago. The production of gasoline during February was 46,000,000 gallons less than for January, but was 10,000,000 gallons more than for February a year ago. The total production for February amounted to 398,223,146 gallons; the imports totaled 4,979,625 gallons, exports 38,169,593 gallons, and the domestic consumption amounted to 251,759,440 gallons.

Stocks of lubricating oils reported to the Bureau of Mines show an increase of 15,000,000 gallons during the month of February. The supply of these oils on hand March 1, amounting to 260,000,000 gallons, is the greatest since June, 1921, and lacks but 2,000,000 gallons of the high point reached in the storage of lubricating oils in May, 1921. Stocks of gas and fuel oils on hand March 1 amounted to 1,314,740,284 gallons.

* * *

New Zealand's new tariff law, as published by the British Board of Trade Journal, contains several evidences of preferential duties for imports from other parts of the British Empire. Machinery and metal products are either free or assessed at various duties up to 20 per cent if from other parts of the Empire, but are subject to from 10 to 35 per cent duty if from other parts of the world. For the most part the duties are ad valorem.

Pipe Threading Tools and their Manufacture

Methods Used in Making Die-stocks and Chasers—Second of Two Articles

THE first article on pipe threading tools and their manufacture, published in May MACHINERY, contained a description of several machining operations required in the manufacture of Beaver die-stocks, as well as a detailed description of a special machine for milling the pin slots in the chaser cam-plates. The present article describes the methods employed in manufacturing the thread chasers, including the heat-treatment and inspection. The methods used for determining the pull required in threading pipe, expressed in pounds, is also included.

Making the Chasers

The steel used in manufacturing the chasers is a hot-rolled high-carbon tool steel. It is claimed that hot-rolled steel gives better results than cold-rolled steel, because the desired accuracy of the chaser can be more easily maintained with the hot-rolled product. The bars are cut off on a Becker milling machine of the Lincoln type, on the arbor of which a gang of cutting-off saws is carried. The set-up is illustrated in Fig. 13, which shows the stock held in a special fixture. The jaws of this fixture are spring-actuated, which permits the stock to be readily freed after the blanks have been cut off and it is desired to advance the bar into the jaws preparatory to cutting off another series of blanks. After the blanks are cut off, they are ground on a Blanchard or a Pratt & Whitney grinder and the pin-holes drilled in which the pins that engage the cam-plates are assembled.

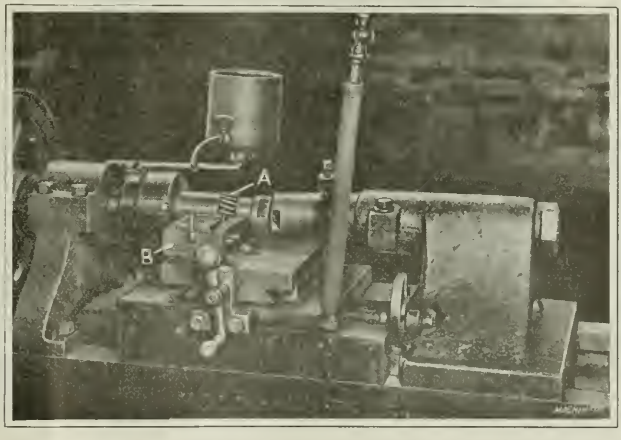

Fig. 14 Equipment used in milling the End Surfaces of the Chasers in which the Threads are subsequently cut

The next operation is that of milling a curved surface on the end of the die blanks. This surface, besides being curved, is in an angular plane, so that a taper cutter mounted in the horizontal plane of the center of the chaser is required. In Fig. 14 is shown a special milling machine equipped with a tapered cutter *A* such as just referred to. The blank is held in a slot in tool-block *B*, and is located by means of the previously assembled cam-plate pin. There is nothing novel about the design of this machine, but the outstanding feature in its construction is its rigidity. The carriage is heavy and the tailstock substantially braced. The milled surfaces produced on this machine are those in which the threads are subsequently milled.

For the thread-milling operation a special machine of the type illustrated in Fig. 15 is employed. The blank *A* is clamped to the fixture *B*, and is positioned by the pin in the work, and stop *C*. In connection with this operation, it should be borne in mind that the lead of the threads in each chaser of a set is advanced one-fourth of a turn, so that all chasers for the first position are milled at one setting of the machine. When the second lot of chasers is to be milled, it is simply necessary to advance the position of the lead-screw nut *E* a distance equal to one-fourth the pitch of the thread (provided that four chasers constitute a set), throw the nut into mesh with feed-screw *F* by means of handle *G*, and proceed as before. There is a micrometer adjustment, the knurled adjusting screw of which is shown at *D*. for setting the lead-screw nut accurately when another chaser in a set is to be milled. The third and fourth sets will be milled after advancing the lead-screw nut a like amount.

There are two operations of great importance, as regards the operation of the die-stock, which follow the thread-milling operation. These are the grinding away of the thin fin where the thread starts, and the grinding of what is termed the "lead," which is a bell-mouthed enlargement of the chaser opening to facilitate the start in cutting the thread.

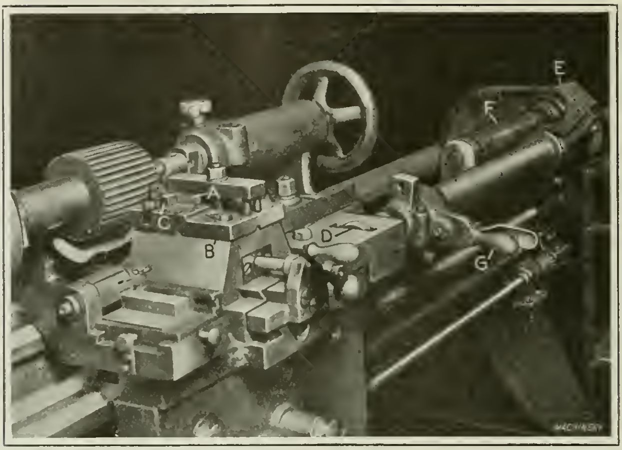

Fig. 15. Milling the Threads in the End of Chaser Blanks, using Special Machine and Tapered Milling Cutter

Chasers used on die-stocks of the type shown in Fig. 3, of the first installment of this article have an angular surface at the rear which has a cam action in relation to the inner wall of the outer housing. This angular surface is ground on the grinding machine shown in Fig. 12, to which there is attached an auxiliary rest, tilted at an angle, on which a swiveling block *A* is attached. This swiveling block has two radial slots *B* and a circular clearance space around the center post *C*, on which washers of various thicknesses may be placed so that chasers of various lengths may be ground. Two of these washers are shown at *D* and *E* hanging on a set-screw.

The swiveling block is swung back and forth, passing the end of the chasers over the grinding wheel, by means of the lever *F*. The angle at which the swiveling block is mounted corresponds, of course, with the angle required at the end of the chasers. The carriage *G* rides in parallel ways in the cast-iron base, and is operated against spring tension by handle *H*. when carriage adjustments are required. Before being sent to the hardening room, the chasers are marked to show their relative position in the die-head.

Heat-treating and Inspection

The dies are heated in molten lead, first being preheated to a temperature of between 1000 and 1100 degrees F., and later to a final hardening temperature of 1550 to 1600 degrees, depending on the grade of steel used. The quenching medium is salt water, which is agitated by a circulating pump. After hardening, the parts are drawn in oil at 350 to 400 degrees F. Two hardness tests are employed; first the hardness is tested by a file, and then it is checked by the scleroscope, the required reading being between 65 and 75. Finally, the chasers are ground on the side to gage limits on a disk grinder and sharpened.

There are a number of interesting gages used in the inspection of the chasers, three of which are illustrated in Fig. 18. The gage shown at *A* is used for inspecting the chasers for the small dies, both for length and for lead and location of the thread. There is a set of master blocks *D* provided with the gage for the purpose of setting the center indicator *E* at zero prior to the inspection of a lot of chasers. The adjustment is accomplished by means of the knurled screw *G*. After adjusting the indicator with handle *M*, it may be swung down against the chaser *F* to determine the length.

The chaser is located by stop-pin *H* against block *I*, the threads of the chaser engaging with threads in the master mating members. There are four of these masters, one at each station, as may be clearly seen at *J*. This gage may be used to check the elements of all the chasers in a set of four by indexing the turret *K*, which may be locked by key *L*. If the chaser does not properly engage the master on the turret, it is too long, and this will be indicated on the graduated scale of the center indicator.

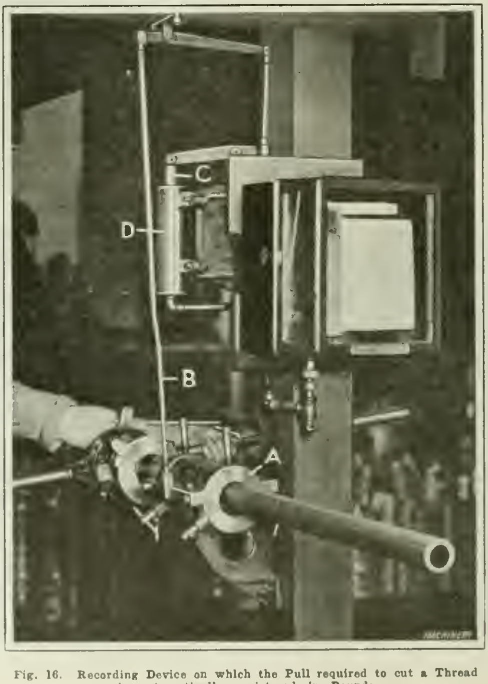

Fig. 16. Recording Device on which the Pull required to cut a Thread is automatically registered in Pounds

The gage shown at *B* in this illustration is used for checking the over-all length and the pitch of threads on the larger sized chasers. The chasers are located by the cam-pin against block *N*, in which position they are inspected by means of the two micrometer heads with which the gage is provided. The anvil *O* of one of these heads has a conical point to correspond with the angle of thread, in which it engages for checking the length. The other micrometer spindle is then used to check the distance from the thread in which the pointed anvil is engaged to the side of the gage against which the chaser rests. This checks the proper location of the threads.

The gage shown at *C* consists of a block carrying a master gage *P* which has the appearance of a pipe tap. By turning this master gage so that the chasers of a set may be successively inspected, and by the use of a dial gage, the length and thread may be quickly tested. The chaser is

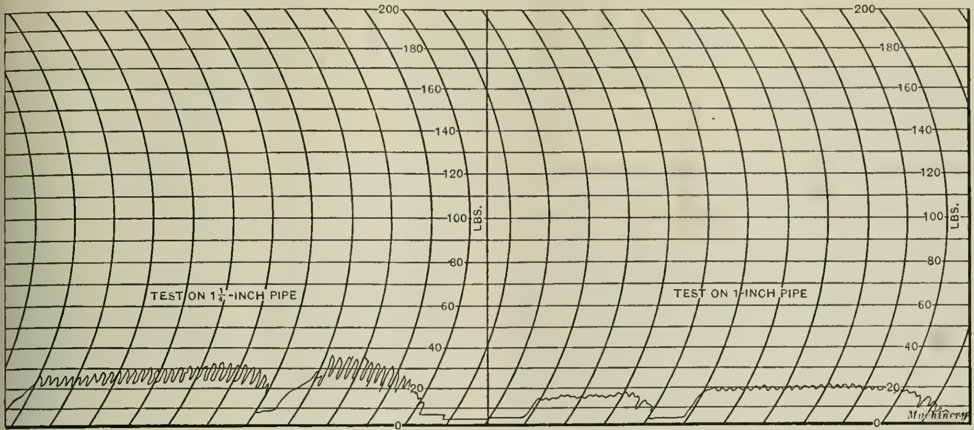

Fig. 17. Reproduction of a Section of the Recorder Tape on which the Amount of Pull in Pounds is registered

located in the gage against a block, and is held in contact with the master gage by a spring block Q, which may be withdrawn from contact with the end of the chaser by means of knob R. A flat spring S exerts tension against the side of the chaser and serves to hold it in the proper position for gaging.

After the work has been placed in the position described, the operator permits the spring block Q to bear against the end of the chaser, noting at the same time the reading of the dial indicator. This shows him, at a glance, the deviation, if any, that exists in the length; the engagement of the threads of the chaser with the master gage may also be readily observed. The spring block carries a pin T on the side which is held in contact with another pin U, driven into the small cross-shaft V, by a light coil spring. As the cross-shaft V is rocked when the spring block is moved in and out, a finger on the opposite side of the shaft extends under the vertical plunger W of the dial indicator and operates the indicator needle. In setting this master gage, it is necessary, of course, to obtain a zero reading on the dial, and this is done by regulating the adjusting screw X at the rear of the gage.

Recording the Pull Required to Cut a Pipe Thread

The method of testing the pull required to cut a thread with die-stocks of various sizes is of considerable interest. The apparatus used is illustrated in Fig. 16 and consists, briefly, of a Bristol recording instrument, which is operated by hydraulic pressure through the medium of a series of levers, so that the exact amount of exertion required to thread a pipe is graphically recorded on a chart. As the die-stock is turned, the vise A in which the pipe is held, can swivel slightly, due to the force exerted by the operator, with the result that the connecting-rod B and a series of levers operate the plunger C in the oil cylinder D, producing an amount of pressure which shows the exertion required to cut a thread. The number of pounds pull required is recorded on the chart.

The tape in the recorder travels at the rate of 6 inches per minute, so that in addition to the pull required, it is possible to determine very closely the amount of time consumed in the operation. A section of one of these recorder tapes is reproduced in Fig. 17, showing the results of tests made on pipe of 1 inch and 1¼ inches diameter, respectively. In the first instance a pull of 20 pounds was exerted during the first part of the work. It will be noticed that the traced line then drops abruptly down, during which period the operator was probably engaged in oiling the chasers. At the resumption of the pull after oiling, the pressure is shown to be about 3 pounds less than before oiling. Referring to the other test, it will be noticed that the maximum pull was 38 pounds before oiling; the recording needle dropped down during the oiling operation, and afterward a maximum pull of 34 pounds was exerted.

MACHINE TOOL STANDARDIZATION

The important decision reached at the last meeting of the National Machine Tool Builders' Association, to undertake extensive standardization work, will be welcomed by the entire metal-working industry. Lack of standardization, which prevents using cutting tools, fixtures, and accessories interchangeably on different makes of machine tools, has added greatly to manufacturing costs by increasing the amount of tool equipment required. The cooperation now existing between the National Machine Tool Builders' Association and the American Society of Mechanical Engineers, fostered by the American Engineering Standards Committee, will undoubtedly result in noteworthy economies, both to builders and users of machine tools.

In his address before the National Machine Tool Builders' convention, A. H. Tuechter, the president, emphasized the needs for standardization, and referred to the growing demand for it from users of machine tools. Mr. Tuechter mentioned one case where the standardization of the dimensions of one hole enabled the manufacturer to utilize more than $5000 worth of tool equipment which he was using on another machine. Mr. Tuechter also referred to the standardization of milling machine spindles by the Associated British Machine Tool Makers, which will enable the interchangeable use of milling cutters and arbors.

In connection with this new departure by the National Machine Tool Builders' Association, it is not intended to standardize the individual features of machines which may be considered superior to those of competing tools—driving and feeding mechanisms, for example, may be of different designs without being subject to standardization. It is to the advantage of the user that improvements are continually being made in such features. Standardization is required principally in the work-holding and tool-holding parts or appliances of machines, and this important feature of the work should be undertaken first. Should it be found desirable later to standardize other features, this can be done step by step, in accordance with the judgment and experience of the manufacturers themselves. The buyer is interested principally in the interchangeability of tooling equipment between machines of different makes, and he is justified in asking for the standardization that directly affects this.

UNIFORM APPRENTICESHIP SYSTEMS

The need for a uniform apprenticeship system in the metal-working industries is generally recognized and a most promising step toward meeting it has been taken by the National Metal Trades Association in endorsing the report presented at the annual meeting by Harold C. Smith, president of the Illinois Tool Works of Chicago, who is chairman of the Industrial Training Committee of the association. His report provides for an apprenticeship system in which is embodied many good features of several systems that have been in use in American shops, and also includes a number of suggestions relating to new and improved features. A thorough examination of apprenticeship systems now used in various shops and in communities where manufacturers cooperate in the training of young shop men, was made by the committee. The report frames courses of shop training, suggests a standard diploma for apprentices in the metal-working industries, and provides for an exchange of apprentices among shops which are too small to furnish alone thorough and all-around training.

The committee dealing with the problem is one that commands the respect of the entire metal-working industry, the members, besides Mr. Smith, being John C. Spence, works manager of the Grinding Machine Division of the Norton Co., Worcester, Mass., and William Taylor of the Chandler & Taylor Co., Indianapolis, Ind. Manufacturers everywhere are strongly urged to investigate thoroughly the proposed apprenticeship system, and to arrange for putting it into effect in their own plants.

Where shops are too small to maintain individually the kind of apprenticeship system proposed, some active manufacturer should begin immediately to cooperate with his neighbors and start a group movement in his community. If shops are running at greatly reduced capacity it may not be possible to begin actual operation immediately; but plans can be formulated now, while there is ample time for that part of the work, and carried out when business is more active. The future of the American machine-building industries undoubtedly depends upon a constantly increasing supply of highly skilled all-around mechanics.

SHOP PRACTICE AND DESIGN

A designing engineer said recently that the present tendency in technical book publishing was to bring out a great many books on shop practice but very few on subjects pertaining specifically to machine design. He felt that the needs of the designer were being overlooked; but in this assumption he was in error.

During the early period of technical book publishing, the larger number of volumes related to machine design—the theoretical or preliminary part of the work necessary to produce a machine or mechanism. In recent years the tendency has been to record more accurately and comprehensively than formerly, methods of building or manufacturing machines and mechanisms efficiently—that is, at the lowest cost commensurate with the required quality. There is a very good reason for this change.
